Madison (1975) reported that *P. metcalfii* from Highlands, North Carolina, also can distinguish odors of familiar and unfamiliar individuals. However, his experiments differed from those with *P. cinereus* in that test animals were not exposed to odors of other individuals in the laboratory. Instead, animals collected within three m of one another were considered "neighbors," and those collected at least 30 m apart were considered "non-neighbors." Salamanders were given a choice of airborne odors of neighbors and non-neighbors in an olfactometer. Outside the breeding season, both males and females showed a significant preference for neighbors, but females shifted to a preference for non-neighbors in the breeding season. It is not clear how these results relate to the mating system of this species.

Aggression, Spacing, and Territoriality in Urodeles

Salamanders exhibit aggressive behavior in a number of different contexts. Sometimes individuals fight over discrete resources, such as prey items. Such behavior has been observed in plethodontids, salamandrids, and both adult and larval ambystomatids, mostly in captivity (Licht 1973; Thurow 1976; Walls and Jaeger 1987; Ducey 1989; Walls 1990; Ducey and Heuer 1991; Walls and Semlitsch 1991; Mathis et al. 1995; V. Townsend and Jaeger 1998). Evidence for such behavior in the field is largely anecdotal, because researchers are unlikely to encounter two individuals just at the moment they find the same prey item. A special case of resource-item competition is fighting over females by males during the mating season. This is common in many salamanders and is discussed in more detail in the section on "Mating Systems," following.

Some salamanders also exhibit strong attachment to specific sites and advertise and defend them against other individuals. This type of site defense is similar to that seen in lizards that are not otherwise territorial, such as skinks, lacertids, teiids, and some varanids (Stamps 1977; E. Martins 1994). In salamanders, the sites most commonly defended are retreat sites, such as logs, rock crevices, or tunnels, and nest sites where females are brooding eggs (Mathis et al. 1995). Much of the evidence for site defense comes from studies of captive animals, although brief observations have been made of salamanders in the field defending either retreat sites or nest sites against conspecifics (R. Gordon 1952; Hutchison 1959; Brandon and Huheey 1971; Hillis and Bellis 1971; Nickerson and Mays 1973a; Nussbaum, Brodie, and Storm 1983). Some salamanders might go further and defend all or part of the home range as an exclusive territory. Evidence for home range defense comes mainly from studies showing lower than expected overlap among home ranges of different individuals (Nishikawa 1990; Mathis 1991b) and a few observations of aggressive interactions away from obvious retreat sites (Gergits and Jaeger 1990a). In practice, it often is difficult to distinguish between complete or partial home range defense and site defense. In some species, these two forms of aggression grade into one another, with individuals defending home ranges to some extent, but showing much stronger defense of specific retreat sites or nests. In the following discussion, both site defense and home range defense are considered forms of territoriality.

Territorial Behavior of the Red-backed Salamander

Due to the efforts of Robert Jaeger and members of his laboratory, we now know more about the territorial behavior of the red-backed salamander (*Plethodon cinereus*) (fig. 9.19) than that of any other salamander (Jaeger 1986; Jaeger and Forester 1993; Mathis et al. 1995). Red-backed salamanders are inhabitants of deciduous forests throughout much of eastern North America and can reach densities of several individuals per square meter. Burton and Likens (1975b) estimated that the biomass of these salamanders in the Hubbard Brook Experimental Forest in New Hampshire exceeded that of birds during the breeding season. The high density of some populations means that competition for food and suitable retreat sites is likely to be intense.

Red-backed salamanders have three major microhabitats available to them: the forest leaf-litter, surface cover objects such as logs and rocks, and underground tunnels constructed by other animals (Jaeger 1980b). In wet weather, the salamanders move through the leaf litter in search of small invertebrates, particularly soft-bodied animals such as springtails (Collembola; Jaeger 1972, 1980a; Burton 1976). In dry weather, the salamanders retreat under logs and other cover objects that protect them from desiccation. This restricts their ability to forage and limits the types of food available to them (Jaeger 1980a). They often feed on prey associated with logs, such as ants and termites. The latter are greatly preferred, even by individuals that previously fed on ants (Jaeger, Schwartz, and Wise 1995), because their less chitinous bodies are more easily digested and therefore are more profitable (Jaeger and Barnard 1981; Jaeger and Rubin 1982; Gabor and Jaeger 1995). In very dry weather, salamanders are forced underground, where food is much less abundant (Taub 1961; Fraser 1976a; Jaeger 1980b), or they aggregate under cover objects, thereby avoiding desiccation, but reducing their ability to search for food (Test 1955). Presumably individuals that can maintain territories with adequate, moist retreats and feeding sites will be those most likely to remain in good condition in dry weather (Jaeger 1980a).

Fig. 9.19. The red-backed salamander (*Plethodon cinereus*), the subject of many studies of territorial behavior. Photo by Wayne Van Devender.

Several lines of evidence from field studies in Virginia indicate that both male and female red-backed salamanders are territorial for much of their activity season, although this is not necessarily true in all parts of the species' range (Maerz and Madison 2000). In an early study, Jaeger (1979) found that adults often did not share the same retreat sites. He also found that individuals were spaced farther apart in the summer than in the spring, perhaps because warmer, drier weather intensifies competition for choice foraging sites. During the summer, when the salamanders are not courting, it is rare for more than one salamander to be found under the same cover object, and when this does occur, the log usually is large enough to allow salamanders to use different foraging areas with little overlap (Mathis 1989). Adults are relatively sedentary, occupying small home ranges for periods of weeks or months, to which they readily return if displaced (Kleeberger and Werner 1982; Gergits and Jaeger 1990b; Jaeger et al. 1993). Many individuals even returned to precisely the same cover object after being displaced.

The most convincing evidence of territoriality in the field comes from a series of studies by Alicia Mathis. In one study, she removed resident salamanders from cover objects, and these sites were reoccupied by new individuals more often than were cover objects that had not had a salamander in residence (Mathis 1990a). This indicates that the best-quality sites were those already occupied by salamanders. Mathis also found that the original residents of these sites were larger than the individuals that moved into the vacated sites, suggesting that large adults had monopolized the best territories, and smaller individuals either were in lower-quality sites or were nonterritorial floaters. A survey of natural cover objects showed that large animals were more likely to be found under large logs than were small animals (fig. 9.20), even though small individuals preferred large cover objects in both laboratory and field choice experiments. Large cover objects probably provided better microhabitats because soil temperatures were slightly cooler, and soil moisture presumably was higher.

Other studies have shown that large salamanders do not necessarily defend the largest cover objects (Gabor 1995; Faragher and Jaeger 1997). This suggests that the quality of

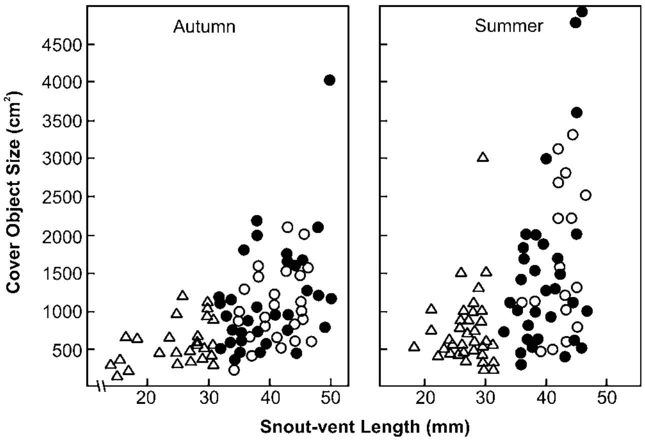

Fig. 9.20. Relationship between cover object size and snout-vent length for *Plethodon cinereus* in Virginia during the autumn courting season and the summer noncourting season. Open circles are adult males; closed circles are adult females; triangles are juveniles. In both seasons there was a similar positive relationship between body size and cover object size. After Mathis (1990a).

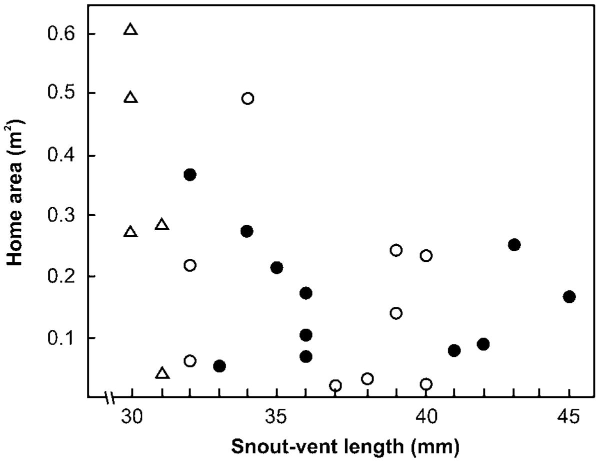

Fig. 9.21. Relationship of home range size to snout-vent length in red backed salamanders (*Plethodon cinereus*) in Virginia for males (closed circles), females (open circles), and juveniles (triangles). After Mathis (1991b).

food resources rather than size of a cover object is the most important determinant of territory quality. Indeed, Gabor (1995) found that territories held by large salamanders also provided more prey than did territories held by smaller individuals, especially soft-bodied prey (Diptera) of the type favored by the salamanders. Mathis (1991b) found that large salamanders actually had smaller home ranges than did small salamanders (fig. 9.21). This could be because food is patchily distributed and large salamanders occupy the best sites, or smaller individuals could be floaters that have not yet settled in a permanent home range. Those individuals that appeared to have established permanent territories were in better condition than were presumed floaters, as indicated by the length of the tail, an important energy-storage organ in salamanders (Maiorana 1977; Fraser 1980; see also chapter 5).

Mathis (1991b) also examined the spatial relationships of males and females in her population. Previous studies had shown that both males and females are aggressive toward conspecifics and defend territories in laboratory containers (Horne 1988; Horne and Jaeger 1988). Nevertheless, there also are indications from laboratory studies that males are somewhat more tolerant of intrusions by females than by males (Wrobel, Gergits, and Jaeger 1980; Jaeger 1984; Horne 1988; Thomas, Jaeger, and Horne 1989), and males are less aggressive toward females with which they are familiar (Guffey, MacKinster, and Jaeger 1998). This is to be expected if females must enter territories of males to find mates (Hom, Jaeger, and Willits 1997) or if they remain more or less permanently within male home ranges. In one field site, most adults of both sexes had home ranges that did not overlap those of other individuals, suggesting that both males and females were territorial. When home ranges did overlap, their residents were likely to be of different sexes, and individuals of both sexes were most likely to have a member of the opposite sex as a nearest neighbor (Mathis 1991b). Large males appear to have an advantage over small males in their access to females. In the field, males found within 10 centimeters of a female were larger than those not associated with females. In laboratory trials, females tended to associate more with large males than with small males, and large males dominated small males in contests over females. Subsequent field studies showed that males and females of this species were much more likely to share the same cover object than were same-sex pairs (Jaeger et al. 1995), and these associations persist even outside the reproductive season (Jaeger et al. 2001). There also is evidence from laboratory studies that females prefer to associate with particular males with which they are familiar (Gillette et al. 2000).

Work on captive animals by Lang and Jaeger (2000) suggested that males and females sometimes codefend a common territory during the breeding season, although they do not do so cooperatively. Males were more aggressive toward other males than toward intruding females, whereas females were more aggressive toward other females. Intruders were introduced into territories, in the laboratory, that were defended by a pair, by a single male, or by a single female. Male intruders did not leave pair-defended territories any faster than they left territories defended by single individuals, whereas females did leave pair-defended territories more quickly. The spatial strategies of males and females are not identical, however. Males appear to dominate preferred feeding territories (Gabor 1995). Some females are able to live within the territories of males, but others apparently act as nonterritorial floaters or are relagated to lower-quality territories. When individuals were removed from territories in the field, the vacated cover objects were more likely to be invaded by females than by males, regardless of the sex of the original inhabitant (Toll, Jaeger, and Gillette 2000). Thus, females probably spend more time moving around in search of high quality retreat sites and feeding territories than do males, and they may use fecal pellets of other individuals, either males or females, to assess the quality of potential foraging sites (Karuzas, Maerz, and Madison 2004).

Juvenile red-backed salamanders do not exhibit the territorial behavior seen in adults. Instead, they move between the leaf litter and adult territories under logs and other cover objects, depending on the weather and the amount of moisture in the litter. In laboratory tests, juveniles were actually attracted to pheromones of adults, rather than being repelled by them, even though adults are large enough to injure or kill juveniles. In laboratory encounters, adults displayed aggressively to juveniles by raising the trunk off of the ground, but they did so less frequently than in encounters with other adults, and they almost never bit juveniles. These results suggest that adults are relatively tolerant of intrusions by juveniles into their territories. There was a difference in response depending on whether the adults were familiar with the juveniles; they showed greater tolerance to familiar individuals. Jaeger, Wicknick, Griffis, and Anthony (1995) hypothesized that such responses reflect recognition and tolerance of close kin, but the genetic structure of natural populations and the proximity of close relatives remains to be investigated.

The postural displays by which red-backed salamanders signal aggression and submission during agonistic encounters have already been discussed (fig. 9.2). Overt aggression consists mainly of biting attacks directed at an opponent's tail, trunk, and snout (Jaeger 1981b, 1984; Jaeger, Barnard, and Joseph 1982). Attacks are directed disproportionately to the snout region, often injuring the nasolabial grooves (fig. 9.22). This can interfere with an animal's ability to find food (David and Jaeger 1981) or mates, and it makes it difficult for a salamander to monitor chemical territory markers of other individuals or find its way back to a home site (Graves 1994). Thus, even though fighting is rarely fatal, it can significantly reduce an individual's lifetime fitness (Jaeger 1981b). Territorial defense also can be costly if it reduces foraging time or causes animals to choose less profitable prey (Jaeger, Nishikawa, and Barnard 1983). Unfortunately, because overt aggression is so rarely observed in nature (Gergits and Jaeger 1990a), it probably is impossible to estimate the frequency of escalated fights or injury in natural populations. In laboratory encounters, a number of factors influence the outcome of aggressive interactions. Not surprisingly, body size is important, with large salamanders dominanting smaller individuals, thereby gaining access to more food

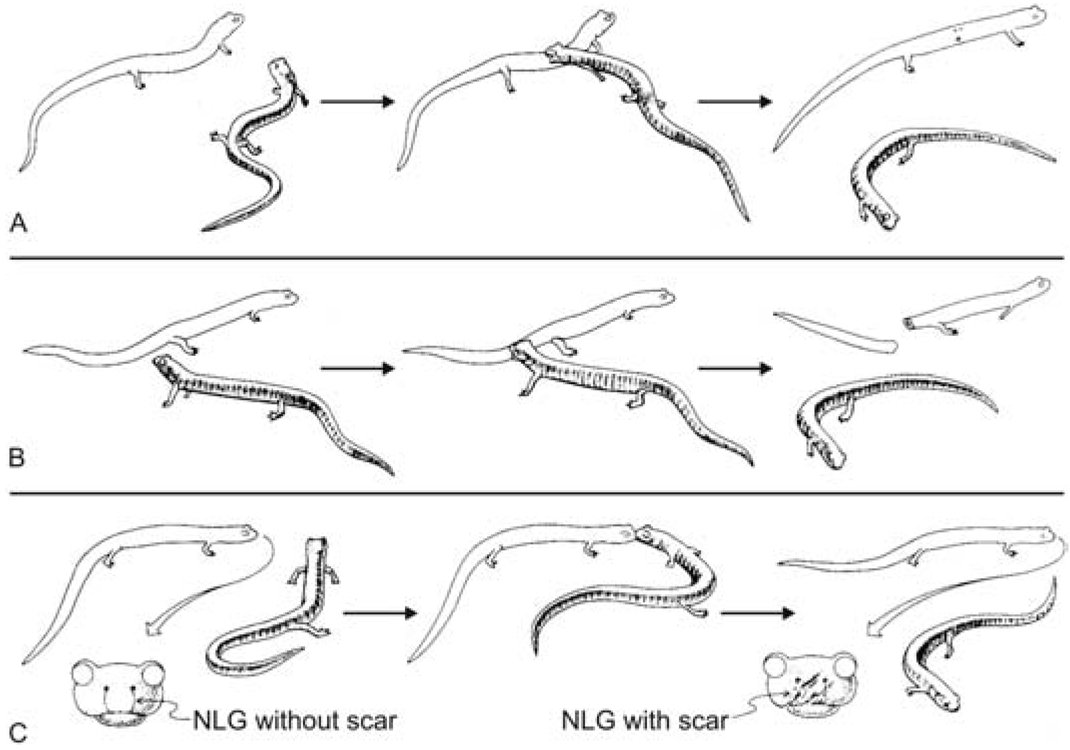

Fig. 9.22. Areas of body attacked during aggressive encounters in red-backed salamanders (*Plethodon cinereus*). (A) Attack on trunk region. (B) Attack on tail, sometimes resulting in loss of the tail. (C) Attack on the snout, sometimes resulting in injury and scarring of the nasolabial groove (NLG). After Jaeger (1981c).

(Townsend and Jaeger 1998). In addition, individuals with territories containing their preferred food (termites) initiated more aggressive displays and were more likely to bite intruders than those in territories with lower quality food (ants; Gabor and Jaeger 1999). Threat displays appear to be relatively inexpensive to produce and are not always followed up by biting attacks, suggesting that residents sometimes bluff their opponents in territorial encounters.

An important component of the territorial behavior of red-backed salamanders is the use of chemical signals in advertising ownership of territories and possibly conveying information about the size of territory owners and the quality of their territories. Early experiments demonstrated that red-backed salamanders can distinguish between their own substrates and those previously inhabited by other individuals, as well as the odors of familiar and unfamiliar individuals (Tristram 1977; McGavin 1978; Jaeger and Gergits 1979; Jaeger 1981b). Later, G. Simon and Madison (1984) tested the hypothesis that either fecal pellets or cloacal odors were the source of chemical cues used for identification. They scored odor preferences by the position of an animal in a test arena and found that salamanders preferred their own fecal or cloacal odors to those of other individuals. They hypothesized that one or more of the cloacal glands were the source of pheromones in fecal pellets.

In a more sophisticated experiment, Jaeger et al. (1986) placed salamanders in containers with artificial burrows. The investigators marked burrow entrances by placing a fecal pellet of the test animal, a fecal pellet of another animal, or a paper surrogate fecal pellet on the substrate. Males spent more time in burrows marked with their own fecal pellets than in those marked with either conspecific or surrogate pellets, and they spent more time in surrogate-marked burrows than in those marked with another individual's pellets. This indicated that males not only were attracted to their own fecal pellets, but also avoided those of other salamanders. Test males also were more likely to assume a flattened submissive posture (fig. 9.2) in the presence of a pellet from another individual. Like Simon and Madison, Jaeger et al. (1986) suggested that cloacal glands, probably the vent glands, were responsible for chemical signals deposited with the fecal pellets.

Subsequent work demonstrated that female red-backed salamanders behave in much the same way as do males when confronted with their own fecal pellets or those of other individuals (Horne and Jaeger 1988). They spent more time in burrows marked with their own pellets and showed submissive behavior to pellets of other salamanders. They also showed more interest in fecal pellets than did males, not only investigating them by nose-tapping, a behavior that conveys odorants to the vomeronasal organ, but actually squashing the pellets with their snouts. Some females also displayed aggressive postures in the presence of other salamanders' pellets. Mathis (1990b) demonstrated that females deposited fecal pellets most rapidly when confronted with their own pellets, whereas males deposited pellets in response to the odors of females. She suggested that substrate marking serves different functions in the two sexes, with females using chemical signals when advertising ownership of territories and males using them in both territory advertisement and attraction of females.

The fact that females exhibit many of the same forms of territorial behavior as do males, and apparently mark their territories with fecal pellets, indicated that the vent gland probably is not the source of pheromones deposited with fecal pellets, because female salamanders do not have vent glands. More recent work has shown that the likely source is a gland or set of glands located on the underside of the tail, just behind the cloaca. Presumably pheromones can be deposited on a fecal pellet by dragging or pressing the gland over the pellet after it has been deposited. Salamanders responded to extracts of postcloacal glands by nose-tapping (Simons and Felgenhauer 1992), and residents were more likely to assume aggressive postures when they had marked a substrate with secretions of the postcloacal glands (Simons, Felgenhauer, and Jaeger 1994). Test animals showed more interest in substrates marked with postcloacal gland secretions of other animals than unmarked substrates.

A surprising finding of these experiments was that salamanders did not avoid marked substrates when a resident salamander was absent. This suggested that chemical markers do not repel intruders, but instead provide information about the identity of the resident. When a resident is present, an intruder can attempt to match chemicals on the substrate with the odor of the resident to determine if that animal is, in fact, the owner of the territory. Intruders into territories in laboratory tests often contacted residents and investigated the region of the tail where marking glands are located (Jaeger and Gabor 1993), sometimes even pushing their snouts under the tail of the resident. This sort of detailed investigation probably enables a salamander to assess the resident's status, individual identity, size (Mathis 1990b), and perhaps fighting ability of opponents, allowing them to avoid costly escalated fights when they are unlikely to prevail (Simons, Jaeger, and Felgenhauer 1997). It also appears that residents are more aggressive when they are in territories marked with their own pheromones (Jaeger 1981b; Nunes and Jaeger 1989; Simons, Jaeger, and Felgenhauer 1997), and indeed, they probably use the presence of these pheromones to identify their own territories. Residents also tend to be more aggressive if they are in good-quality territories (Nunes 1988a), if they have been in a territory for a long time (Nunes and Jaeger 1989), and if they are large individuals (Mathis and Simons 1994).

The amount of information conveyed by the seemingly simple behavior of placing pheromones and fecal pellets in a territory is quite remarkable. In addition to information about a male's identity, status, and fighting ability, fecal pellets apparently provide females with a considerable amount of information about the qualities of males as potential mates. When females were given a choice of artificial burrows marked at the entrance with fecal pellets of males that had eaten termites (a high-quality food) or ants (a lower-quality food), they spent more time in the burrows with pellets containing termite remains (Walls et al. 1989). A field survey also revealed that females were more likely to be associated with males that had been feeding on termites, even though ants were much more abundant in the area. Gravid females are more likely than nongravid females to inspect fecal pellets closely by squashing them with their snouts (Jaeger and Wise 1991). It is not clear why females should prefer to associate with males that feed on a higher quality diet. One possibility is that females make use of food resources in the male's territory to produce eggs. Another is that they lay eggs in the male's territory, and their offspring gain access to the male's resources (see the following discussion of Mating Systems). Whatever the reason, males are more efficient foragers on termites, the prey type that makes them more attractive to females (Jaeger, Schwarz, and Wise 1995).

There is evidence that the benefits of territoriality extend to competitive interactions between species. Jaeger and Gergits (1979) reported that when red-backed salamanders were given a choice of substrates marked with their own odors or those of a closely related species, *Plethodon shenandoah,* they spent more time on their own substrates. Similar results were obtained when *P. shenandoah* was tested. These results were interpreted as evidence that salamanders avoid the pheromones of other species. In the field, *P. cinereus* and *P. shenandoah* have parapatric distributions, with the latter limited to drier talus slopes in areas surrounded by wetter habitats favored by *P. cinereus* (Jaeger 1970). *Plethodon cinereus* cannot invade the drier habitats, but they are able to exclude the other species from moist habitats (Jaeger 1971a, b, 1972; see also chapter 15). *Plethodon cinereus* is more aggressive than is *P. shenandoah* in laboratory encounters (Wrobel, Gergits, and Jaeger 1980), and *P. cinereus* can defend territories against the other species in preferred habitat (Griffis and Jaeger 1998). The parapatric distributions of the two species result from the ability of *P. shenandoah* to tolerate drier conditions, combined with aggressive interspecific territoriality of *P. cinereus* in preferred habitats (Jaeger 1974). Experimental removal of resident *P. cinereus* from rocks near talus slopes inhabited by *P. shenandoah* allowed the latter species to invade the surrounding habitat (Griffis and Jaeger 1998).

Populations of red-backed salamanders also have parapatric distributions with several other salamanders of similar size (*P. wehrlei, P. hubrichti, P. nettingi, P. hoffmani*), suggesting that they are aggressive toward these species as well (Pauley 1978; Jaeger and Forester 1993). In fact, *P. cinereus* is highly aggressive toward *P. hoffmani,* and is aggressively superior to that species (Jaeger, Prosen, and Adams 2002). Red-backed salamanders also are aggressive toward similar-size juveniles of a much larger species, *P. glutinosus,* and apparently exclude them from their territories in the field, but they do not interact with larger adults of the same species (Lancaster and Jaeger 1995; Jaeger, Gabor, and Wilbur 1998). In laboratory encounters, *P. cinereus* dominated adults of *Eurycea bislineata,* a relatively nonaggressive species that sometimes uses similar retreat sites (J. Markow, personal communication), as well as the closely related species *E. cirrigera* (Jaeger, Gabor, and Wilbur 1998). In contrast, adults of *Desmognathus ochrophaeus* and *D. fuscus* were able to displace red-backed salamanders from retreat sites in laboratory encounters, even when they were somewhat smaller than the residents (E. Smith and Pough 1994; Jaeger, Gabor, and Wilbur 1998). This reflects the even more aggressive nature of many desmognathine salamanders (see the following). Red-backed salamanders probably avoid contact with species of salamanders large enough to prey on them, such as large *Desmognathus* and *Ambystoma maculatum* (Ducey, Schramm, and Cambry 1994; Jaeger, Gabor, and Wilbur 1998).

A caveat to the story of territoriality in red-backed salamanders is that their behavior is not necessarily uniform across their very broad geographic range. For example, studies of a population in northern Michigan revealed that individuals were much less likely to be distributed in a uniform spatial pattern typical of territorial animals than were those from Virginia, where most of the previous work has been done (Quinn and Graves 1999). Michigan salamanders also were more likely to be found in aggregations under the same cover objects than were those from Virginia. Furthermore, when salamanders from these two regions were housed in the laboratory under identical conditions, the Michigan salamanders showed a much greater tendency to aggregate than did Virginia salamanders. The reasons for these differences in behavior are not known, but they could be related to differences in the abundance or predictability of food resources, which appear to be less seasonally variable in Michigan than in Virginia.

Aggression and Territoriality in Other Plethodontines

Other species of salamanders have not been studied in as much detail as *P. cinereus,* but there is evidence that many other species in the subfamily Plethodontinae are aggressive and probably territorial (Mathis et al. 1995). Several small eastern species of *Plethodon* that are ecologically similar to *P. cinereus* exhibit very similar territorial behavior, including *P. serratus* (Mathis, Deckard, and Duer 1998; Camp 1999), *P. websteri* (Camp 1999), and *P. angusticlavius* (Mathis and Britzke 1999; Mathis, Schmidt, and Medley 2000). These species share many of the elements of aggression and display behavior seen in *P. cinereus,* but their behavior and spatial relationships in the field have not been studied in detail. In western North America, *P. dunni,* a small species similar in appearance and ecology to *P. cinereus,* exhibits many of the same types of territorial behavior, including scent-marking (Ovaska and Davis 1992) and aggressive interactions (Ovaska 1993). In contrast, another very similar sympatric species, *P. vehiculum,* does not appear to be territorial, because groups of individuals sometimes use the same retreat sites (Ovaska 1988b), and aggressive interactions between residents and intruders are rare (Ovaska 1993). Males do exhibit some aggressive behavior, including biting, during the mating season (Ovaska 1987). The more aggressive nature of *P. dunni* enables that species to exclude *P. vehiculum* from choice microhabitats (Dumas 1956), either through overt aggression (Ovaska 1993) or avoidance of chemically marked substrates by the less aggressive species (Ovaska and Davis 1992).

Both intra- and interspecific aggression and territoriality have been reported for a number of larger species of *Plethodon* as well. The best-studied example is the interaction between sympatric members of the *Plethodon glutinosus* and *P. jordani* complexes in the southern Appalachians (see also chapter 15). Both *P. metcalfi* (a member of the *P. jordani* complex) and *P. teyahalee* appear to be intraspecifically territorial (the latter was called *P. glutinosus* by Nishikawa [1985, 1987], *P. teyahalee* by Nishikawa [1990], and *P. ocunaluftee* by Hairston [1993]). Adult males, females, and juveniles all occupy relatively fixed home ranges that overlap those of other individuals, particularly of the same age and sex, less than expected by chance (fig. 9.23). The home ranges of *P. teyahalee* in the Great Smoky Mountains were smaller and more exclusive than were those of *P. metcalfi* in the Balsam Mountains, and always were associated with retreat holes that probably were defended against other individuals. Those of *P. metcalfi* were not always associated with retreat holes or cover objects, suggesting that this species defends territories in the leaf litter. Members of both species complexes were highly aggressive toward conspecifics in laboratory encounters (Nishikawa 1985, 1987), and adults in the field often had conspicuous bite wounds (Nishikawa 1990).

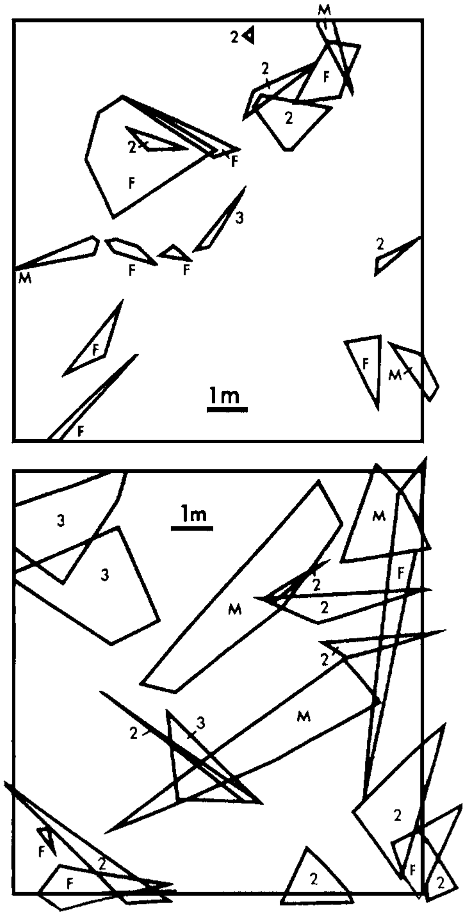

Fig. 9.23. Spatial relationships of home ranges of large *Plethodon* on plots in the Smoky Mountains (top) and Balsam Mountains (bottom) of North Carolina. The top figure shows home ranges of *Plethodon teyahalee.* The bottom figure shows home ranges of *P. metcalfi.* Home ranges were larger and overlapped more in the Balsam Mountains. M = male. F = female. 2 = 2-year-old juvenile. 3 = 3-year-old juvenile. After Nishikawa (1990).

Individuals of *Plethodon teyahalee* from the Great Smoky Mountains, where the two species experience intense interspecific competition (see chapter 15), were more aggressive toward both conspecifics and heterospecifics than were those from the nearby Balsam Mountains, where interspecific competition was less intense (fig. 9.24). Members of the *Plethodon jordani* complex did not show a similar level of variation. Adult *P. jordani* from the Great Smoky Mountains and *P. metcalfi* from the Balsam Mountains were aggressive toward both conspecifics and heterospecifics in both populations (see also Selby, Winkel, and Petranka 1996). Members of the *P. jordani* complex generally occur at much higher densities than does *P. teyahalee,* suggesting that intraspecific competition for choice territories is likely to be intense in both populations (Nishikawa 1985). *Plethodon teyahalee* tended to treat both conspecific and heterospecific intruders as equally important intruders in all populations, whereas members of the *P. jordani* complex were less aggressive toward *P. teyahalee* than toward conspecifics where intraspecific competition was intense, but interspecific competition was not (Nishikawa 1987). Members of these two complexes apparently are not aggressive toward one another in all localities, however. For example, Rissler, Barber, and Wilbur (2000) did not observe any aggressive behavior between conspecific or heterospecific adults of *P. glutinosus*

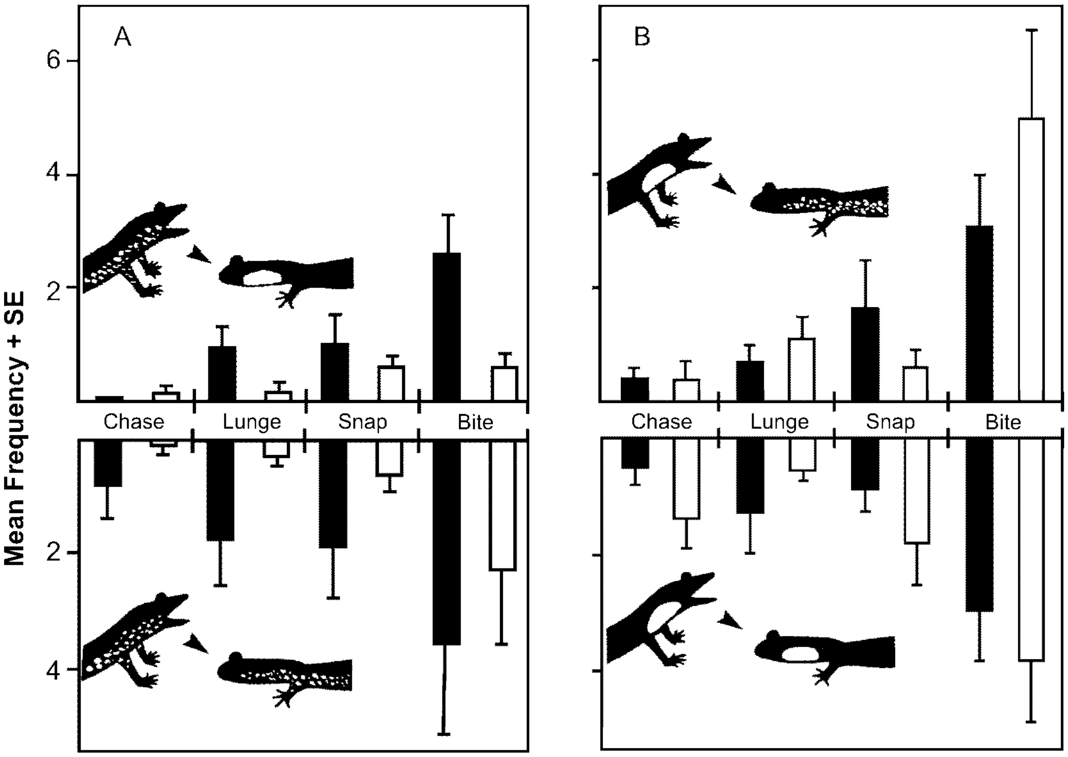

Fig. 9.24. Intra- and interspecific aggressive interactions between members of the *Plethodon jordani* and *P. glutinosus* complexes. (A) Average frequency ± 1 SE of aggressive behavior patterns exhibited by resident *Plethodon teyahalee* from the Smoky Mountains (solid bars) and Balsam Mountains (open bars) during encounters with heterospecifics (top) and sympatric conspecifics (bottom). (B) Average frequency ± 1 SE of aggressive behavior patterns exhibited by resident members of the *P. jordani* complex from the Smoky Mountains (solid bars) and Balsam Mountains (open bars) during encounters with sympatric *P. teyahalee* (top) and sympatric conspecifics (bottom). *Plethodon teyahalee* is shown with small white spots. Members of the *P. jordani* complex, shown with white cheeks, are *P. jordani,* a red-cheeked species, in the Smoky Mountains, and *P. metcalfi,* a gray-cheeked species, in the Balsam Mountains. Behavioral categories increase in level of aggressiveness from left to right. Individuals of *P. teyahalee* from the Smoky Mountains were more aggressive to both conspecifics and heterospecifics than were those from the Balsam Mountains, but this was not true for the *P. jordani* complex. After Nishikawa (1985).

and *P. montanus,* an introduced member of the *P. jordani* complex, at Mountain Lake in Virginia.

Anthony (1993) studied intra- and interspecific interactions in two relatively large salamanders from the Ouachita Mountains in Arkansas, *Plethodon ouachitae* and *P. albagula* (a member of the *P. glutinosus* complex). He found that both species investigated fecal pellets of conspecifics, but were not repelled by them. Some individuals squashed fecal pellets with their snouts, a behavior similar to that of *P. cinereus,* and some also appeared to mark over conspecific pellets by pressing postcloacal glands over the pellets. Adults of *P. ouachitae* tend not to co-occur under the same cover objects in the field and are highly aggressive toward one another in laboratory encounters (Thurow 1976; Anthony and Wicknick 1993). The fights observed in this species were much more violent than those reported for other species of *Plethodon,* with prolonged biting and wrestling bouts in which the opponents rolled over one another and became twisted into knots (fig. 9.25). Adults also tried to bite juveniles, but the latter usually ran away. Juveniles did not avoid substrates marked by adults, but cannibalism of juveniles was not observed. The very aggressive nature of *P. ouachitae* enabled this species to compete with and sometimes displace adults of the larger, but less aggressive *P. albagula* (fig. 9.26; Anthony, Wicknick, and Jaeger 1997). The aggressive interspecific territoriality of *P. ouachitae* probably accounts in part for its greater abundance in favorable habitat where the two species are sympatric.

Both intra- and interspecific territoriality has been reported in *P. kentucki* and *P. glutinosus* that live together in the mountains of Kentucky (Marvin 1998a, b). In the field, adult *P. kentucki* maintained relatively fixed home ranges that did not overlap with those of same-sex individuals. Home ranges of males and females, however, often overlapped, especially when females were gravid. Those of juveniles were randomly distributed, but juveniles did exhibit some aggression toward other salamanders. In laboratory encounters, males were more aggressive toward other males in the

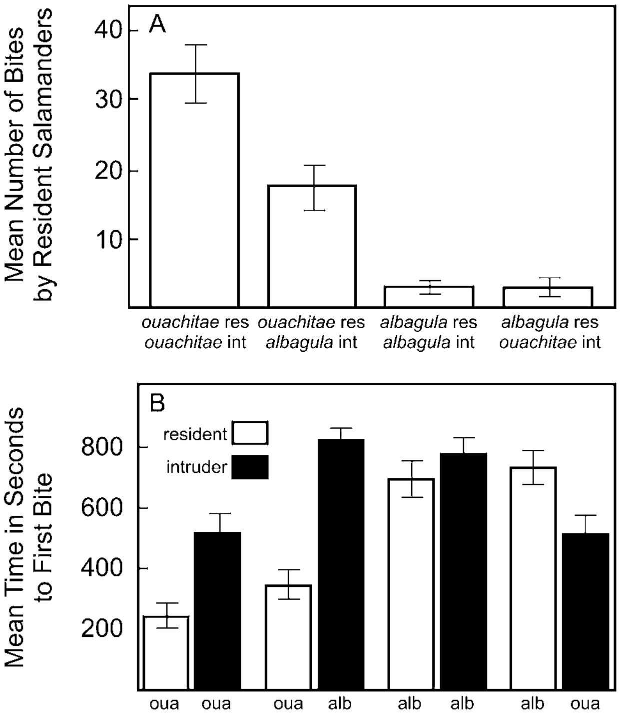

Fig. 9.26. Intraspecific and interspecific aggression in *Plethodon ouachitae* and *P. albagula.* (A) Mean number of bites delivered by the resident salamander (res) to the intruding salamander (int) in intra- and interspecific encounters. *Plethodon ouachitae* residents were much more aggressive toward conspecific and heterospecific intruders than were *P. albagula* residents. (B) Time to first bite by residents and intruders. *Plethodon ouachitae* residents attacked intruders of both species quickly, while *P. albagula* residents did not. Both graphs show that *P. ouachitae* was more aggressive toward conspecifics than toward heterospecifics. After Anthony, Wicknick, and R. G. Jaeger (1997).

breeding season than at other times of year, whereas females and juveniles showed the same level of aggressiveness toward males, females, and juveniles at all times of year. The overall level of aggressiveness by females and juveniles was much lower, however, than that of breeding males. In a high-density population, large males had territories that overlapped more home ranges of gravid females than did the territories of smaller males, but this was not true for a low-density population. Both *P. kentucki* and *P. glutinosus* were equally likely to attack conspecifics and heterospecifics in the laboratory, although the intensity of aggression was greater in conspecific encounters. These salamanders appear to compete for choice retreat and foraging sites both intra- and interspecifically, with *P. glutinosus,* the larger species, being dominant over *P. kentucki.*

Two other genera of plethodontine salamanders exhibit relatively high levels of aggression and evidence of territoriality. Members of the genus *Aneides* from both eastern and western North America are aggressive toward conspecifics and defend retreat sites such as rock crevices and tree holes as territories (Gordon 1952; Cupp 1980; Staub 1993; T. Davis 2002a). These salamanders have exceptionally large jaw-closing muscles, especially in males, long, sharp teeth, and various anatomical features that strengthen the skull (fig. 9.27). Fights include prolonged biting similar to that seen in *Plethodon ouachitae,* but not in most other species of *Plethodon.* Males in particular are capable of inflicting serious wounds on opponents, and bite scars are common in animals collected in the field, especially in three western species in the *A. lugubris* complex (*A. lugubris, A. ferreus,* and *A. flavipunctatus;* Staub 1993).

A relatively large salamander from the West Coast of the United States, *Ensatina eschscholtzii,* also appears to be territorial (Wiltenmuth 1996). In laboratory encounters, established residents were more aggressive than were intruders, and males were more aggressive than were females. Overt aggression included chasing, pushing opponents with

Fig. 9.27. Male *Aneides lugubris,* showing very large jaw muscles used in fighting. Photo by Nancy Staub.

the head, and biting. *Ensatina* lacks the hypertrophied jaw muscles and long teeth found in *Aneides,* and serious wounds were not observed in this species. *Ensatina* is a classic example of a "ring species," in which lineages have diverged as they moved from a common point of origin, with genetically divergent populations then coming into secondary contact where their ranges come together. Divergence of lineages has been accompanied by some divergence in aggressive behavior, particularly among females (Wiltenmuth and Nishikawa 1998). Females in coastal populations tend to be more aggressive and exhibit greater avoidance of other females than do those in inland populations. Presumably this divergence is related to ecological differences between populations, but these have not been studied in detail.

Aggression and Territoriality in Desmognathines

As in the genus *Aneides,* desmognathine salamanders have unusually large jaw-closing muscles and are capable of inflicting serious injuries on other salamanders. Males and females of several species of *Desmognathus* defend retreat sites against conspecifics, and biting attacks have been observed both in the field and in the laboratory (Brandon and Huheey 1971; Keen and Sharp 1984; Keen and Reed 1985; Jaeger 1988; Verrell and Donovan 1991; Camp 1996; Camp and Lee 1996). In some species, an attacker sometimes bites off part of the tail of an opponent, and large adults sometimes cannibalize smaller juveniles (Keen and Sharp 1984; Camp 1996). Scarring of the snout region, probably resulting from intruders being bitten while investigating occupied retreat sites, also is common. Several experiments have shown that large individuals can exclude smaller salamanders from retreat sites. The social behavior of one desmognathine, *Phaeognathus hubrichti,* a large burrowing species, is largely unknown. Males are larger and are more muscular than females, and they often exhibit extensive scarring, apparently from bites. This suggests that aggressive behavior among males may be common (Bakkegard and Guyer 2004).

The spatial distribution of desmognathines in a population is influenced by both the density of suitable cover objects and the presence of resident salamanders (Keen and Sharp 1984; Keen and Reed 1985; Kleeberger 1985; Jaeger 1988; Colley, Keen, and Reed 1989). Aggression and territorial behavior extend to interspecific interactions as well. Large species, such as *D. quadramaculatus* and *D. monticola,* can exclude smaller species, such as *D. fuscus* and *D. ocoee,* from preferred retreat sites. This can affect the microhabitat use and spatial distribution of individuals in a multispecies community, although there is variation among populations in the frequency of interspecific aggression (Southerland 1986a; see chapter 15 for a more detailed discussion of interspecific competition).

There also is some evidence from laboratory studies that desmognathine salamanders can recognize substrate-borne or airborne odors of other salamanders. In some experiments, salamanders preferred their own odors to those of other individuals, but there is not a consistent tendency for individuals to avoid the odors of conspecifics (Keen, McManus, and Wohltman 1987; Evans and Forester 1996). When females of a population of *D. ochrophaeus* from Maryland were given a choice of substrates marked by males from their own population and those from a nearby population, they spent more time on the substrates from the other population (A. Evans, Forester, and Masters 1997). The experimental design did not, however, discriminate between attraction to odors of males from other populations and avoidance of males from the same population. There is some evidence that juveniles of *Desmognathus* avoid the odors of adults, which sometime prey on them (Evans and Forester 1996). Roudebush and Taylor (1987b) reported that *D. monticola* avoided substrates marked by the larger *D. quadramaculatus,* although they did not avoid feces or cloacal gland odors of that species (Jacobs and Taylor 1992). At present, evidence for chemical advertisement of territories is not nearly as strong for desmognathines as it is for plethodontines. In part, this is simply because they have been studied less intensively. It also seems likely that the semiaquatic habitats used by many desmognathines are less suitable for deposition of long-lasting chemical markers than are the drier terrestrial habitats used by *Plethodon, Aneides,* and *Ensatina.*

Aggression in Ambystomatids and Dicamptodontids

Aggressive behavior has been reported in both the larvae and adults of ambystomatid salamanders. Aggression in larval ambystomatids includes apparent visual displays and biting, and it sometimes grades into cannibalism. Both aggressive competition and cannibalism tend to increase as population density increases, and represent forms of interference competition for limited food resources (Walls and Jaeger 1987; Semlitsch and Reichling 1989; Petranka 1989a; C. K. Smith 1990; Van Buskirk and Smith 1991; Walls and Semlitsch 1991; Mathis et al. 1995; Walls 1998; Wildy et al. 2001). Larval competition is discussed in more detail in chapter 13. There is no convincing evidence that larvae of ambystomatids or any other family of salamanders are terrritorial.

Aggressive behavior of terrestrial juveniles and adults of ambystomatid salamanders has been observed in the laboratory. Outside of the breeding season, these animals spend most of their time in hidden retreat sites, especially small mammal tunnels through the soil and leaf litter (Semlitsch 1981a; Madison 1997; Madison and Farrand 1998). Marked individuals often move to the same general area each year after leaving breeding ponds (see chapter 6), but it seems unlikely that they occupy precisely the same tunnels, because these probably are somewhat ephemeral. It is conceivable that animals advertise ownership of particular tunnels or burrows with chemical markers and defend them aggressively against intruders, but such behavior has not been observed in the field.

Ducey and Ritsema (1988) housed adult spotted salamanders (*Ambystoma maculatum*) in cages with artificial plastic tunnels. When two individuals were housed together, they tended to occupy different tunnels. They also defended tunnels by elevating the body, advancing toward or touching intruders, and by biting intruders on the snout. Subsequent work with several other species (*A. opacum, A. talpoideum, A. macrodactylum,* and triploid hybrids of the *A. jeffersonianum* complex) housed in the same type of cages with artificial tunnels revealed similar types of aggressive behavior, although the frequency of biting varied among species (Ducey 1989). Biting by captive adults was previously reported in *A. gracile* by Licht (1973), and has been observed in newly metamorphosed juveniles of several species (Walls 1990, 1991). There also are anecdotal observations of similar aggression in *Dicamptodon,* the sister group to the ambystomatids (Nussbaum, Brodie, and Storm 1983). Ducey and Heuer (1991) reported that aggression in several ambystomatid species was reduced when the animals were well fed. They interpreted this as evidence that aggression serves mainly to defend feeding territories rather than tunnels used as retreat sites, but the absence of field observations makes this conclusion highly speculative. If ambystomatids do defend retreat sites in the field, such defense appears to be relatively ineffective. Multiple spotted salamanders (*Ambystoma maculatum*) sometimes are found in the same burrows in the field, and they readily occupied the same artificial burrows in the laboratory (Regosin, Windmiller, and Reed 2004). Whether these salamanders actually are attracted to conspecifics, as in *Salamandra luschani* (Gautier et al. 2006) or simply tolerate them, is not yet known.

There is relatively little evidence for pheromonal marking of territories by ambystomatids. Ducey and Ritsema (1988) and Ducey (1989) did not report any behavioral acts that seem clearly related to substrate marking, such as pressing the cloaca to the substrate. Furthermore, none of the species tested showed a tendency to avoid substrates marked by other conspecifics (see also D. Martin, Jaeger, and Labat 1986) or to distinguish between odors of familiar and unfamilar conspecifics (Ducey, 1989). Indeed, in some cases, individuals spent more time on substrates from cages of conspecifics than on their own substrates. Mathis et al. (1995) interpreted these results as evidence that resident individuals were attempting to confront intruders or mark over their chemical signals, but it also is possible that the observed behavior simply reflects a tendency for salamanders to investigate unfamiliar odors in their environment. Ambystomatids do not have naso-labial grooves to conduct odorants from the substrate to the vomeronasal organs, but they do tend to press their snouts against substrates and other salamanders when investigating them, a behavior that probably has a chemosensory function. Nevertheless, the question of scent marking and its effect on the spacing behavior of ambystomatids requires further investigation.

Aggression in Salamandrids

Territorial behavior appears to be rare among salamandrids. J. Davis and Brattstrom (1975) reported that captive individuals of *Taricha torosa* defended rocks in aquaria with elaborate visual and vocal displays. However, aggressive behavior has never been reported in the field, so the significance of the behavior is not known. Terrestrial adults of European fire salamanders (*Salamandra*) occupy limited home ranges (Degani and Warburg 1978; Plasa 1979) and often return to familiar retreat sites that appear to be marked with chemical signals (Gautier and Miaud 2003). Kastle (1986) observed wrestling bouts in *S. salamandra,* but not biting, between males, which appeared to be defending prominent landmarks, such as piles of rocks and tree roots, as territories. Whether such behavior occurs only during the breeding season, and whether it represents true territorial behavior, is unclear. Andreone (1992) reported similar behavior in another member of the same genus, *S. lanzai.* Males of this species also occupied elevated perches at night, and two males were found clasped together in an apparent fight.

Males of some aquatic salamandrids are aggressive toward other males during the breeding season, and several large species of European newts have leklike mating systems in which males defend small mating territories (see "Mating Systems and Sexual Selection," following). Most other newts are nonterritorial and exhibit relatively little aggressive behavior. There is mixed evidence about the possible use of scent marking by salamandrids. An early paper by Gauss (1961) reported that males of *Triturus cristatus* advertised their territories by placing chemical markers on the substrate. Subsequent work has shown that males in some populations of this species form leks and defend small mating territories, but scent-marking has not been reported in these studies (Zuiderwijk and Sparreboom 1986; Hedlund and Robertson 1989). Apparent cloacal scent marking also was reported in another aquatic salamandrid, *Calotriton asper,* by Lengvenus and Parzefall (1992), who also observed males biting one another. It is not clear whether the aggression observed in this species represents territorial behavior or sexual interference during courtship (Thiesmeier and Hornberg 1990).

Aggression in Other Families

Aggression in salamanders was first described in aquatic cryptobranchids (Kerbert 1904; S. Bishop 1941b; Hillis and Bellis 1971). Males establish territories under large rocks in streams or rivers and vigorously defend them by biting intruders, especially other males. In the Japanese giant salamander (*Andrias japonicus*), very large males hold the best territories, which serve as both retreat and oviposition sites. Intruding males are vigorously attacked, but multiple sneaker or satellite males often enter a nest when females are laying eggs. Cryptobranchids have external fertilization, so these intruding males probably have opportunities to fertilize some of the female's eggs (Kawamichi and Ueda 1998). Once the eggs have been laid the female leaves, but the male remains with the eggs and guards them after they are deposited (see chapter 11). These salamanders essentially have a resource-defense mating system similar to that of some frogs (see the following discussion and chapter 8). Some hynobiids, which also have external fertilization, are reported to defend territories under rocks in the breeding season (Thorn 1962, 1963, 1967; Tanaka 1986, 1987, 1989), and they probably have resource-defense mating systems as well (Nussbaum 1985).

Some sirenids, the only other group of salamanders with external fertilization, also might be territorial, but the evidence is circumstantial (Mathis et al. 1995). Individuals have been seen fighting over retreat sites (Asquith and Altig 1987), and both males and females often have bite wounds (Godley 1983). Unfortunately, the behavior of sirenids is so poorly known that even mating behavior has never been observed. Nevertheless, the occurrence of bite scars only in sexually mature individuals, and primarily in the breeding season, suggests that the scars result from aggressive interactions among males, although it also is possible the some females acquire scars during courtship or while guarding eggs against conspecific predators (Fauth and Resetarits 1999). Observations of proteids in captivity suggest that males defend territories under rocks, but observations of aggression are anecdotal (Briegleb 1962; Parzefall 1976; Parzefall, Durand, and Richard 1981; R. Ashton 1985). These salamanders have internal fertilization, and guarding of eggs, if it occurs, is more likey to be done by the female (see chapter 11).

Mating Systems and Sexual Selection in Urodeles

The mating systems of salamanders exhibit many similarities to those of anurans (chapter 8) and can be analyzed according to the same principles (Verrell 1989c; Sullivan, Ryan, and Verrell 1995). Nevertheless, the details of courtship, reproductive competition, and sexual interference differ substantially from those of anurans. This is because most salamanders have internal fertilization by means of spermatophores, which contrasts with the external fertilization found in most anurans. This can affect the evolution of mating systems in several ways. First, it allows for the temporal and spatial separation of courtship and mating from oviposition. In some plethodontids, for example, courtship and mating occur in the fall and spring, but oviposition does not take place until summer. This makes it unlikely that males will adopt a mating strategy of defending oviposition sites that are attractive to females (resource defense polygyny), although this does seem to occur in the externally fertilizing cryptobranchids (S. Bishop 1941b) and hynobiids (Tanaka 1989; Kawamichi and Ueda 1998). The use of spermatophores also requires relatively close coordination between males and females to ensure successful pickup of spermatophores by females. This seems to have led to the evolution of much more elaborate courtship behavior in urodeles than that seen in most anurans (Arnold 1977; Halliday 1990). Finally, internal fertilization changes the nature of sperm competition (Halliday and Verrell 1984; T. Halliday 1998). Simultaneous fertilization of a female's eggs by several males, like that seen in some arboreal frogs (see chapter 8), is not possible with internal fertlization, although sequential fertilization by several males is possible. This is expected to lead to the evolution of various forms of sexual interference in which males try to disrupt the mating attempts of other males before mating takes place, and to mate guarding as a means of denying rival males access to a female. Such mate guarding can occur both before and after a male completes courtship with a female (Arnold 1976; Halliday and Verrell 1984; Verrell 1989c; Halliday 1990, 1998; Halliday and Tejedo 1995). Postmating mate guarding is likely to have limited effect, however, if females can store sperm for long periods of time (e.g., E. Adams, Jones, and Arnold 2005).

The range of mating systems described for urodeles is similar to that seen in anurans. These include explosive mating aggregations with scramble competition, competitive mate searching and mate guarding, leks, and resource defense (Verrell 1989c; Halliday and Tejedo 1995; B. Sullivan, Ryan, and Verrell 1995). It is important to recognize that these mating systems represent points along a continuum of mating strategies, with the distinct categories being defined largely for the convenience of investigators. For example, the type of scramble competition seen in explosive mating aggregations tends to grade into competitive mate searching and mate guarding, depending on the degree of synchrony in the mating season and the density of competing males. Similarly, active mate searching grades into lekking behavior largely as a function of population density, characteristics of the breeding site, and the degree of site fidelity exhibited by displaying males.

Temporal and Spatial Patterns of Reproduction

Like anurans, salamanders can be divided into species with prolonged and explosive courtship periods. Highly explosive breeding is relatively rare in salamanders, perhaps because few species breed in temporary water. This pattern is found mainly in ambystomatids, most of which breed in late fall, winter, or early spring, including *Ambystoma annulatum, A. cingulatum, A. jeffersonianum, A. macrodactylum, A. maculatum, A. opacum,* and *A. texanum* (Arnold 1976, 1977; McWilliams 1992; Krenz and Scott 1994; Verrell and Pelton 1996). Explosive breeding also occurs in some hynobiid salamanders that breed in winter or early spring (Hasumi 1994). Most other salamanders have courtship periods lasting from several weeks to several months, and many tropical species probably court throughout the year (Houck 1977a). So little is known about sirenids and amphiumids that their courtship patterns cannot be characterized.

Arnold (1976, 1977) emphasized the impact of temporal variation in female availability on patterns of male courtship. Salamanders appear to have a limited supply of spermatophores available each year (Halliday 1976; Verrell 1986a, 1988a; Verrell, Halliday, and Griffiths 1986), so temporal variation in female arrival will determine how a male can best allocate his sexual resources (W. Harris and Lucas 2002). As in frogs, short breeding seasons and intense male-male competition probably select for rapid courtship of females and expenditure of considerable effort in courting the first female encountered, even at the expense of reduced fertilization efficiency. On the other hand, if the male has the opportunity to court many females each year, then selection should favor husbanding of resources and maximum efficiency in courtship and mating. Patterns of sperm allocation are expected to be affected not only by the availability of females, but also by the intensity of competition among males, since reproductive payoffs will be relatively low when many males are present (W. Harris and Lucas 2002). The duration of the courtship season also affects the form of male-male competition. In dense aggregations of explosive breeders such as some *Ambystoma,* one would expect various forms of scramble competition to predominate, whereas in low-density populations of more prolonged breeders, other forms of competition, including guarding of individual females and territoriality, might be employed (Wells 1977a; Verrell 1989c; Halliday and Tejedo 1995; B. Sullivan, Ryan, and Verrell 1995). Finally, in species with short courtship seasons, male-male competition restricts opportunities for female choice to operate, as it does in frogs. In more prolonged breeders, females can compare potential mates and actively choose among them. Consequently, one might expect greater sexual dimorphism in display structures and more complex courtship behavior in prolonged breeders.

Explosive Mating Aggregations and Scramble Competition

Explosive mating aggregations occur when the arrival of males and females at a breeding site is highly synchronized and the duration of the mating season is short. Often this results in high densities of males competing for access to limited numbers of females. The predominant form of competition is scramble competition, in which males attempt to mate with females as rapidly as possible (Verrell 1989c; Halliday and Tejedo 1995; B. Sullivan, Ryan, and Verrell 1995). Males typically search for females in breeding ponds and probably are attracted to chemical cues emanating from females. There is little evidence that females are attracted to males (P. Verrell, Strand, and Hanson 2001).

Ambystomatidae

Most ambystomatid salamanders make synchronized movements to breeding sites after warm rains in winter or early spring. Males usually arrive before females and often outnumber them, sometimes by 10 to 1. The effective bias in sex ratio is increased by the much shorter residence time of females, which probably engage in courtship only once and leave the ponds soon after oviposition (Douglas 1979; Semlitsch 1985a; Beneski, Zalisko, and Larsen 1986; Sexton et al. 1986; McWilliams 1992; Verrell and Pelton 1996; Verrell and Krenz 1998; W. Harris and Lucas2002). In spotted salamanders (*Ambystoma maculatum*), courtship lasts no more than a month, and often lasts only a few days in any given pond. Males greatly outnumber females at the breeding site. Males move about the pond searching for females, and several males often attempt to court the same female simultaneously, each depositing many spermatophores scattered over a large area. Courtship behavior is relatively simple, with little direct interaction between individual males and females. Males do not attempt to monopolize females, but they do compete by placing their spermatophores near those already present, resulting in clusters of spermatophores on the bottom of the pond. Males also sometimes place their spermatophores directly on top of those already deposited by other males (fig. 9.28), a form of sexual interference (see the following "Alternative Mating Tactics"). Each male deposits an average of 40 spermatophores per courtship—nearly half his total complement for the year—but there is a low probability that any particular spermatophore will be located by a female (Arnold 1976). This species exhibits an extreme form of scramble competition, with little or no opportunity for females to choose mates. Genetic studies have shown that multiple paternity is common, but there is a clear advantage to males that mate first with females, and this probably favors early arrival of males in ponds (Tennessen and Zamudio 2003; E. Myers and Zamudio 2004).

Similar behavior has been described in *A. texanum* (Garton 1972; Petranka 1982a; McWilliams 1992; W. Harris and Lucas 2002). A male sometimes deposits up to 128 spermatophores in a single courtship, suggesting that males enhance their chances of fertilizing a female mainly by depositing as many spermatophores as possible, instead of investing a lot of time in courtship before spermatophore deposition. The precise allocation of sperm to each courtship event will be affected by the size of a male's sperm reserves and the expected future availability of females as the number of females declines during the breeding season (W. Harris and Lucas 2002). Males are aware of the presence of females, probably relying on chemical cues for sex identification, and they deposit spermatophores most rapidly when females are nearby. There is little direct interaction among males in a courting group, but as in *A. maculatum,* males sometimes cover previously deposited spermatophores with their own. Females pick up large numbers of spermatophores (average of 26 spermatophores per courtship), so there is the potential for sperm competition among males if several males court a female simultaneously. In laboratory experiments, males deposited more spermatophores if other males were present than if they were alone (McWilliams 1992). The effect of this behavior on actual male reproductive success remains to be determined.

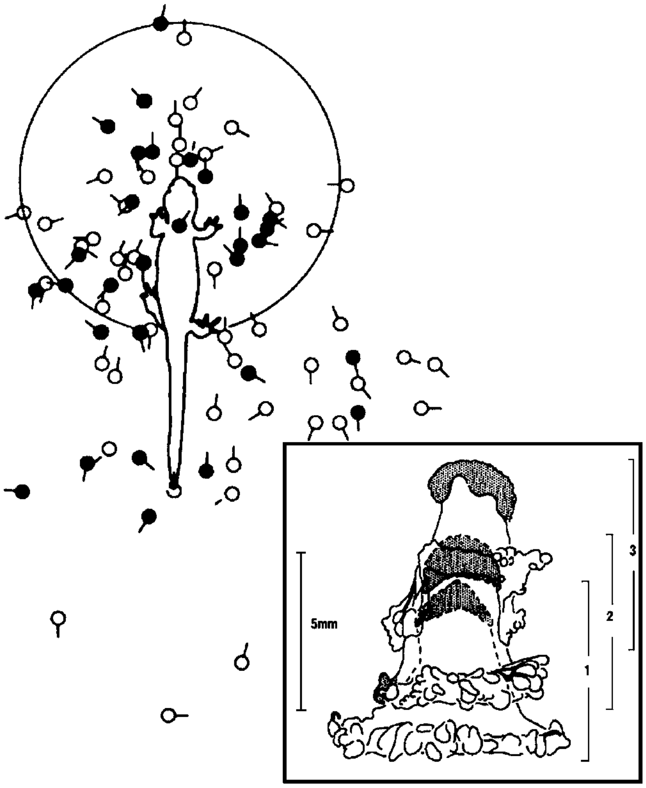

Fig. 9.28. Pattern of spermatophore deposition by *Ambystoma maculatum* in relation to the female's body. Small solid circles show the position of single spermatophores. Small open circles show spermatophores deposited on other spermatophores (see inset). Lines indicate direction male was facing at onset of spermatophore deposition. The large circle indicates a radius of one body length around the female's snout. Large numbers of spermatophores are randomly distributed around the female's body. After Arnold (1976).

Marbled salamanders (*A. opacum*) and ringed salamanders (*A. annulatum*) both have similar mating systems, but in these species, courtship takes place on land after adults have migrated to dry or partially filled pond basins in the fall (Noble and Brady 1933; Spotila and Beumer 1970). Males typically outnumber females and engage in scramble competition for mating opportunities. Krenz and Scott (1994) discovered that some females in a population of marbled salamanders in South Carolina arrived at the breeding area having already mated, suggesting that some males intercept and court females as they are moving toward the breeding area. This would enable males to avoid competition from other males at the breeding site, reducing the likelihood of sexual interference, such as covering of spermatophores.

Hynobiidae

Some hynobiids also have explosive breeding periods, but in contrast to ambystomatids, these salamanders have external fertilization. Females lay eggs in paired jelly sacs, which are then fertilized by males as they clasp the sacs with their front legs. In explosive-breeding species, including *Hynobius retardatus, H. dunni,* and *H. nigrescens,* males form mating balls around newly deposited egg sacs, competing for the chance to fertilize the eggs (Sasaki 1924; Hasumi and Iwasawa 1990; Sato 1992; Hasumi 1994). In *H. nigrescens,* a male clasps a female around her pelvic region as soon as she begins to deposit an egg sac, but shifts his grasp to the egg sac itself as it emerges, releasing sperm immeditately. Other males cluster around the sacs, jostling one another and competing to clasp the egg sac, with as many as eight males participating in a mating ball. Males also bite at competing males and twist their bodies and tails from side to side to dislodge competitors. In general, the first male to clasp the egg sacs was the most successful in maintaining a hold long enough to fertilize eggs (Hasumi 1994). As in explosive-breeding ambystomatids, there is little or no opportunity for females to select mates. In *H. leechii,* multiple insemination has been observed when different males clasp each of the two paired egg sacs produced by a female (S.-R. Park, Park, and Yang 1996; Park and Park 2000). This species also exhibits postmating guarding of egg sacs. Such guarding is relatively brief, averaging only about half a minute, but presumably is sufficient to reduce the chances of a second male attempting to fertilize the eggs immediately after the first male has mated.

Salamandridae

Scramble competition and formation of balls of males competing for access to a single female also has been reported in *Taricha granulosa,* but in this species fertlization is internal by means of spermatophores. A male clasps a female in amplexus from above, and other males sometimes attempt to wrestle the female away from the original male (Arnold 1977; Janzen and Brodie 1989). This behavior resembles that of explosive-breeding frogs, but presumably courtship cannot proceed to spermatophore deposition until all of the intruding males have been repelled. Males allowed to court females in the absence of competitors normally spend a considerable amount of time in courtship before depositing a spermatophore (Propper 1991). Janzen and Brodie (1989) reported that males that were found paired with females or participating in mating balls were larger than unpaired males, but they did not present data on the relative sizes of males that were ultimately successful in completing courtship. Females are known to mate with more than one male, but the first male to mate with a female normally fertilizes the largest proportion of her eggs (A. Jones et al. 2002). In the field, sex ratios normally are heavily skewed toward an excess of males, and this is likely to lead to increased mating skew and an increased intensity of sexual selection acting on males (A. Jones, Adams, and Arnold 2004).

Mate Searching and Mate Guarding

Mate searching is defined here as a mating system in which males move about the breeding area or their normal year-round habitats in search of females, rather than remaining in one place and waiting for females to come to them. Once a male locates a female, he sometimes guards her against rival males. Mate guarding behavior includes seizing females in amplexus during courtship, transporting females away from rival males, or aggressively repelling competitors. Competitive mate searching and mate guarding are widespread among salamanders and probably is the most common mating system in this group.

Ambystomatidae

As the length of the breeding season increases, or as population densities at breeding sites decrease, the various forms of scramble competition seen in explosive-breeding ambystomatids tend to grade into a system of competitive mate searching and mate guarding. In a study of tiger salamanders equipped with radio transmitters, Madison (1998) found that males initially gathered in the deepest, clearest part of a breeding pond, presumably to search for females where visibility was highest. In mate-searching species, a male typically invests time and energy in monopolizing females and courting them individually before depositing spermatophores, instead of scattering groups of spermatophores around females. For example, male tiger salamanders (*A. tigrinum*) push females away from competitors (fig. 9.29); each female is then courted individually and led over a spermatophore in a tail-nudging walk (Arnold 1976). Although a male deposits only about 20 spermatophores per courtship, the chances of each one being found are higher than in *A. maculatum.* Rival males interfere with courtship by interposing themselves between a courting male and his female. By mimicking female behavior in the tail-nudging walk, the intruding male causes the leading male to deposit a spermatophore, which he then caps with his own (fig. 9.30). This tactic is used mainly by males that are smaller than those already courting females; larger individuals are more likely to push females away from rivals (R. D. Howard, Moorman, and Whiteman 1997). There is some opportunity for females to choose or reject particular males as mates, but male-male competition probably is a major determinant of male mating success.

Other ambystomatids with mating systems resembling that of *A. tigrinum* include *A. jeffersonianum, A. laterale, A. dumerili, A. talpoideum, A. macrodactylum,* and *A. gracile.* In all of these species, males court females individually, deposit relatively few spermatophores, and lead females over spermatophores (Mohr 1931; J. Anderson 1961; Licht 1969b; Storez 1969; Uzzell 1969; Brandon 1970b; Arnold 1977; Verrell and Pelton 1996; Verrell and Krenz 1998). In several of these species, mate guarding is carried further than in *A. tigrinum.* Males actually seize females in amplexus, clasping them with their forelimbs. A male often engages in a prolonged period of courtship stimulation, rubbing his chin against the cheek of the female. Evidentally this is primarily a tactile signal, because mental courtship glands have not been described in ambystomatids (Verrell and Pelton 1996). The female signals her receptivity by

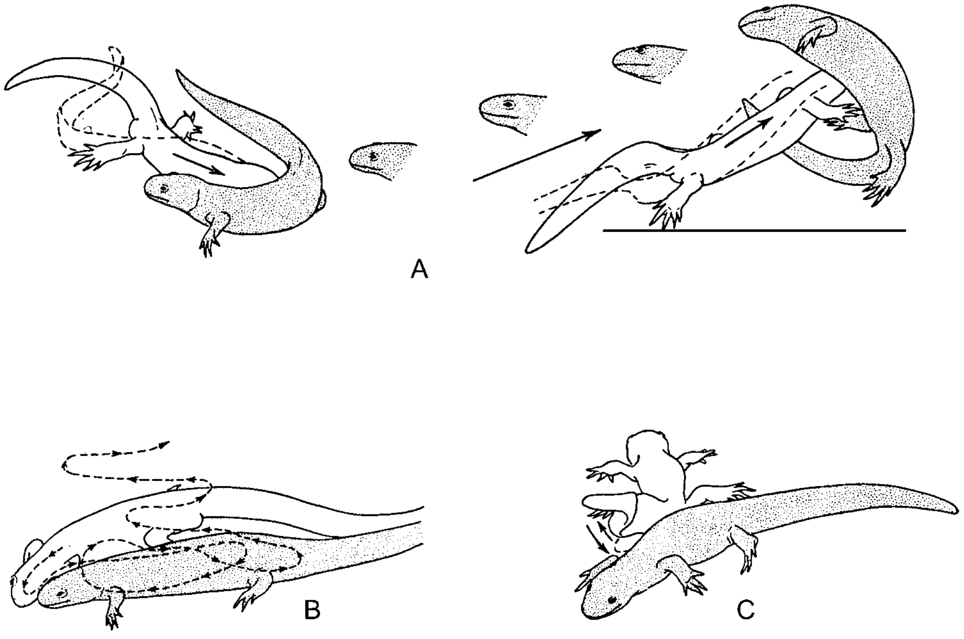

Fig. 9.29. Initiation of the tail-nudging walk during courtship in *Ambystoma tigrinum.* The male is shown in white, the female in gray. (A) The male transports the female away from rival males by shoving her through the water. (B) The male rapidly slides his snout over the back of the female and then moves away from her on a path indicated by the dashed line. (C) The male pauses while facing away from the female and repeatedly taps his tail on her dorsum. After Arnold (1976).

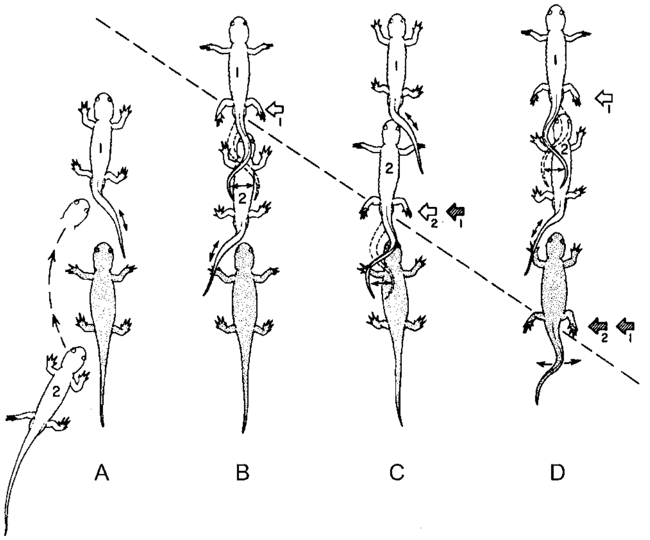

Fig. 9.30. Sexual interference in *Ambystoma tigrinum.* Males are shown in white, females in gray. (A) A second male intrudes as the first male leads the female in a tail-nudging walk. (B) The second male has inserted himself between the first male and the female and monitors the female's position by tapping his tail. The first male deposits a spermatophore (white arrow). (C) The second male deposits a spermatophore (gray arrow) on top of the first male's spermatophore. (D) The female attempts to pick up a sperm cap from the double spermatophore (double gray arrow), but only the second male's sperm is accessible. The first male subsequently deposits a second spermatophore (white arrow). After Arnold (1976).

lifting her head, and the male responds by proceeding to spermatophore deposition.

Salamandridae

Many genera of Old World salamandrids engage in some sort of amplexus during courtship (Houck and Arnold 2003). In *Salamandra, Mertensiella, Chioglossa, Pleurodeles, Echinotriton,* and *Tylototriton,* the male seizes the female from below by looping his front legs over those of the female (fig. 9.3). Presumably amplexus functions as mate guarding behavior, allowing the male to court the female without interference from other males. Nevertheless, the precise nature of the mating systems of these salamanders is not clear, because observations of courtship have been made mostly in the laboratory. There is some evidence that males of *Salamandra* are territorial (Kastle 1986; see previous discussion), but whether females mate in the territories of males is not known. In laboratory observations, males maintain an alert posture and actively pursue any moving salamanders, suggesting that males search for mates (Himstedt 1965; Joly 1966; Arnold 1987). Similar behavior has been seen in *Chioglossa lusitanica,* which probably is closely related to *Salamandra* (Arnold 1987; Houck and Arnold 2003). In both of these genera, the male holds the female tightly throughout amplexus, but moves aside after depositing a spermatophore to lower the female's cloaca over the spermatophore. This close guarding of females suggests that attempted interference by other males is common in these species, something that seems unlikely if males courted females in exclusively held territories. Unfortunately, courtship in the presence of rival males has not been investigated, nor is there any information on spatial relationships and movements of males and females in the field.

Males of *Mertensiella caucasica* exhibit courtship amplexus like that of *Salamandra* and *Chioglossa* (fig. 9.3), clasping females throughout courtship and moving aside to lower them over the spermatophore. In this species, and in another previously placed in the genus *Mertensiella, Salamandra luschani,* males have an unusual morphological feature not found in any other salamanders. This is a fleshy protuberance at the base of the tail, just above the cloaca (fig. 9.31). This is placed in the cloaca of the female during amplexus (Schultschik 1994) and probably serves to align the female's cloaca with that of the male, ensuring that she will be lowered directly over the spermatophore (Arnold 1987). There are subtle differences in the histology of the glandular structure of the tubercles in the two species, which suggests the possibility of independent evolution of this trait (Sever et al. 1997). This interpretation is supported by recent phylogenetic work showing *S. luschani* to be more closely related to other species of *Salamandra* than to *M. caucasica* (Larson, Weisrock, and Kozak 2003).

Males of the genus *Pleurodeles,* which court females in water, also seize females from below, but the mode of sperm transfer is different. After depositing a spermatophore, the male releases one of the female's forelimbs and pivots around her so he is facing toward her. The female is then turned around to align her cloaca with the spermatophore (Arnold 1977; Houck and Arnold 2003). In laboratory observations, rival males sometimes attempted to wrestle males off of females or clasped females during spermatophore transfer, thereby disrupting the mating attempt. Again, this suggests that the tight amplexus of these salamanders helps a male monopolize a female.

In the European genera *Euproctus* and *Calotriton,* males have evolved a completely different form of mate guarding and spermatophore transfer. The female is seized from below, as in the previous genera, but she is held tightly by the male's tail, which is looped around her body, rather than his forelimbs (fig. 9.32). Sometimes the male also holds the female with his hind legs or his jaws. Amplexus can be a prolonged affair in these salamanders, lasting up to 30 hours in *Calotriton asper* (Thiesmeier and Hornberg 1986). Rival males often attempt to displace males from amplexus with aggressive attacks, and more than one male has been observed clasping the same female (Thiesmeier and Hornberg 1986, 1990). The mode of spermatophore transfer is unique to this genus; spermatophores are placed directly into the cloaca of the female in what amounts to copulation. The cloaca of the male is formed into a conical protuberance that facilitates placement of sperm into the female's cloaca. Again, the precise nature of the mating systems of these salamanders is unclear. Observations by Thiesmeier and Hornberg (1990) suggest that males of two species, *Euproctus platycephalus* and *E. montanus,* actively search for females and sometimes seize them aggressively with their jaws before clasping them with the tail. In contrast, males of *C. asper* are reported to assume a conspicuous display posture that attracts females, with the tail elevated above the body. Males of this species also seem to seize females more gently. These observations suggest that the mating system of *C. asper* more closely resembles lekking behavior than mate searching, but additional field observations are needed.

North American newts of the genus *Notophthalmus* also search for mates and seize them in amplexus as a means of guarding them from rival males (Verrell 1982, 1983, 1990a; Massey 1988). In this genus, however, males capture females from above with their hind legs (fig. 9.11 B). Other males often try to insert themselves between the male and the female, or displace the courting male by wrestling with him (fig. 9.33). Usually the original male retains possession of the female, but occasionally a larger intruder will displace

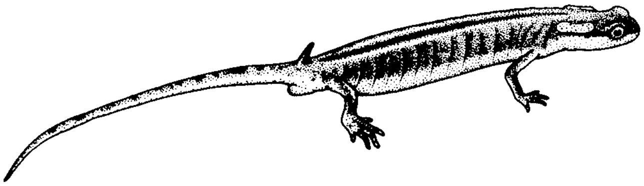

Fig. 9.31. Breeding male of *Salamandra luschani,* showing the dorsal protuberance at the base of the tail, which is used in courtship. This type of structure also occurs in *Mertensiella caucasica* and formerly was used as a character to unite these two species in the genus *Mertensiella.* Molecular phylogenetic studies suggest that *S. luschani* is more closely related to other species of *Salamandra* than to *M. caucasica,* in which case the tubercle probably evolved independently in the two species. This conclusion is supported by differences in the histology of the structure in the two species. From Halliday (1990).

the courting male (Verrell 1986c). Males sometimes skip the amplexus stage of courtship when rival males are absent and proceed directly to a brief display before initiating spermatophore deposition (Verrell 1983). Male-male competition clearly influences mating success, but females also have opportunities to accept or reject particular males. In a natural population, most courtship attempts were unsuccessful, either because of interference from rival males or because the female simply left after being released by the male (Massey 1988).

Males of most Old World newts (*Triturus, Neurergus, Paramesotriton, Cynops,* and *Pachytriton*) probably search for mates in breeding ponds, approaching anything that resembles a female newt, although some species of *Triturus* form leks (see the following discussion). These genera lack amplexus, but males engage in elaborate courtship of individual females. The details of these displays have already been discussed in the section on "Modes of Communication." The absence of amplexus and the use of elaborate visual, chemical, and tactile signals during courtship appear to be derived conditions within the family Salamandridae (Halliday 1990; fig. 9.3). Because males do not physically monopolize females, rival males frequently interrupt courtship bouts and attempt to insert themselves between the courting male and female, often just before the original male would deposit a spermatophore (fig. 9.34). The intruder then attempts to lure the female away from the orignal male and complete the courtship sequence with her. Males of several species also have been observed engaging in female mimicry (fig. 9.35). This involves a male inserting himself between a courting male and female, following the lead male while touching his tail. This sometimes induces the first male to deposit a spematophore, which often is not picked up by the female and is wasted. Sometimes the female moves away from the original courting male and follows the intruder and completes courtship with him (Verrell 1984a, 1988c; Giacoma and Crusco 1987; Verrell and McCabe 1988; Halliday 1990; Faria 1995; Halliday and Tejedo 1995; Sparreboom 1996; Sparreboom and Faria 1997). Often both males fail to inseminate the female, because females tend to move away from competing males. Insemination of females by multiple males appears to be relatively common in some species of *Triturus* (Rafiński 1981; Rafiński and Osikowski 2002; Garner and Schmidt 2003) and very likely occurs in other newts as well. There is evidence that in one species, *T. alpestris,* females benefit from multiple matings by having increased fertilization of eggs (Osikowski and Rafiński 2001). Given a choice, females of this species also appear to discriminate against closely related males and mate differentially with less related males (Garner and Schmidt 2003).

Many of these newts, especially the smaller species of *Triturus,* are notable for their lack of aggression and overt mate guarding behavior by males. Males compete for females by chasing them (Verrell and McCabe 1988), by displaying more intensively to females in the presence of rival males (Verrell 1984b), or by altering the temporal pattern of some courtship elements (Sparreboom 1996; Denoël, Poncin, and Ruwet 2001a). Two closely related genera of Asian newts, *Cynops* and *Paramesotriton,* exhibit more aggressive forms of mate guarding that are seldom seen in most species of *Triturus.* Male Chinese fire-bellied newts (*Cynops orientalis*) have been observed biting females for up to five minutes after spermatophore deposition, a behavior that usually immobilizes the female (Sparreboom and Faria 1997). The function of this behavior is unclear, but it could serve as a form of postmating guarding behavior that prevents the female from immediately mating with another male. Japanese sword-tailed newts (*Cynops ensicauda popei*) also have been observed biting females, but only before spermatophore deposition. In most cases, the male actually picked up the female and transported her away from a rival male (Sparreboom1996). Biting is more aggressive in *Paramesotriton.* Males of several species often violently bite one another and engage in prolonged fights for possession of females (Sparreboom 1984b). The courtship behavior of these two genera is similar to that of *Triturus,* but with less complex display elements than those seen in species of *Triturus* that lack aggressive mate guarding behavior (Sparreboom 1993; Sparreboom and Faria 1997). If the courtship of *Triturus* represents a more derived condition, then competitive display might have replaced more aggressive forms of competition for mates. In larger species of *Triturus,* however, both display behavior and aggression are well developed (see the following leks discussion).

Plethodontidae

The courtship behavior of plethodontid salamanders has been studied in considerable detail, but most of these studies have been done in the laboratory, and their mating sys-

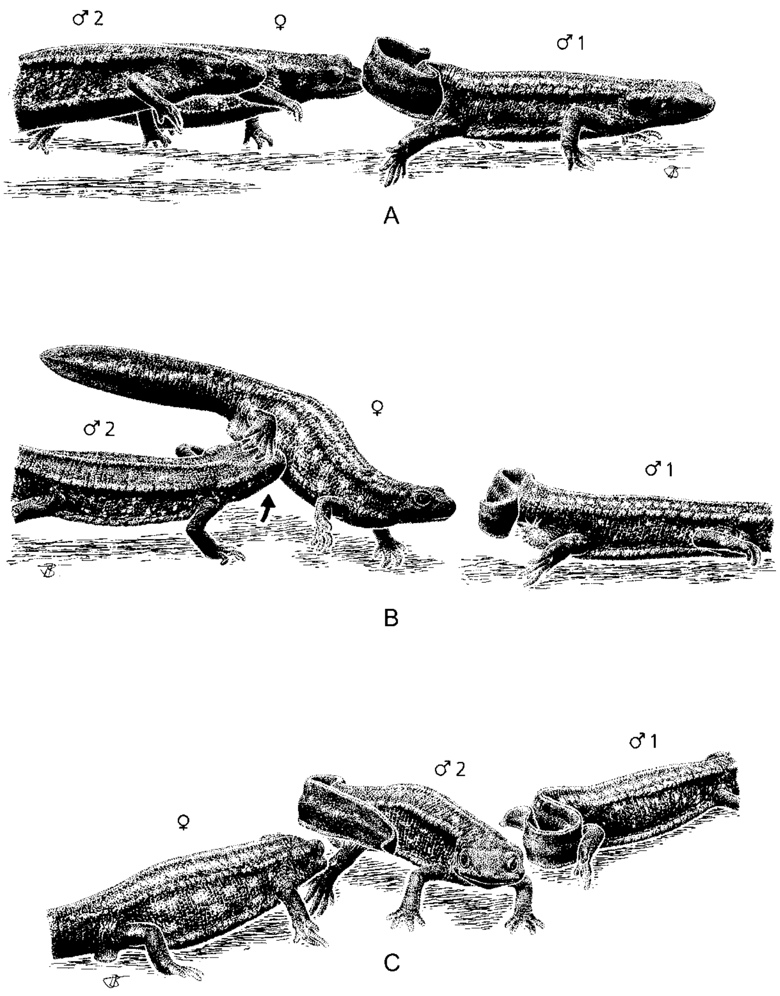

Fig. 9.34. Sexual interference in Japanese newts (*Cynops ensicauda popei*). (A) The courting male (♂1) is creeping and being followed by the female, while the interfering male (♂2) approaches from beside the female. (B) The interfering male (♂2) nudges the belly and cloaca of the female. (C) The original courting male (♂1) remains in creeping position, while the interfering male (♂2) turns in front of the female and gives fan displays. From Sparreboom (1996).

tems are not well understood (Houck and Verrell 1993). For most plethodontids, we have so little information on the daily movements of males and females (chapter 6) that it is impossible to determine whether males search for females or females search for males. Both lekking and resource defense have been proposed as possible mating systems in plethodontids (Mathis et al. 1995; Sullivan, Picard, and Madison 1995), but in many cases, competitive mate searching and mate guarding are equally plausible explanations for their behavior. In several species, there appears to be greater home range overlap between males and females than between individuals of the same sex (Nishikawa 1990; Mathis 1991b; Marvin 1998b). In some species, males and females are more likely to be found under the same cover object than are individuals of the same sex (Wells 1980c; Lang and Jaeger 2000), or members of one sex are more likely to have members of the opposite sex as nearest neighbors (Mathis 1991b). Nevertheless, it is not always clear whether females move into male home ranges or males leave their home ranges to search for females (Toll, Jaeger, and Gillette 2000).

Most plethodontids have relatively long courtship seasons, and courtship behavior is remarkably uniform in the family. Males never gather in dense aggregations or engage in mass courtship. In every species, males court individual females with an elaborate behavioral repertoire involving both chemical and tactile stimulation, as described earlier in this chapter. Invariably this ends in a tail-straddling walk. The female rests her chin on the base of the male's tail, and the male leads her over a single spermatophore (Arnold 1977; Marvin and Hutchison 1996). Males of the *Plethodon jordani* complex invest considerable time in each courtship (average = 56 minutes), but the probability of each spermatophore being picked up is very high. A male seldom produces more than one spermatophore per courtship (Arnold 1976), although multiple spermatophore production has been observed in *P. kentucki* (Marvin and Hutchison 1996). Postmating guarding of mates does not seem to be common in plethodontids. This might be because females become unreceptive to further courtship soon after mating and remain unreceptive for several days (Verrell 1998a, 1991a). Some females do eventually court with additional males. Because they can store sperm for some time, this sets the stage for direct sperm competition (Tilley and Hausman 1976; Houck, Tilley, and Arnold 1985; Halliday 1998; E. Adams, Jones, and Arnold 2005).

Various forms of sexual interference and male-male competition are common in plethodontids. Female mimicry has been observed in several genera, including *Plethodon, Pseudotriton, Ensatina,* and *Desmognathus* (Arnold 1977). Usually this involves an intruding male engaging in a tail-straddling walk with another male, causing the leading male to deposit a spermatophore. Although the second male does not cover the spermatophore, it is not available to females and therefore represents wasted sperm (Arnold 1976). Aggressive competition among males, including biting of rivals, has been observed in *Plethodon, Eurycea, Pseudotriton, Gyrinophilus, Aneides,* and *Desmognathus* (Organ 1958, 1960a, b; Arnold 1972, 1976, 1977; Jaeger 1984; Ovaska 1987; Houck 1988; Verrell and Donovan 1991; Staub 1993; Halliday and Tejedo 1995; Mathis et al. 1995; Bernardo and Arnold 2002). Sometimes this is related to defense of territories, but in other cases, males compete for access to individual females (Arnold 1976; Houck 1988; Gergits and Jaeger 1990a; Verrell and Donovan 1991).

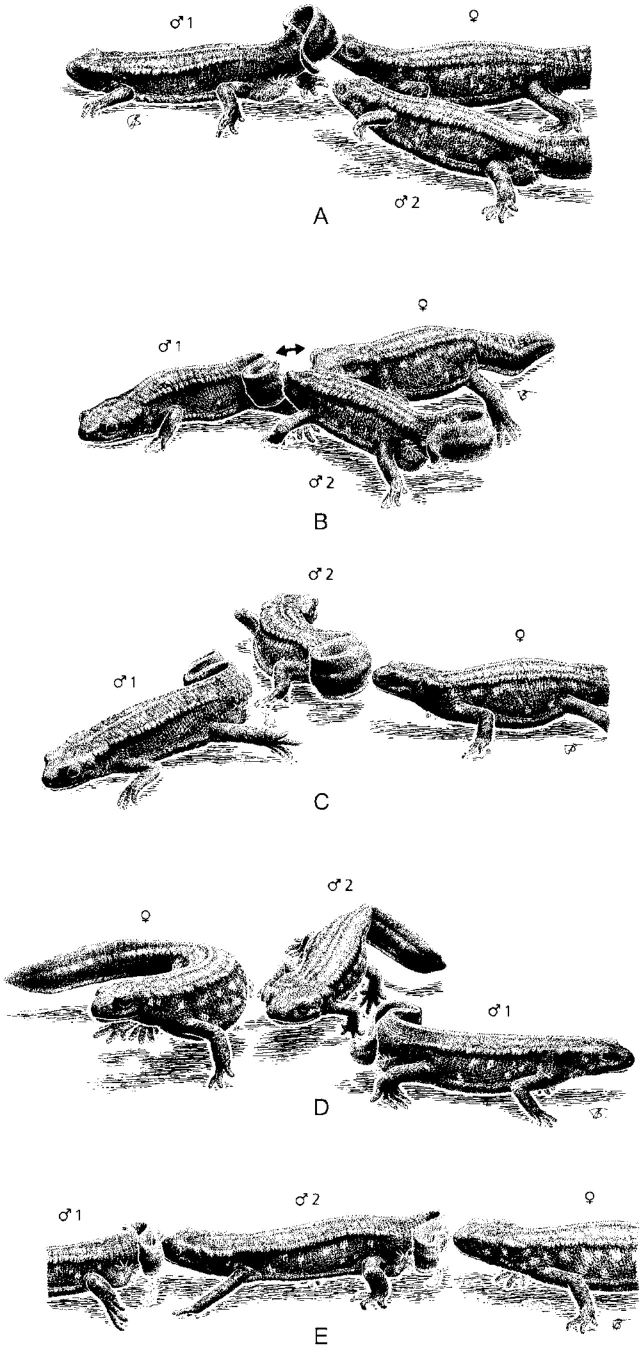

Fig. 9.35. Examples of sexual mimicry in Japanese newts (*Cynops ensicauda popei*). (A) A courting male (♂1) is creeping, with the female following; an interfering male (♂2) interrupts the courtship. (B) The interfering male (♂2) then inserts himself between ♂1 and the female, while swinging his head and moving the female away from the original male. (C) The original male (♂1) has deposited a spermatophore, but ♂2 has led the female away. (D) In another interaction, an interfering male (♂2) has interrupted a courtship, and the female moves away. (E) An interfering male (♂2) has induced ♂1 to deposit a spermatophore by touching his tail; ♂2 then deposits a spermatophore while being followed by a female. From Sparreboom (1996).

Leks

Lek mating systems are distinguished from other types of mating aggregations and mate searching in that males exhibit site fidelity, they tend to defend courtship sites against other males, and they perform elaborate courtship displays that attract females and help to bring them into receptivity. Although there are hints that some species of *Desmognathus, Plethodon,* and *Calotriton* might have leklike mating systems (Thiesmeier and Hornberg 1990; Sullivan, Ryan, and Verrell 1995), the best documented examples of lekking behavior are several of the largest and most brightly colored species of *Triturus*. These include *T. vittatus, T. marmoratus, T. cristatus, T. carnifex, T. karelini,* and *T. dobrogicus* (the last three were formerly considered subspecies of *T. cristatus*). Lekking has not been described in detail for all of these, and does not necessarily occur in all populations. *Triturus marmoratus* and the *T. cristatus* group appear to form a well-defined clade allied to *T. vittatus,* although the phylogenetic position of the latter is not entirely clear (Arntzen and Sparreboom 1989; Halliday 1990; MacGregor, Sessions, and Arntzen 1990; Halliday and Arano 1991). These phylogenetic relationships make it likely that leklike mating systems have evolved only once or twice in the genus. Exactly why such a mating system might evolve is not clear, however.

Males of these species establish small territories on the bottoms of ponds after dark. Often they spend daylight hours hiding in dense vegetation, but move to more open areas for courtship display. This can lead to aggregation of males in suitable display areas. In contrast to many lekking birds (Höglund and Alatalo 1995), male newts exhibit only temporary attachment to specific territories or aggregations, often moving to new display sites on successive nights. Males of all of these species have elaborately marked crests and tail fins, making them the most sexually dimorphic species in the genus (fig. 9.36). As discussed previously, courtship displays emphasize lateral display of crests and tail fins to females, often accentuated by the lean-in and cat-buckle displays, in which the male leans toward the female and kinks his body around hers (fig. 9.8). Aggressive interactions among males are relatively common, although this varies among populations, and many of the displays used in courtship, especially the lateral displays, are used in aggressive encounters as well (Zuiderwijk and Sparreboom 1986; A. Green 1989; Hedlund and Robertson 1989; Raxworthy 1989; Hedlund 1990b; Sparreboom and Teunis 1990). The principal function of aggressive territoriality in these lekking species presumably is to allow a male to court females while minimizing sexual interference by neighboring males. Hence, it serves much the same function as mate guarding in other salamanders.

Resource Defense

Defense of resources that are attractive to females is an uncommon mating system in salamanders, for reasons discussed earlier. The mating system of the red-backed salamander (*Plethodon cinereus*) has been described as resource defense because there is evidence that females associate with males that have high-quality food resources in their territories (Mathis et al. 1995; Sullivan, Ryan, and Verrell 1995; Lang and Jaeger 2000; Toll, Jaeger, and Gillette 2000). It is not clear, however, how females might benefit from choosing males on the basis of territory quality. Three possibilities are: (1) females benefit directly by foraging in male territories, (2) the offspring of females grow up in the territories of their mates and have access to high-quality food resources, or (3) females use the quality of territories to assess the over-

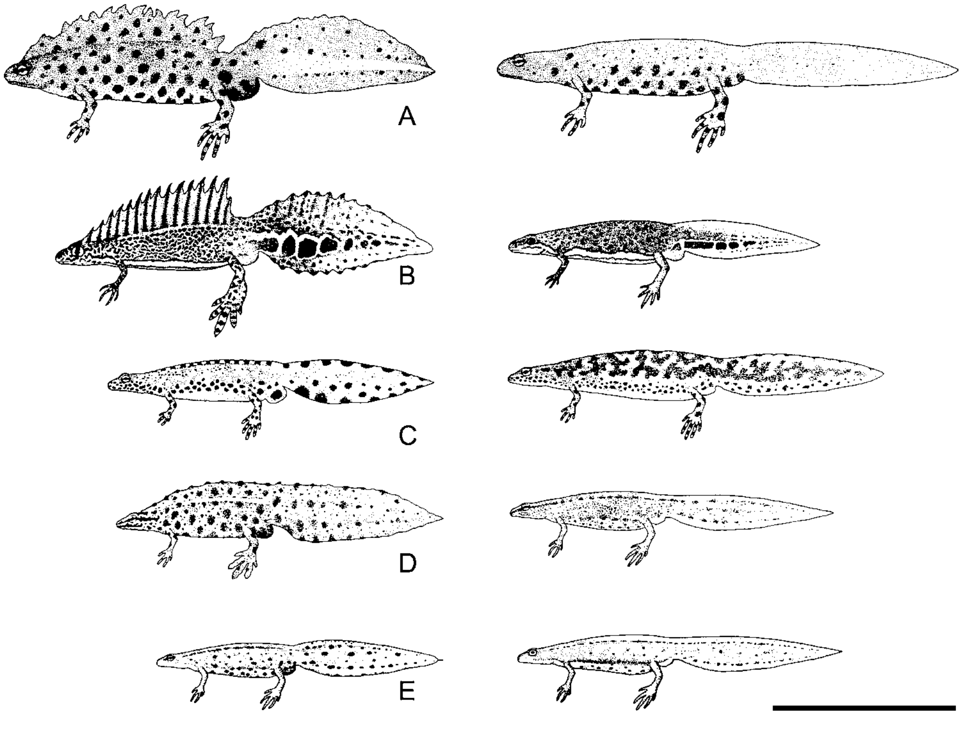

Fig. 9.36. Sexual dimorphism in five species of European newts. Males are on the left, females on the right. (A) *Triturus cristatus* and (B) *T. vittatus* have lek mating systems and exhibit the greatest sexual dimorphism in ornamentation. (C) *T. alpestris.* (D) *T. vulgaris.* (E) *T. boscai.* Scale bar represents 5 cm. From Halliday and Arano (1991).

all genetic quality of potential mates (Jaeger et al. 2000). At present, all of these hypotheses remain to be tested.

The best-documented examples of resource defense mating systems are in the cryptobranchids and hynobiids, salamanders in which external fertilization sets the stage for defense of oviposition sites by males. In *Cryptobranchus alleganiensis,* males have been observed defending nest sites under large flat rocks against other males, but accepting females into their territories, where they lay eggs attached to the underside of the rocks. Males guard the eggs after they are laid, but they continue to accept females into their territories, and some males have been observed tending several egg clutches simultaneously (B. G. Smith 1907; Bishop 1941b; Nickerson and Mays 1973a). The Asian giant salamanders (*Andrias*) have a similar mating system, with males defending suitable oviposition sites as territories (Kerbert 1904; Stejneger 1907; Tago 1929; Kuwabara et al. 1989; Kawamichi and Ueda 1998). In these salamanders, small males have been observed entering the nests of large males when females are laying eggs (Kawamichi and Ueda 1998). This type of sexual interference is analogous to the satellite behavior seen in many frogs (chapter 8) and fishes (Taborsky 1994), with intruding males attempting to fertilize some of the eggs deposited in another male's territory.

Males of some hynobiid salamanders also defend territories centered around suitable oviposition sites (Tanaka 1986, 1987, 1989). In Japan, *Hynobius nebulosus* has a prolonged breeding season, from November through February. In a population studied in a ditch by Tanaka (1989), adults migrated overland to the breeding site, with the largest males arriving somewhat earlier than smaller males. The largest males established territories around the roots of horsetails, under fallen leaves, or near holes in mud, and sometimes occupied them for several weeks. Territories with abundant horsetails or other vegetation suitable for attachment of egg sacs were preferred, and received the largest number of egg sacs (up to 11 sacs in some territories). Smaller, nonterritorial males adopted a satellite or sneaker tactic. They entered the territories of large males as females were depositing eggs and attempted to clasp and fertilize egg sacs. Satellite males were most abundant around the highest-quality sites. Satellite males frequently moved between territories, hiding in mud while waiting for females to appear, and some males switched between territorial and satellite behavior. The mating system of this salamander is remarkably similar to those of resource-defending frogs, such as *Rana clamitans* and *R. catesbeiana* (see chapter 8).

Determinants of Male Mating Success

In contrast to the voluminous literature on determinants of male mating success in anurans, there has been relatively little work on this topic with urodeles. In part this is because these animals are much more difficult to observe in the field and less suitable for experimental work than the highly vocal anurans. Consequently, any conclusions about factors that influence variation in male mating success must be somewhat tentative. As in anurans, the amount of time a male spends engaged in reproductive activities is likely to have a major effect on male mating success, and this probably accounts for the early arrival of males at breeding sites in many species (e.g., Douglas 1979; Tanaka 1989). The amount of time a male spends at a breeding site or the length of his courtship season might be constrained by depletion of energy reserves (Halliday 1987). Unfortunately, information on individual variation in energy reserves, male tenure at breeding sites, and individual reproductive success is not available for any species of urodele. Both tenure at the breeding site and number of eggs obtained in territories were positively correlated with male body size in *Hynobius nebulosus,* but reproductive success was clearly influenced by male territory quality as well (Tanaka 1989).

Physiological constraints on male performance could limit male mating success on a shorter time scale as well (Halliday 1987). In newts, repeated courtship of a female increases the probability of successful spermatophore transfer (Teyssedre and Halliday 1986), and males that court many females are likely to have the highest reproductive success. One constraint on courtship time is the need for aquatic animals to breathe. Time spent surfacing to breathe reduces time available for courting (Halliday and Sweatman 1976; Halliday and Worsnop 1977; Halliday and Houston 1991), and males engage in longer bouts of courtship when aquatic oxygen concentrations are increased (Halliday 1977b). It is possible that males with large crests and tail fins relative to body size enjoy some increase in cutaneous respiration (see chapter 4) that would enable them to remain longer under water, but this has not been demonstrated experimentally. Energetic investment in courtship display also could be constrained by depletion of energy reserves, forcing males to reduce the frequency of costly display elements. This might have a significant effect on male mating success in competitive situations, because male newts typically increase display rates in the presence of other males (Verrell 1984b; Green 1991a). Consequently, males with depleted reserves would be at a competitive disadvantage in trying to court females. In other species, however, the energetic cost of courtship is relatively trivial (Bennett and Houck 1983; see chapter 5).

Physiological traits related to locomotor ability or stamina might influence male mating success when males search for females. For example, two studies of red-spotted newts (*Notophthalmus viridescens*) have shown that male mating success is positively correlated with tail fin size. There is no evidence that females prefer males with large tails in this species, but larger tail fins appear to enhance the ability of males to capture females in amplexus (Able 1999; Gabor, Krenz, and Jaeger 2000). Direct scramble competition for females also can select for traits that enhance a male's ability to hold on to females once they are encountered. In *Taricha granulosa,* males engage in scramble competition for females, and both a large tail and a bulky body appear to enhance male mating success (Janzen and Brodie 1989; Halliday 1998). Males of this species increase in bulk during the breeding season due to hormonally regulated uptake of water (Propper 1991; Moore 1994). The same is true of some hynobiid salamanders, which engage in scramble competition for egg sacs rather than females. In some species, uptake of water results in enlargement of the head, which confers an advantage in competition to fertilize egg sacs (Hasumi and Iwasaw 1990; Hasumi 1994; see also "Patterns of Sexual Dimorphism," following).

Aggressive interactions among males probably influence male mating success in many species of salamanders (Halliday and Tejedo 1995). In several species, large males have been shown to dominate small males in contests over females or territories (Tanaka 1987; Houck 1988; Janzen and Brodie 1989; Mathis 1990b; Verrell and Donovan1991; Wiltenmuth 1996; R. D. Howard, Moorman, and Whiteman 1997; Marvin 1998b; Mathis and Britzke 1999), although this is not true for some species (Camp 1999). This is likely to be true for most species in which males fight over females, but not necessarily for species that engage in relatively nonaggressive scramble competition (Hasumi 1994). The various forms of sexual interference that commonly occur in urodeles also are likely to affect male mating success, because many courtship attempts are disrupted before mating is completed. In some cases, the use of interference tactics by small males reduces the competitive advantage of large males attempting to monopolize females (Tanaka 1989; R. D. Howard, Moorman, and Whiteman 1997).

Female choice probably has some effect on male mating success in most salamanders except those with explosive breeding periods. In both newts and terrestrial salamanders, many courtship attempts end with the female leaving before mating is completed. Again, information about the criteria used by female salamanders to choose mates is meager compared to the large literature for anurans (Sullivan, Ryan, and Verrell 1995). In salamanders that have resource-based mating systems, variation in territory quality might influence female choice of mates. The possibility that female red-backed salamanders select mates based on the quality of food found in their territories has already been discussed. Although both laboratory and field observations tend to support this hypothesis (Mathis et al. 1995), we do not yet have much evidence that females move from one male territory to another to compare them. Variation in resource quality probably influences female choice in cryptobranchids and hynobiids in which males defend oviposition sites. In cryptobranchids, the size or other features of retreat sites under rocks probably influence the choice of mates by females. In *Hynobius nebulosus,* the density and quality of vegetation available for egg attachment appears to have a major influence on female choice (Tanaka 1989).

In most other salamanders, female choice would necessarily be based on morphological features of males, aspects of their behavior, or a combination of the two. This question has been addressed in most detail in studies of European newts. In both *Triturus cristatus* and *T. vulgaris,* females pick up more spermatophores deposited by males with large crests than by those with small crests (Malacarne and Cortassa 1983; Hedlund 1990b; A. Green 1991b; Gabor and Halliday 1997). It is not known whether females make visual assessments of relative crest height or choose mates based on features of courtship displays that are correlated with crest height. In either case, the height of the crest appears to provide females with reliable information about male quality. Only males in good condition develop large crests, and those provided with extra food develop larger crests (A. Green 1991b; J. M. R. Baker 1992). On the other hand, neither crest height nor body size appears to be a reliable indicator of the inherent mating capacity of a male, as measured by the number of spermatophores he produces (J. M. R. Baker 1990).

Female newts also might select mates on the basis of differences in courtship behavior of males. However, Michalak (1996) found little consistency within males for several elements of courtship behavior in *T. montandoni,* and little consistency in preferences of females for particular courtship elements. Breeding coloration, perhaps in combination with other sexually dimorphic traits, might influence mate choice in some newts. In a study of a population of alpine newts (*Triturus alpestris apuanus*) that included both paedomorphic and metamorphosed males, females preferred to mate with metamorphosed males. These males develop bright blue breeding coloration and other sexually dimorphic traits that are absent in paedomorphic males (Bovero, Giacoma, and Andreone 1997).

There is some evidence that females change their selectivity toward males, depending on whether they have mated previously. In an experimental laboratory study, Gabor and Halliday (1997) found that female smooth newts (*Triturus vulgaris*) did not discriminate between males with large and small crests when they were the first males encountered. In contrast, females that had already mated once would remate only with males with large crests. This suggests that females might mate relatively quickly with the first male encountered, as long as he meets some minimum standard for quality, to ensure that her eggs would be fertilized, but would remain receptive to other males of higher apparent quality. Because female newts can store sperm, there is the potential for direct sperm competition to occur (A. Jones, Adams, and Arnold 2002; Garner and Schmidt 2003). In the laboratory, males sometimes are selective in their choice of mates as well. Males that were presented with more than one female simultaneously reduced the amount of time spent in amplexus with any one female (Verrell 1985b) and were more likely to initiate courtship with the larger of two females, presumably because this will result in the male fertilizing more eggs. Verrell (1985b, 1986b) proposed that males discriminate between large and small females using either visual or chemical cues, but Rowland, Robb, and Cortwright (1990) argued that discrimination of female body size based on chemical cues is unlikely. In any case, it probably is rare for males to encounter multiple females simultaneously in natural populations, where sex ratios usually are heavily skewed toward an excess of males.

Information on female choice of mates for other salamanders is so fragmentary that little can be said about it. Neither size nor age was correlated with courtship success of male *Desmognathus* in noncompetitive situations (Houck 1988; Houck and Francillon-Viellot 1988; Verrell 1991a). Donovan and Verrell (1991) reported that pairs of *D. ocoee* that were familiar with one another were less likely to complete spermatophore transfer than were unfamiliar pairs, but it was not clear whether this was due to male rejection of females or the reverse. Several studies of *Desmognathus* have shown that males exhibit siginificant differences in mating success in laboratory trials, but in most cases, information on variation in male behavior was not available (Houck, Tilley, and Arnold 1985; Shillington and Verrell 1996). Vinnedge and Verrell (1998) and Gershman and Verrell (2002) addressed this problem by examining the mating success of *D. ocoee* males paired with females in noncompetitive trials. They then examined variation in several aspects of male courtship behavior. They found that males that had achieved a high level of mating success had significantly higher frequencies of persuasive courtship displays, based on a composite score of several individual courtship elements. In particular, males that performed the highest frequency of "snap" behavior involved in transferring pheromones to females achieved the highest reproductive success.

Females also might use differences in body size to assess mate quality. Females of *Plethodon cinereus* were more likely to associate with large males than with small males in laboratory experiments, but it is not clear whether females were assessing male body size directly or were responding to some other cue that is correlated with body size (Mathis 1991b). Male body size did not appear to influence female choice of mates in *Ambystoma tigrinum,* but those males that achieved successful spermatophore transfer had slightly longer tails (R. D. Howard, Moorman, and Whiteman 1997). Again, the way in which females might assess differences among males is not known. In some salamanders, there is evidence for males discriminating among females on the basis of body size. For example, male *Desmognathus* that were offered access to a large and a small female simultaneously preferred to court the larger individuals (Verrell 1989b, 1994b). How often males might encounter two females simultaneously in the field is not known. A preference for larger females might be expected in species in which males search for females and invest considerable time and energy in courtship, and in those in which males are likely to have access to many females. Such a preference seems less likely in species in which the time and energy costs of courtship are small, or males seldom encounter females.

Patterns of Sexual Dimorphism

The various problems associated with interpreting patterns of sexual size dimorphism were discussed in chapter 8. Differences in body sizes of males and females result from different selection pressures acting on the two sexes, and it often is difficult to predict exactly how these will affect relative adult body sizes (Halliday and Tejedo 1995). In most species of urodeles, fecundity selection is likely to favor large body size in females because of size-related increases in clutch size, egg size, or both (see chapter 10). Indeed, the typical pattern for most urodeles, as in anurans, is for females to reach larger sizes than do males. In some species, aggressive competition among males probably favors large body size as well, because large males are almost certain to win more fights than are small males. In a preliminary analysis, Shine (1979) reported a significant association between reports of male combat in urodeles and males being either larger than or about the same size as females. His analysis was flawed, however, because he lacked information on aggressive behavior in many species, some of which have subsequently been shown to be aggressive (Halliday and Verrell 1986). He also relied on literature records for data on body sizes, and in many cases, only average body sizes were available. In most ectothermic animals, including salamanders, growth tends to be asymptotic, and the asymptotic or maximum body size typically gives a better estimate of sexual dimorphism than does average body size (Stamps 1993). Finally, Shine's (1979) analysis did not incorporate phylogenetic information, making his statisical inferences suspect.

It seems clear that there is not a simple relationship between sexual size dimorphism, measured as a difference in body length, and the occurrence of male combat in urodeles. In cryptobranchids and hynobiids, males of some species are reported to be as large as or larger than females, and some of these species also exhibit male combat (Nickerson and Mays 1973a; Shine 1979). However, there has not been a comparison of closely related hynobiids that have different mating systems. Large body size apparently influences male mating success in *Hynobius nebulosus,* a territorial species (Tanaka 1989), but not in *H. nigrescens,* a species with scramble competition (Hasumi 1994). In the latter species, the heads of males become swollen during the breeding season, apparently through hormone-mediated water uptake, and this swelling apparently confers some advantage in scramble competition for control of egg sacs.

Shine (1979) listed several species of salamandrids in which males are at least as large as females, including *Calotriton asper* and *Pleurodeles waltl,* both of which compete by clasping females in amplexus, but in most other genera, males reach shorter body lengths than do females. This is true even for species of *Triturus* that defend territories on leks and for genera in which males have been observed fighting, such as *Paramesotriton* and *Salamandra.* In the genus *Plethodon,* females of most species reach greater body lengths than do males, even in species that are territorial and sometimes violently aggressive. The genus *Desmognathus* is unusual in that males of many species reach sexual maturity at a younger age than do females, but ultimately achieve a larger body size (Organ 1961a; Tilley 1977, 1980; Juterbock 1978; Bruce 1993). Aggressive competition among males is common in this genus, and large males typically dominate smaller individuals (Houck 1988). Nevertheless, the pattern of sexual dimorphism probably has more to do with the very large energetic investment in egg production by females and the dramatic slowing of growth after sexual maturity (Hom 1988; Bruce 1993). Males also are larger than females in the only other desmognathine salamander, *Phaeognathus hubrichti* (Bakkegard and Guyer 2004).

Features of male morphology other than body size can confer an advantage in aggressive contests, and degrees of sexual dimophism in these traits need to be investigated in more detail. For example, biting is common in many plethodontid salamanders, and one might expect this mode of fighting to favor relatively wider heads or stronger jaw musculature in males. Juterbock (1978) reported that the heads of male *Desmognathus* are wider and more massive than those of females, but he did not present a detailed analysis of head size allometry in relation to body size in the two sexes. Most species of *Plethodon* do not exhibit obvious differences in head size or shape between males and females, perhaps because aggression and territoriality are common in both sexes. Members of the genus *Aneides* have conspicuously hypertrophied jaw muscles and reinforcement of parts of the skull that are related in part to fighting (Staub 1993). Both males and females are aggressive in several species, and sexual dimorphism is not pronounced (Staub and Paladin 1997), but in *A. hardii,* males have much more massive jaw musculature and skulls than do females, a feature that is very likely related to aggressive behavior.

Salamanders have many other sexually dimorphic traits that are related to mating behavior or reproductive competition among males, even in species that lack overt aggression (Halliday and Tejedo 1995). Males of species that clasp females in amplexus usually have enlarged hind or forelimbs, sometimes equipped with horny nuptial pads to facilitate holding onto females. Such features are particularly conspicuous in salamandrids, such as *Notophthalmus.* These morphological features typically develop during the breeding season in response to elevated levels of sex hormones (Houck and Woodley 1995). The same is true for the many sexually dimorphic display organs, such as wide tail fins in salamandrids, and courtship glands used for female persuasion; their role in courtship and reproductive competition has already been discussed in some detail. The evolution of sexually dimorphic morphological traits in urodeles has yet to be studied thoroughly or placed in an explicitly phylogenetic context. There have been attempts to examine the phylogenetic evolution of behavioral traits that are related to morphology, such as courtship in newts (fig. 9.6; Arntzen and Sparreboom 1989). Further investigations along these lines should be a promising area of research.

Summary and Conclusions

Urodeles tend to be much less conspicuous than anurans, so information about their communication and social behavior is more limited. Nevertheless, research over the last 30 years or so has revealed a rich repertoire of communication signals and behavioral interactions in both aquatic and terrestrial species. In contrast to anurans, urodeles do not use sound to communicate. The ears of salamanders are sensitive mainly to low frequencies well below those found in the hisses, squeaks, and clicks that are produced by some species, so the importance of these vocalizations as communication signals is unclear. Salamanders do make use of visual, tactile, and chemical signals, which are given primarly during courtship or aggressive interactions.

Many salamanders are most active at night, so visual signals often take a form that can be perceived in dim light, such as changes in body posture and movements of the tail. Color markings that develop during the breeding season in some salamanders often appear to increase the reflectivity of the animal or a particular body part, or to increase contrast between the animal and its background. Highly reflective signals that enhance the conspicuousness of displaying males include white patches on the throat in *Hynobius,* light yellow body coloration and bright tail spots in *Paramesotriton,* and silvery blue body coloration in *Neurergus* and some species of *Triturus.* Many species of *Triturus* also have bright coloration on belly and tail, often with contrasting black spots or other markings that tend to make the tail especially conspicuous. Within the family Salamandridae, the ancestral form of courtship involves males clasping females in amplexus and stimulating them with chemical signals, with visual signals being less important. In more derived species, especially in the genus *Triturus* and its relatives, amplexus has been lost, and visual signals have become more important in the initial stages of courtship, although chemical signals also are used. In the largest, most derived species of *Triturus,* many of which have lek mating systems, visual signals have become elaborated, with males using displays that present females with a lateral view of their sexually dimorphic body coloration, crests, and tail fins.

Many of the displays of newts combine visual, tactile, and chemical signals in ways that make it difficult to distinguish between these modes of communication. For example, the tail-fanning display found in most Old World newts not only conveys chemical signals to the female, but probably also provides tactile stimulation through water movements and visual stimulation as well. In some newts, new display elements have appeared that seem to emphasize either visual signaling (the wave display) or tactile signaling (the whip and flick displays). In plethodontids and ambystomatids, many forms of courtship behavior appear to combine tactile signals with chemical signals, with visual signals being of secondary importance. These include the application of pheromones from courtship glands by slapping the female with a chin gland or raking her with sharp teeth in plethodontids. Tactile signals are widely used by female salamanders to signal receptivity to males during courtship and usually involve a female nudging or touching the male.

Chemical signals probably are of primary importance for most urodeles and convey information about the species, sex, and sexual receptivity of individuals, as well as serving as persuasive signals that increase female receptivity during courtship. Chemical signals are produced by a variety of specialized glands located mostly in the cloacal or head region. In general, male salamanders do not appear to produce chemical signals to attract females. Males often are attracted to chemical cues emanating from females, but it is not known whether females of most species produce specialized male-attracting pheromones. Males of many salamander species produce special courtship pheromones that are either applied directly to the female's body or wafted toward the female during courtship displays. It is assumed that these pheromones serve to increase female sexual receptivity, although this has been demonstrated experimentally in only a few species of salamandrids and plethodontids.

Chemical signals produced by males can be detected by receptors in the skin of females, by specialized receptor organs in the nasal cavity, or, in some plethodontids, by brain receptors responding to pheromones injected directly into the bloodstream of the female. Chemosensory organs in the nasal cavity include the main olfactory chamber, which detects mainly volatile airborne odors or waterborne chemical cues, and the vomeronasal organ, which detects less volatile chemicals. The vomeronasal organ is best developed in plethodontids, which have nasolabial grooves that convey chemicals from the substrate by capillary action directly to the vomeronasal organ. In some plethodontids, the vomeronasal organ is sexually dimorphic and is much larger in males than in females. This probably relates to the tendency for males to search for females during the breeding season.

Numerous experimental studies have demonstrated that salamanders can use chemical cues to identify the species, sex, and even individual identity of other individuals. Chemical signals probably are of primary importance in reproductive isolation of closely related species, many of which have nearly identical courtship behavior. The evolution of reproductive isolation apparently has been a gradual process, at least in closely related species of *Desmognathus.* Populations generally considered to be distinct species generally exhibit strong behavioral isolation, whereas geographically close populations of the same species tend to show less behavioral isolation than those that are geographically separated.

Many terrestrial salamanders use pheromones to mark substrates in their territories, and other individuals can use these chemical signals to determine the identity of the territory holder. The red-backed salamander (*Plethodon cinereus*) has been used as a model system for understanding territorial behavior in terrestrial salamanders, although not all populations of this species are territorial. Territories in this species and in other terrestrial plethodontids are centered on retreat sites such as fallen logs, which provide moist microhabitats for shelter and foraging. Both males and females are territorial, and the largest indivduals tend to acquire the best sites. Territories that contain highly profitable, easily digested prey such as termites are preferred over those containing less profitable prey, such as ants. There is some evidence that females use the fecal pellets of males to assess the quality of their diets, and they use this information to select males with the best territories as mates. In some cases, males and females appear to defend the same territory, although they do not act cooperatively. Females are most aggressive toward other females, whereas males are most aggressive toward other males. Possible benefits to a female in selecting a male with a high-quality territory include access to preferred prey for herself and access to prey for her offspring, which might grow up in the vicinity of the male's territory. These putative benefits have yet to be demonstrated experimentally, however.

Red-backed salamanders and a number of other terrestrial plethodontids are interspecifically territorial and readily attack other species of salamander of similar size. Indeed, this form of interference competition appears to be the most important mechanism of interspecfic competition in salamander communities (see chapter 15). In some cases, aggression by a larger or more dominant species limits the microhabitats available to a competitively subordinate species. A classic example is the restriction of *Plethodon shenandoah* in Virginia to relatively dry talus slopes that cannot be inhabited by the more widespread species *Plethodon cinereus,* which occupies most of the surrounding wetter microhabitats. In at least one instance, a local population of *P. shenandoah* was driven to extinction by its inability to move into moister habitats during a drought. Both intra- and interspecific aggression and territoriality are common in the genus *Desmognathus* as well. These salamanders have very robust jaw musculature, which probably evolved originally for prey capture, but which also equip them with powerful weapons for fighting. Larger species often exclude smaller species from microhabitats nearest to streams through aggression and occasional predation (see chapter 15). Species of *Desmognathus* also have been found to be aggressive toward species of *Plethodon* and *Eurycea* of similar size, and can dominate these salamanders in aggressive encounters. Aggression is relatively uncommon in adults of other families of salamanders, and evidence for territoriality is mostly lacking or anecdotal.

Salamanders have an array of mating systems similar to that seen in anurans, including scramble competition in explosive mating aggregations, mate searching and mate guarding, leks, and resource defense. Scramble competition is characteristic of ambystomatids and some hynobiids that have very short breeding seasons. Males often gather in large numbers and compete vigorously to fertilize the eggs of females, either by deposition of many spermatophores, as in *Ambystoma,* or by monopolizing egg sacs, as in *Hynobius.* Various forms of sexual interference, including covering the spermatophores of rival males, and shoving females away from rival males, are common in explosive-breeding ambystomatids. Some salamandrids, such as *Taricha granulosa,* also engage in scramble competition, in which males compete for females by clasping them in amplexus, a form of mate guarding that prevents rival males from courting females and depositing spermatophores.

This type of scramble competition grades into various forms of mate searching and mate guarding behavior, with males seeking out individual females, sequestering them from rival males, and courting them individually. Mate searching and mate guarding are common in ambystomatids with somewhat longer breeding periods than those of explosive breeders, as well as many newts in the family Salamandridae. In the latter family, the ancestral form of competition among males involves males clasping females in amplexus to physically prevent other males from gaining access to them. Rival males often attempt to displace other males from amplexus, so sexual selection favors enlarged feet and other structures that allow a male to hold tightly to a female. Most Old World newts, apparently a derived clade within the family Salamandridae, have abandoned amplexus and court females using visual, tactile, and chemical cues. Sexual interference is common in these species as well, but males do not physically restrain females and usually do not attack rival males.

Some of the largest, most derived species in the genus *Triturus* have evolved lek mating systems in which males are aggressive toward other males and establish small mating territories on the bottoms of ponds. This form of competition can be seen as an alternative to guarding individual females or physically transporting females away from rival males. Newts with lek mating systems exhibit the greatest degree of sexual dimorphism, especially in traits related to visual courtship displays. This type of mating system provides the greatest opportunities for females to choose among available males, and there is evidence that females of some species prefer males with visually conspicuous traits, such as large tail fins.

Resource defense mating systems are much less common in urodeles than in anurans. This probably relates to the mode of fertilization, which in most salamanders involves transfer of sperm into the female's reproductive tract by means of spermatophores. This allows for the separation of mating and oviposition in both space and time, making it difficult for males to defend resources as a way to attract females. The exceptions are cryptobranchids and some hynobiids, which have external fertilization. Males often defend nest sites as territories, and it seems likely that females select mates in part on the basis of nest site quality. As in anurans with resource defense mating systems, satellite males are common, often clustering around the territories of the largest males and attempting to fertilize eggs of females entering the nest. Some terrestrial plethodontids may have resource defense mating systems as well, but in these cases, the benefits to females in choosing certain territories are less clear. They could gain benefits for themselves in the form of good foraging sites, or, if their offspring remain in the territories of their mates, they could gain valuable resources for their young.

Patterns of sexual dimorphism in salamanders are not clearly related to differences in aggressive behavior. Early analyses suggested that males may be larger relative to females in species that engage in male combat. This probably accounts for the large size reached by males in some territorial species, such as the cryptobranchids. Nevertheless, more recent work has revealed that aggression among males is common in many salamander species in which males reach considerably smaller adult sizes than do females. Many sexually dimorphic traits in salamanders undoubtedly are related to competition among males to attract or monopolize females. These include morphological structures used to clasp females in amplexus, such as enlarged hind legs, as well as traits that enhance a male's ability to chase after females, such as enlarged tail fins. In species of newts with lek mating systems, the elaboration of visually conspicuous crests, tail fins, and colorful markings on the body and tail very likely is due in part to preferences among females for such traits.

Chapter 10 The Natural History of Amphibian Reproduction

When with their croaking voyces the male provoketh the female to carnal copulation, which he performeth not by the mouth (as some have thought) but by covering her back: the instrument of generation meeting in the hinder parts, and this they perform in the night season, nature teaching them the modesty and shamefastness of this action. The land frogs are ingendered out of Eggs. . . . When the Egge breaketh or is hatched, there cometh forth a little black thing . . . having no visible part of a living creature upon them, besides their eyes and their tails, and within a short space after their feet are formed, and their tail divided into two parts, which tail becometh their hinder-legs.
—Edward Topsell, *The History of Serpents* (1658)

Reproduction is the most conspicuous feature of amphibian biology, and many species are seldom seen except during the breeding season. Frogs have been considered symbols of fertility in many human cultures, from ancient Egypt to India to the Mayan region of Central America. Their association with reproduction and fertility derives in part from their connection with life-giving water (see chapter 2) and in part because of the prolific nature of their spawning (Briffault 1927; Egger 1931; Wassen 1934; M. Weber 1972; Hamblin 1984). Yet for centuries, the details of amphibian reproduction were poorly understood. The peculiar description given by Topsell actually is a translation of a Latin work by Conrad Gesner, published in the previous century, but Gesner's account in turn was taken almost verbatim from that of Pliny the Elder, a Roman writer of the first century AD (Bastock and Riley 1900). Not until the eighteenth century were accurate descriptions of amphibian reproduction published. The best were those of August Johann Rösel von Rosenhof (1705–1759), whose spectacularly illustrated book, *Historia Naturalis Ranarum Nostratium* (1753–1758), provided accurate and detailed descriptions of fertilization, egg-laying, and development of most of the common European species (Adler 1989; Tunner 1996).

Most European amphibians have a "standard" amphibian life history, with aquatic eggs and aquatic larvae that metamorphose into terrestrial adults. However, even by the mid-eighteenth century, it was becoming clear that not all amphibians have this type of life history. The only European frogs with an unusual mode of reproduction, the midwife toads (*Alytes*), were first discovered in the 1740s (Boulenger 1912), and the live-bearing habits of European fire salamanders (*Salamandra*) were well known in Rösel von Rosenhof's day as well. Furthermore, as European explorers ventured into the tropics, all sorts of frogs with peculiar reproductive habits were discovered. For example, Linnaeus described the bizarre Surinam toad (*Pipa pipa*) in 1758. Soon afterward, the French physician Philipp Fermin, who spent some time in Surinam, provided the first, albeit somewhat inaccurate, description of its odd reproductive biology, with eggs undergoing development in cavities in the back of the female (Fermin 1765; cited in Rabb and Snedigar 1960). Similar discoveries of species with foam nests, nonaquatic oviposition, direct development, and various forms of parental care were made throughout the nineteenth century (Sampson 1900).

This chapter presents a broad overview of the natural history of amphibian reproduction, with a particular focus on life-history traits such as modes of egg deposition and development, egg size, clutch size, and reproductive effort. The role of energy storage in reproductive energetics is discussed in chapter 5, while behavioral aspects of courtship, mating, parental care, and the evolution of mating systems are discussed in chapters 8, 9, and 11. The first part of this chapter reviews modes of fertilization in the three major amphibian groups. The next section presents a detailed descriptive review of modes of egg deposition and development and discusses possible selective pressures affecting oviposition behavior in different environments. The third section discusses interspecific variation in egg size and clutch size as a function of body size, reproductive mode, and taxonomic group, as well as possible selective pressures affecting the evolution of these life-history traits. The final section examines intraspecific variation in egg size and clutch size and the relative contribution of genotype and environment to this variation, with a particular focus on the fitness consequences of variation in life history traits both within and between populations.

Mating Behavior and Modes of Fertilization

There is little doubt that external fertilization is the ancestral condition in amphibians, but internal fertilization has evolved independently in all three groups. This is most developed in the caecilians, all of which have internal fertilization, and least developed in anurans, most of which retain the ancestral condition.

Amplexus Position and External Fertilization in Anurans

Nearly all species of anurans fertilize their eggs externally. Usually the male clasps the female in amplexus, and eggs are fertilized as they emerge from the female's cloaca. At some point in the evolution of modern frog families, a major shift occurred in amplexus position. The ancestral condition appears to be inguinal amplexus, with the male clasping the female around the waist (fig. 10.1 A), while the derived condition is axillary amplexus, with the male clasping the female behind the front legs (fig. 10.1 B). Groups with inguinal amplexus include all of the "primitive" frogs: *Ascaphus, Leiopelma, Rhinophrynus,* as well as the bombinatorids, discoglossids, pelobatids, pelodytids, pipids, myobatrachids, and sooglossids (Lynch 1973; Nussbaum 1980; Duellman and Trueb 1986; Ford and Cannatella 1993). Some South American leptodactylids also have inguinal amplexus. These frogs (*Eupsophus, Pleurodema, Batrachyla, Somuncuria*) are found in relatively cold regions in the southern beech (*Nothophagus*) forests at the southern end of the continent, thought to be where the family originated (Formas 1976; Duellman and Veloso 1977; Cei 1980; Formas and Vera 1980; Ortiz, Ibarra-Videl, and Formas 1989). Heyer (1975) suggested that these leptodactylids are descended from ancient leiopelmatid stocks, and they apparently have retained the form of amplexus that is the ancestral state for all frogs (Lynch 1978). The small toadlike frogs in the family Brachycephalidae also have inguinal amplexus (fig. 10.1 C), but males shift to a more dorsal position (fig. 10.1 D) during oviposition (Pombal, Sazima, and Haddad 1994), a behavior similar to that seen in the midwife toads (*Alytes*). Because the relationships of brachycephalids to other anurans are unclear (Ford and Cannatella 1993; Frost et al. 2006), it is hard to know whether inguinal amplexus in this family represents retention of ancestral behavior, or secondary derivation of this form of amplexus.

Inguinal amplexus has been reported in several bufonids from South and Central America. These include *Osornophryne bufoniformis* and *O. percrassa* from Colombia and Ecuador and two toads from Central America, *Bufo holdridgei* and *B. fastidiosus* (Novak and Robinson 1975; Ruiz-Carranza and Hernandez-Camacho 1976; Graybeal and de Queiroz 1992). The last two species probably are closely related to each other, but the relationship of *Osornophryne* to other bufonids is unclear. Ruiz-Carranza and Hernandez-Camacho (1976) suggested these toads might be related to the primitive leptodactylids that retain inguinal amplexus, whereas Hoogmoed (1987) considered this to be a secondary derivation of inguinal amplexus from the axillary amplexus that is typical of other bufonids. Graybeal and de Queiroz (1992) suggested that inguinal amplexus probably is secondarily derived in the two species of *Bufo* as well, but left open the possibility that these species actually are more closely related to *Osornophryne* than to other species of *Bufo* with axillary amplexus. Since amplexus position is an evolutionarily conservative character in most anurans, the reasons for one or more reversions to inguinal amplexus in bufonids are unknown. However, in most of these species, sexual dimorphism is extreme, with the female much larger than the male, perhaps making it difficult for the male to clasp the female in axillary amplexus (Duellman and Trueb 1986).

Frogs in several other families that normally have axillary amplexus also appear to have evolved inguinal amplexus secondarily (Duellman and Trueb 1986). Inguinal amplexus in these species generally is related to an unusual mode of reproduction or physical constraints of body size and shape. For example, in the burrowing microhylid *Myersiella microps* from Brazil, the male grasps the female around the waist. She then burrows headfirst through leaf litter to lay eggs, dragging the male with her. Presumably, inguinal amplexus in this species makes it easier for the female to get the male into her burrow (Izecksohn, Tenorio de Albuquerque, and Furtado de Mendoca et al. 1971). The same

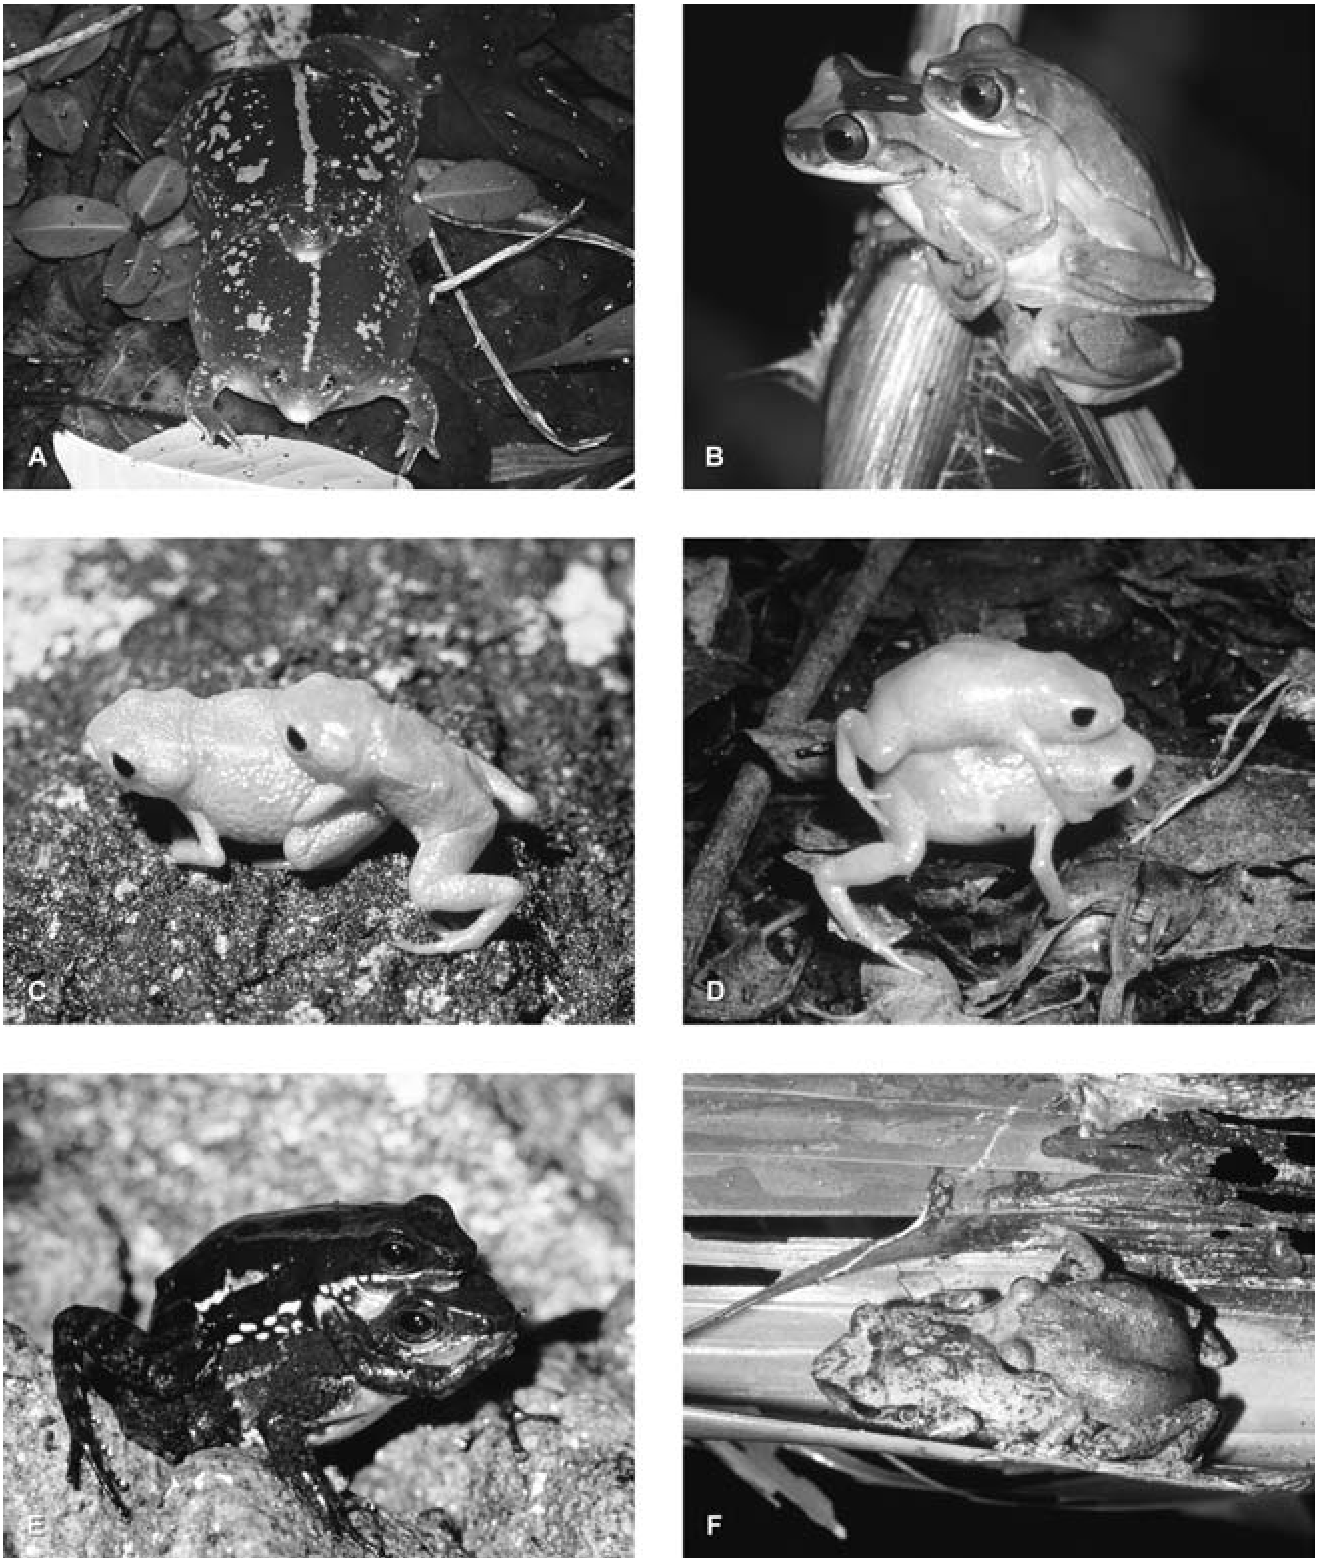

Fig. 10.1. Amplexus positions of anurans. (A) Inguinal amplexus in *Rhinophrynus dorsalis* from Belize. (B) Axillary amplexus in *Hyla ebraccata* from Panama. (C, D) The male of the *Brachycephalus ephippium* shifts from inguinal (left) to cephalic (right) amplexus when the eggs are about to be laid. (E) Cephalic amplexus in *Colostethus panamensis* from Panama. The elongated middle finger of the male is aligned along the jaw of the female. (F) Reverse hind leg clasp in *Eleutherodactylus coqui,* a Puerto Rican frog with internal fertilization. The female places her hind legs over those of the male, locking the male's cloaca in contact with her cloaca. Photos by Kristiina Hurme (A), Kentwood D. Wells (B, E), Marcio Martins (C), Ivan Sazima (D), and Daniel S. Townsend (F).

probably is true for the African frog, *Hemesis guineensis,* another headfirst burrower with inguinal amplexus (Amiet 1991). In a burrowing microhylid, *Breviceps adspersus,* from southern Africa, the male is much smaller than the female and is unable to reach around her rotund body; during amplexus, the male becomes glued to the female with mucus skin secretions (Wager 1965). In several other burrowing microhylids, the male clasps the female in axillary amplexus, but he also becomes glued to the female for a stronger hold. This has been reported in two species of *Kaloula* from the Philippines (Inger 1954), two North American species of *Gastrophryne* (Fitch 1956; Conaway and Metter 1967), and a South American species of *Elachistocleis* (Scrocchi and Lavilla 1990).

Functional Significance of Amplexus Position

The functional significance, if any, of the evolutionary switch from inguinal to axillary amplexus in the transition from primitive to advanced frogs has never been fully explained. Rabb and Rabb (1963b) suggested that inguinal amplexus is "less efficient" than axillary amplexus because the male's vent is not positioned directly above that of the female, so the male must move into position as eggs are deposited by the female (Eibl-Eibesfeldt 1956). There is no evidence, however, that eggs of species with inguinal amplexus are any less likely to be fully fertilized than those of more advanced frogs with axillary amplexus. Lynch (1973) argued that the somewhat awkward mating posture of species with inguinal amplexus is best suited to oviposition in quiet waters and suggested, without further explanation, that axillary amplexus allows for reproduction in a greater diversity of habitats, including moving water. While it is true that most frogs that lay eggs in flowing streams are members of derived families with axillary amplexus (Leptodactylidae, Bufonidae, Hylidae, Ranidae), there are some frogs with inguinal amplexus that have evolved similar breeding habits. These include megophryids of the genus *Scutiger* from the mountains of China, which attach eggs to rocks and vegetation in small streams (Liu 1950). Some Australian myobatrachids, including *Crinia riparia* and several species of *Taudactylus,* also inhabit moderate to fast-flowing streams and lay their eggs at the edge of a stream or attached to rocks underwater (Littlejohn and Martin 1965a; Barker and Grigg 1977; Hero, Littlejohn, and Marantelli 1991; Cogger 2000).

I believe a major advantage of axillary amplexus is that it enables the male to keep his vent closely aligned with that of the female, and this in turn often allows the entire clutch of eggs to be fertilized at once. In species with inguinal amplexus, the male must arch his back to bring his vent close to that of the female each time she releases eggs, and it probably is difficult to maintain this posture for very long. Consequently, frogs with inguinal amplexus typically fertilize eggs in a series of bouts in which only a small proportion of the eggs is released and fertilized. Each bout lasts only a few seconds and is separated by intervals of several seconds to several minutes. Most commonly, eggs are laid individually or in small packets or strings floating on the surface, attached to submerged vegetation or stones, or lying on the bottom of shallow pools.

This appears to be the typical pattern of oviposition and fertilization in many basal clades of anurans. These include *Discoglossus* (Knoeppffler 1962; Herrmann et al. 1987), *Bombina* (R. Savage 1932; C. Liu 1950; Birkenmeir 1954; Heusser 1961; Akef and Schneider 1985; Herrmann et al. 1987), *Scaphiopus* and *Spea* (Wright and Wright 1949; Stebbins 1954a; Bragg 1965), *Pelobates* (Eibl-Eibesfeldt 1956; Nöllert 1984), *Pelodytes* (Elzen 1976; Raehmel 1983; Hartley 1990; Toxopeus 1985; Toxopeus, Ohm, and Arntzen 1993; Guyétant, Temmermans, and Avrillier 1999), *Xenopus* (Bles 1906; Rabb 1973), *Hymenochirus* (Österdahl and Olsson 1963; Rabb and Rabb 1963b), and the myobatrachid genera *Neobatrachus, Crinia,* and *Uperoleia* (Barker and Grigg 1977; Hero, Littlejohn, and Marantelli 1991; Cogger 2000). Foam-nesting myobatrachids are exceptional in that they deposit eggs in a series of bouts, but all of the eggs are combined into a foam nest that floats on the water's surface (Tyler and Davies 1979; see the following further discussion of foam-nesting behavior). One consequence of this mode of fertilization and oviposition is that oviposition can be a lengthy process, lasting for many hours in some species (table 10.1).

Some frogs with axillary amplexus also deposit eggs individually or in small isolated packets. This is the typical mode of oviposition in many temperate-zone hylids (*Hyla, Acris,* and *Pseudacris;* Wright and Allen 1908; Noble and Noble 1923; Wright and Wright 1949; Livezey 1952; Eibl-Eibesfeldt 1956; Martof and Thompson 1958; Gosner and Rossman 1959; Fouquette and Littlejohn 1960; Redmer 1998), as well as some hyperoliid frogs (Wager 1965; Backwell 1991). However, in these species, oviposition usually lasts only two to three hours and sometimes is completed in less than one hour (table 10.1). Intervals between bouts of oviposition and fertilization often are much shorter than in species with inguinal amplexus. For example, Wright and Allen (1908) reported intervals of 21 seconds between emissions of sperm in *Pseudacris triseriata,* while Livezey (1952) observed intervals of only seven seconds in *Pseudacris nigrita.* Fouquette and Littlejohn (1960) reported that a pair of *Pseudacris streckeri* deposited 72 separate masses of two to ten eggs each in only 25 minutes. Redmer (1998) reported that a female *Hyla avivoca* released small groups of three to nine eggs at intervals of one to four minutes, with up to 180 eggs being laid in 40 minutes. An Asian fanged frog, *Limnonectes kuhlii,* lays eggs in shallow streams and trickles.

Table 10.1 Time required for fertilization and deposition of eggs in anurans with inguinal and axillary amplexus

Species (source no.)	Type of egg mass	No. of eggs	Oviposition time
Species with inguinal amplexus			
Bombinatoridae			
Bombina bombina (29)	Individual eggs or small packets	100	4 hrs
B. orientatlis (26, 31)	Individual eggs or small packets	200	up to 24 hrs
B. variegata (5, 12)	Individual eggs or small packets	150	5–12 hrs
Discoglossidae			
Discoglossus pictus (17)	Small packets	900	up to 24 hrs
Myobatrachidae			
Limnodynastes peroni (20)	Foam nest	> 1,000	> 2 hrs
Pelodytidae			
Pelodytes punctatus (37)	Short strings	350	2 hrs
Pipidae			
Hymenochirus boettgeri (18)	Individual eggs	450	2–7 hrs
Xenopus laevis (1)	Individual eggs		12 hrs
Species with axillary amplexus			
Bufonidae			
Bufo americanus (3, 9)	Long strings	7,000	3–4 hrs
B. bufo bufo (21)	Long strings	5,000	several hrs
B. bufo spinosus (28)	Long strings	7,240	6–8 hrs
B. cognatus (39)	Long strings	9,376	3–6 hrs
B. fowleri (9)	Long strings	7,000	5 hrs
B. microscaphus (41)	Long strings	4,500	10 hrs
B. raddei (4)	Long strings		2 hrs
B. torrenticola (40)	Long strings	3,500	75 mins
Hylidae			
Hyla arborea (10)	Small packets		< 1 hr
H. brevifrons (34)	Film on leaves	100	5 mins
H. chrysoscelis (15)	Small packets	1,500	26 mins
H. cinerea (22)	Surface film	700	30 mins
H. sarayacuensis (34)	Film on leaves	150	20 mins
H. rosenbergi (24)	Surface film	2,350	10 mins
Litoria vereauxi (23)	Small packets	885	2–4 hrs
Phyrnohyas spilomma (19)	Surface film	3,000	< 1 min
Pseudacris nigrita (11, 13, 14)	Small packets	100	2–3 hrs
P. streckeri (15)	Small packets	350	25–50 mins
P. triseriata (2)	Small packets	100	2 hrs
Hyperoliidae			
Afrixalus delicatus (33)	Packets on leaves	60	3 hrs
Leptodactylidae			
Edalorhina perezi (32)	Foam nest	35	30–60 mins
Lithodytes lineatus (25)	Foam nest	60	3 hrs
Physalaemus ephippifer (30)	Foam nest	410	30–50 mins
P. pustulosus (27)	Foam nest	234	1 hr
Pleurodema diplolistris (36)	Foam nest	650	12 mins

(*continued*)

Table 10.1 (continued)

Species (source no.)	Type of egg mass	No. of eggs	Oviposition time
Microhylidae			
Chiasmocles ventrimaculata (35)	Surface film	380	30 mins
Microhyla ornata (42)	Surface film	225	3–5 mins
Ranidae			
Pyxicephalus adspersus (38)	Surface film	3,500	3–28 mins
Rana boylii (43)	Attached to rocks		8 mins
R. catesbeiana (8)	Surface film	12,000	12 mins
R. clamitans (8)	Surface film	4,000	15 mins
R. nigromaculata (4)	Globular mass	4,000	4 mins
R. pipiens (3, 6)	Globular mass	4,000	4 mins
R. septentrionalis (7)	Globular mass	1,000	10 mins
R. sylvatica (3)	Floating mass	1,750	10 mins
R. temporaria (16)	Floating mass	2,000	< 1 min
R. palustris (3)	Globular mass	2,500	3 mins
Rhacophoridae			
Buergeria japonica (44)	Small packets	38–53	1 min[a]

Note: Only species that lay eggs in water are included.

[a] Pairs lay several small clusters of 1–6 eggs each, with each oviposition bout lasting about 1 minute; total elapsed time about 1 hour.

Females remained in amplexus for about 50 minutes on average, but actual oviposition lasted only half this time. They laid eggs in small batches at intervals of about three minutes, eventually producing about 50 eggs altogether (Tsuji and Lue 1998). Some of these species of frogs remain in amplexus for several hours before they begin laying eggs. Nevertheless, the limited quantitative data in table 10.1 suggest that one advantage of axillary amplexus is that it reduces the amount of time required to actually lay the eggs, a period when the pair is likely to be vulnerable to predation.

The evolutionary shift to axillary amplexus also is correlated with a greater tendency for the more derived frogs to lay their eggs in a single large mass that is fertilized very rapidly. For example, many microhylids, hylids, ranids, and hyperoliids lay all of their eggs as a single unit, consisting of a globular cluster, floating jelly raft, or surface film, while toads (*Bufo*) typically lay eggs in a continuous jelly tube. Such egg masses often are produced by a single convulsive expulsion of eggs by the female, accompanied by simultaneous release of sperm by the male. In some species, a series of egg-deposition and fertilization bouts are required (Wright 1914; C. Liu 1931; R. Savage 1934, 1961; Noble and Aronson 1942; Aronson 1943a, b, 1944; Eibl-Eibesfeldt 1952, 1956; Fouquette and Littlejohn 1960; Pyburn 1967; Garton and Brandon 1975; Kluge 1981; Hödl 1990a, 1991a; Schlüter and Salas 1991).

In some cases, fertilization is extraordinarily fast (table 10.1). For example, R. Savage (1961) reported that less than five seconds is required for deposition and fertilization of the entire egg clutch in *Rana temporaria. Phrynohyas spilomma* deposits its eggs in a surface film in about the same amount of time (Pyburn 1967). Even species that lay thousands of eggs in a surface film or globular cluster, such as *Rana catesbeiana* (fig. 10.2), *R. clamitans,* or *R. pipiens,* often complete oviposition in 10 minutes or less. Oviposition this fast has not been reported for any frog with inguinal amplexus, most of which lay only a few hundred eggs (table 10.1). Toads, which have axillary amplexus, are an exception to this pattern, often taking several hours to deposit their strings of eggs. Much of this time is spent resting between egg-laying bouts and moving around to drape the eggs onto vegetation and other supports; actual oviposition

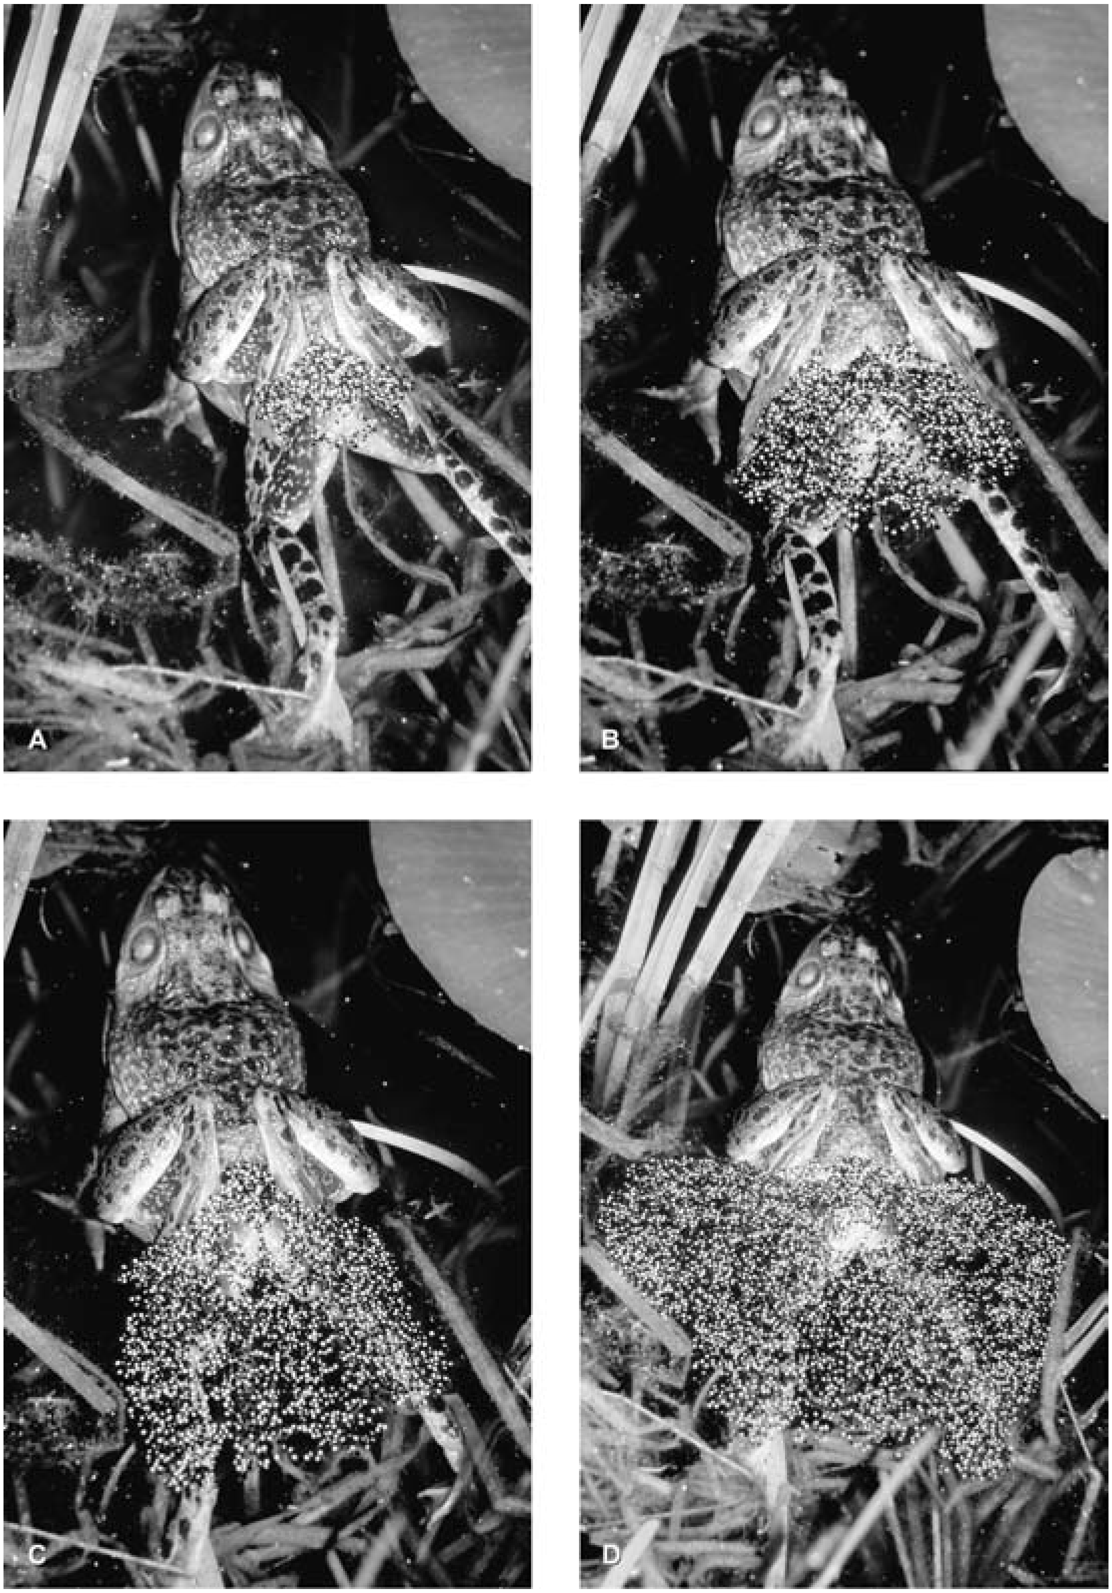

Fig. 10.2. Pair of American bullfrogs (*Rana catesbeiana*) depositing a surface film of eggs. The male forms a basket with his hind legs near the female's cloaca to receive and fertilize the eggs. The sequence from A to D took less than 3 minutes. Photos by Kentwood D. Wells.

and fertilization takes only a few minutes (Aronson 1944). For example, in *Bufo microscaphus,* bouts of fertilization were 42–75 seconds, with long resting periods in between. More than 10 hours would be required for a female to deposit all of her 4,500 eggs (A. Brown et al. 2000). Females of a stream-breeding toad (*Bufo torrenticola*) in Japan had spawning periods lasting about 75 minutes on average, and laid eggs in three or four separate batches. Fertilization of each batch required only about 10–15 seconds, however, with the remaining time being used for resting or moving between spawning sites (Tsuji and Kawamichi 1998). Pairs remained immobile for about 10 minutes after each spawning event, perhaps to ensure complete fertilization of the eggs. Some species of toads also remain in amplexus for several hours before egg laying begins, either because the female is seized by a male before she is ready to lay, or because she has not yet located a suitable oviposition site (J. Krupa 1994; Tsuji and Kawamichi 1998).

Modification and Loss of Amplexus

In some frogs, the male hardly clasps the female at all, but simply rests on her back or clasps her loosely during egg deposition. Most of these are species that lay eggs out of water. In *Rhinoderma darwinii,* a peculiar South American frog that broods its tadpoles in the vocal sac, fertilization is accomplished with only brief contact between the male and female (Pflaumer 1936; Cei 1962). In several species of *Mantidactylus* (Mantellidae) from Madagascar, the female deposits eggs on a leaf. The male fertilizes them while sitting on the female's head and shoulders, apparently releasing sperm to run down her back onto the eggs (Blommers-Schlösser 1975b, 1979). In another species in the same genus with aquatic oviposition, *M. curtus,* amplexus is very brief (Arnoult and Razarihelisoa 1967). Very short amplexus also has been observed in species of *Mantella,* terrestrial breeders in the same family (Arnoult 1966; H. Zimmermann 1992). Mantellid frogs are unusual in that males have femoral glands on the undersides of their thighs (Duellman and Trueb 1986; Glaw and Vences 1994). The function of these glands is unknown, but possible functions include facilitating adhesion of the male to the back of the female, tactile stimulation of the female with the rough surface of the gland, and delivery of chemical pheromones to the skin of the female (see chapter 8 for a discussion of other sexually dimorphic glands in anurans).

Dendrobatid frogs, terrestrial breeders that are remarkably similar to *Mantella* in morphology and behavior, have some unusual forms of amplexus as well. In some species, males clasp females by placing the upper surfaces of their front feet under the female's jaw, a position known as cephalic amplexus (fig. 10.1 C). Males sometimes clasp one another the same way during fights (Myers, Daly, and Malkin 1978; Wells 1980a). This appears to be the ancestral form of amplexus in the family. In derived dendrobatids (*Phyllobates* and *Dendrobates*), cephalic amplexus has been lost during mating, but is used by males of some species in aggressive interactions (Myers 1987). The male either fertilizes the eggs by sitting on them after they have been laid, or eggs are laid while the male and female sit facing away from one another with their vents in close proximity (H. Zimmermann and E. Zimmermann 1988; E. Zimmermann 1990).

Fig. 10.3. Unusual mode of oviposition and fertilization in a ranid frog from India, *Nyctibatrachus petraeus.* The frogs sometimes gather on vegetation over water in mixed-sex groups, and eggs are fertilized after being deposited by the female, without any form of amplexus. Photo by Krushnamegh Kunte.

An unusual case of loss of amplexus has been observed in a ranid frog from India, *Nyctibatrachus petraeus* (Kunte 2004; Das and Kunte 2005). This arboreal frog deposits eggs on leaves overhanging small streams or on bare rocks. Males called from vegetation and defended suitable oviposition sites as territories. Females visited males in their territories and deposited eggs at the male's calling site without amplexus or other physical contact between the male and female. Once the eggs were laid, the male sat on the eggs and fertilized them. Males sometimes attracted several females in succession to the same oviposition site, and in at least one instance, two females approached a male simultaneously and one deposited eggs while the other waited nearby (fig. 10.3).

Internal Fertilization in Anurans

Internal fertilization has evolved independently a number of times in frogs (Sever et al. 2003). In *Ascaphus,* the "tailed frogs" from western North America, the cloaca of the male has been modified to form a copulatory organ that is inserted into the cloaca of the female for mating. These frogs are the only species with internal fertilization that have true inguinal amplexus. The poor alignment of the male and female cloaca during amplexus makes the copulatory organ particularly advantageous, especially in the swift-water habitats where these frogs breed. During mating, the copulatory organ is bent forward toward the female's cloaca while the male clasps her around the waist. Mating is a prolonged affair, lasting for up to 90 hours (Noble and Putnam 1931; Slater 1931; Metter 1964; B. Stephenson and Verrell 2003). The reason for such prolonged amplexus is unknown. It could represent a form of mate-guarding behavior (see chapter 8), but competition among males for access to females has not been observed in these frogs. Female tailed frogs have the capacity to store sperm in the oviducts for long periods of time, which allows for the separation of the mating season and the egg-laying season (Sever et al. 2001), but it also would tend to make prolonged mate guarding ineffective in reducing sperm competition. The eggs are deposited in water and the tadpoles undergo normal aquatic development.

Internal fertilization is known in two species of *Eleutherodactylus* from Puerto Rico. *Eleutherodactylus jasperi,* which was not discovered until 1976, is ovoviviparous, retaining fertilized eggs in the oviducts and giving birth to small froglets (Drewry and Jones 1976; M. Wake 1978). It must have internal fertilization, but mating behavior has not been observed, and unfortunately this species appears to be extinct. Mating leading to internal fertilization has been observed in *E. coqui,* a species that retains the normal mode of terrestrial oviposition and direct development seen in other members of the genus (Townsend et al. 1981). In this species, the male rests on top of the female in a sheltered nest, but does not actually clasp her in amplexus. The pair can remain in this position for more than seven hours. Eventually, the female loops her hind legs over those of the male in a "reverse hind leg clasp" (fig. 10.1 D). This apparently serves to press the male's cloaca downward against the vent of the female. Mating can last more than two hours before oviposition begins. The female normally lays her eggs with the male still resting on her back, but fertile eggs are laid even if the male is removed (Townsend and Stewart 1986). Mating behavior has not been observed in great detail in most other species of *Eleutherodactylus.* It is possible that other examples of internal fertilization will be found, particularly in other Puerto Rican species, but it apparently does not occur in *E. antillensis* (S. Michael 1997a).

All other known examples of internal fertilization in anurans occur in African bufonids. African toads in the genus *Nectophrynoides* and several related genera are of particular interest because this group includes species with a continuum of reproductive modes, from strictly oviparous to fully viviparous (Grandison 1978; M. Wake 1980c; Xavier 1986; see the following further discussion). In some species, the male's cloacal opening faces downward to facilitate internal fertilization (Angel and Lamotte 1948; Lamotte and Xavier 1972; Grandison 1978). Based on reports of field collectors, Grandison (1978) reported that male *Altiphrynoides malcolmi* sometimes clasp females from below (belly-to-belly amplexus) and bend the cloacal opening upward to contact the female's cloaca. Similar behavior has been observed in *Mertensophryne micranotis,* an oviparous African bufonid with internal fertilization (Grandison 1980; Grandison and Ashe 1983), but it is not clear whether this is the typical mating position in either species. *Mertensophryne* males have unusual spines on the cloaca, which are thought to aid in copulation with the female.

External Fertilization in Urodeles

In contrast to anurans, more than 90% of urodeles have internal fertilization. Only the most primitive families (Cryptobranchidae, Hynobiidae, Sirenidae) have external fertilization (Duellman and Trueb 1986). In *Cryptobranchus,* males defend potential oviposition sites under rocks in streams and rivers as territories. Females enter these sites and lay their eggs, which are then fertilized by the male (B. Smith 1907; S. Bishop 1941b). Similar behavior has been observed in the giant Asian salamanders (*Andrias*) (Kerbert 1904; Tago 1929) and in *Hynobius* (Sasaki 1924; Thorn 1962, 1963, 1967; Kusano 1980; Tanaka 1989). Male cryptobranchids fertilize eggs as they are laid by releasing a milky cloud of sperm over them. In contrast, male *Hynobius* seize the egg sacs and release sperm onto them after the female has spawned. Although sirens are assumed to have external fertilization, actual mating behavior has never been observed, and repeated attempts to induce mating in captivity have failed (Hanlin and Mount 1978; Godley 1983).

Spermatophores and Internal Fertilization in Urodeles

The major innovation in the evolution of urodele reproductive modes was the evolution of the spermatophore and internal fertilization (Salthe 1967; Salthe and Mecham 1974; Nussbaum 1985). The selective forces that led to the initial evolution of spermatophore production are unknown. Salthe (1967) believed that spermatophores evolved mainly as an adaptation to flowing water that allowed sperm transfer to take place without the sperm being washed away in a current. Nussbaum (1985) disagreed, arguing instead that the main advantage is that it allows the male to deposit sperm before the female spawns, thus enabling the male to more effectively prevent other males from fertilizing his female's eggs. This contrasts with the situation in explosive breeding species of *Hynobius,* in which several males release sperm simultaneously onto a previously deposited egg mass (Sasaki 1924; Nussbaum 1985; Hasumi and Iwasawa 1990; Hasumi 1994). However, even in species that fertilize eggs internally by means of spermatophores, males have evolved various means of interfering with sperm transfer, sometimes resulting in direct sperm competition or fertilization of a female's eggs by more than one male (Arnold 1976; Halliday and Verrell 1984; Verrell 1989a; see chapter 9).

Whatever initial advantage accrued to salamanders that produced spermatophores, it is clear that the evolution of the spermatophore has had a profound effect on the reproductive biology and social behavior of urodeles. One consequence was the evolution of internal fertilization in all of the derived families of urodeles. Females of some species can retain viable sperm in their reproductive tracts for long periods of time (Boisseau and Joly 1975; Halliday and Verrell 1984; Houck and Schwenk 1984). This sets the stage for the separation of mating from oviposition, something that is virtually nonexistent in the anurans (except for *Ascaphus;* Metter 1964; Sever et al. 2001, 2003). For example, many North American plethodontid salamanders engage in courtship in both the fall and spring, but generally lay eggs only in late spring or early summer (Houck 1977a). This separation of courtship and oviposition allows females to make use of hidden oviposition sites that are not necessarily good courtship sites (Salthe 1967; Nussbaum 1985). The fact that males and females are not together when eggs are laid probably also accounts for the fact that care of the eggs is performed exclusively by the female in salamanders with internal fertilization (Nussbaum 1985; see also chapter 8). Finally, the relatively high cost of spermatophore production (compared to the cost of sperm production alone) limits the rate at which spermatophores can be produced (Verrell, 1986c 1988b; Halliday 1987; Marks and Houck 1989). This has resulted in selection for increased efficiency of spermatophore transfer, which in turn has led to the evolution of elaborate forms of courtship seen in many salamanders, particularly salamandrids and plethodontids (Arnold 1976, 1977; Halliday 1977a, 1990; Verrell 1989a; see also chapter 9).

The spermatophores of salamanders consist of a gelatinous base that supports a whitish or yellowish cap containing the spermatozoa (Jordan 1891; B. G. Smith 1910; Wilder 1923; Noble and Weber 1929; Noble 1931; S. Bishop 1932, 1941b; Blanchard 1933b; Noble and Brady 1933; R. E. Smith 1941; Organ 1958, 1960a, 1968; Briegleb 1961; Organ and Lowenthal 1963; Organ and Organ 1968; Uzzell 1969; J. Anderson 1970; Spotila and Beumer 1970; Arnold 1976; Labanick and Davis 1978; Russell et al. 1981; T. Mann 1984). All spermatophores share a basic similarity in structure, but there are differences in size and shape of the spermatophore, mode of attachment of the sperm mass to the base, and the structure of the sperm cap (see Zalisko, Brandon, and Martan 1984 for a comparative review). The stalk and the cap containing the sperm are produced by male cloacal glands (Sever and Houck 1985). Salamanders with external fertilization have cloacal glands, but not the ones involved in spermatophore production. In these species, the glands apparently function only in production of pheromones to attract females. This ancestral function is retained, and in some cases amplified, in derived urodele families, but the cloacal glands also have taken on the secondary function of spermatophore production (Sever et al. 1990; see also Sever 1991a, 1992a, 1994, 2003a for detailed reviews of the anatomy and evolution of cloacal glands).

In most urodeles with internal fertilization, the male courts the female and deposits one or more spermatophores on the ground, the bottom of a pond, a rock, or other substrate. The female then moves over the spermatophore and picks up the sperm with the lips of her cloaca (see chapter 9). In ambystomatids and salamandrids, the sperm are located near the upper surface of the spermatophore cap. When the female moves over the spermatophore, she removes only the top of the spermatophore cap into her cloaca, leaving part of the cap and the base behind. In contrast, plethodontid spermatophores have sperm concentrated near the center of the cap, which sits on the pointed tip of the gelatinous base. Normally the entire cap is taken into the female's cloaca, leaving only the base behind (Arnold 1976; Zalisko, Brandon, and Martan 1984; Arnold, Reagan, and Verrell 1993).

In the salamandrid genera *Euproctus* and *Calotrion,* the male grabs the female either by biting her, or by encircling her with his tail. The male deposits spermatophores on the female's body, sometimes placing them directly in the cloaca, or pushing them into the cloaca with his feet (Alcher 1981; Thiesmeier and Hornberg 1986, 1990). Often several spermatophores are transferred in a copulation that can last for several hours. Salthe (1967) suggested that this mode of sperm transfer represents a primitive state within the Salamandridae, but it seems more likely that it is secondarily derived from the more widespread pattern of depositing spermatophores on the substrate, perhaps as an adaptation to mating in flowing water. This interpretation is supported by morphological specialization of *E. montanus* and *E. platycephalus.* In both species, the cloaca of the male is elongated into a conical shape that facilitates placement of spermatophores in the female's cloaca (Carranza and Amat 2005). Direct transfer of spermatophores to the cloaca of the female apparently also occurs in *Amphiuma* (C. Baker, Baker, and Caldwell 1947), a species that does not breed in flowing water, but the details of mating behavior are not clearly understood.

Once sperm enter the female's cloaca, they are stored in the spermathecae, structures consisting of a number of tubules that empty directly into the cloaca, or in plethodontids, into a common duct connected to the cloaca (Kingsbury 1895; Wahlert 1953; Sever 1991a, 1992a, 1994, 1995, 1997, 2002; Sever and Kloepfer 1993; Sever et al. 1995; Sever and Bart 1996; T. Halliday 1998; Sever and Brizzi 1998; Sever et al.

2004a, b). The structure of the spermathecae varies, being relatively simple in most families, but more complex in plethodontids. The more complex structure is presumed to be the derived condition (Sever and Brizzi 1998). In some species, including *Notophthalmus viridescens, Triturus vulgaris,* and several species of *Desmognathus,* sperm often is packed into spermathecae in tangled masses (M. Hardy and Dent 1986; Sever and Hamlett 1998; Sever et al. 1999). This could represent an adaptation to restrict movement of sperm from rival males into the spermathecae, thereby reducing the potential for sperm competition.

In some urodeles, the walls of the spermathecal tubules provide nutritional secretions that sustain the sperm for some time (Benson 1968; Dent 1970; Pool and Hoage 1973). The length of time that sperm remain viable has not been precisely determined for most species. There are reports that viable sperm are stored for more than two years in *Salamandra salamandra* (Joly 1960) and several other species (Sever and Brizzi 1998), but more recent work suggests that most species do not retain sperm capable of fertilizing eggs for more than a few months (Sever1995; Sever, et al. 1996; Sever, Rania, and Krenz 1996; Halliday 1998; Sever and Brizzi 1998). In some species, such as ambystomatid salamanders, sperm remains viable for only a few hours to a few days, and eggs normally are laid shortly after mating (Humphrey 1977; Sever 1995; Sever and Brizzi 1998). However, Krenz and Scott (1994) reported that female *Ambystoma opacum* sometimes arrive at oviposition sites with eggs already fertilized, indicating that courtship occurred somewhere else. In plethodontids, which often lay eggs long after mating, sperm must remain viable for several months (Marynick 1971; Pool and Hoage 1973). Since females can mate with several different males during the long mating period, there is the possibility for direct sperm competition among males having a major impact on their reproductive success (Halliday and Verrell 1984; Halliday 1998). Fertilization of egg clutches by more than one male has been detected in *Desmognathus* (Tilley and Hausman 1976; Houck, Tilley, and Arnold 1985; E. Adams, Jones, and Arnold 2005). In some *Desmognathus,* viable sperm are retained even after eggs are laid, setting the stage for sperm competition among males over more than one breeding season (Houck and Schwenk 1984). In contrast, Sever (1991b, 1992b) found that sperm in the spermathecae of *Eurycea cirrigera* degenerate soon after egg-laying, making it unlikely that sperm are viable for more than one season. This seems to be the pattern in most salamanders (Sever and Brizzi 1998).

Internal Fertilization in Caecilians

All caecilians have internal fertilization, but the mode of fertilization is quite different from that of urodeles and clearly is independently derived. In male caecilians, the end of the cloaca is modified into a copulatory organ, the phallodeum. In contrast to *Ascaphus,* which has its copulatory organ permanently extended, the phallodeum is normally folded back inside the cloaca, but is everted during mating by contractions of muscles in the body wall and in the cloaca (M. Wake 1977b, 1992). Fluid for transporting the sperm and nutrients to support them are provided by accessory glands, called Müllerian glands, which are not found in anurans, urodeles, or other vertebrates (M. Wake 1981). Actual mating behavior has seldom been observed in caecilians, even in captivity, so details of courtship and copulation are unknown. We also know nothing about how long viable sperm can be retained in the female's reproductive tract, although female caecilians lack any sort of specialized sperm storage organ like that found in urodeles (M. Wake 1972; Sever 2002)

Modes of Egg Deposition and Development in Amphibians

Amphibians are unique among vertebrates in the variety of ways in which they reproduce. Bony fishes approach amphibians in the diversity of their reproductive modes (Balon 1975, 1981), but lack fully terrestrial reproduction (although some fishes do place their eggs out of water). Anurans, urodeles, and caecilians all include species with aquatic, partially aquatic, and terrestrial reproduction, as well as live-bearing species (Duellman and Trueb 1986). There have been many attempts to classify amphibian reproductive modes by site of egg deposition, type of egg, and patterns of egg and larval development. For example, Boulenger (1886) divided anurans into species with small eggs and aquatic larval development and those with large eggs and direct development. These categories were further subdivided into species with aquatic oviposition, terrestrial oviposition, and parental transport of eggs. Later workers provided general reviews of amphibian reproductive modes (Sampson 1900; Wunder 1932; Lutz 1947; Goin 1960a; Salthe 1969; Salthe and Duellman 1973; Salthe and Mecham 1974; Lamotte and Lescure 1977; Duellman 1985, 1989a; Lescure 1986; Haddad and Prado 2005). Others have published family-level surveys (Noble 1927, 1931; Jameson 1955a, 1957a) and summaries of reproductive modes of amphibians from particular regions (A. Martin 1967; Crump 1974; Duellman 1978, 1988, 1989b; W. Brown and Alcala 1983; Tyler 1985b; Amiet 1989; Hödl 1990b; Rand and Myers 1990; Donnelly 1994; Perotti 1997; Haddad and Prado 2005).

Duellman (1985) listed 29 reproductive modes in anurans, and these were discussed in considerable detail by Duellman and Trueb (1986). Their classification was based on features such as site of egg deposition (in water, on land, or retained in the oviducts), type of eggs (small aquatic eggs, large terrestrial eggs, foam nests, etc.), and mode of development (feeding or nonfeeding aquatic larvae, nonaquatic larvae, or direct development of eggs into small froglets). This scheme has been widely used, with some modifications, by subsequent authors (Hödl 1990b; Donnelly 1994; Perotti 1997; Haddad and Prado 2005). Duellman (1988) used a different numbering scheme in a discussion of reproductive modes in Neotropical anurans, and Duellman (2003) added two new reproductive modes to the list, thereby renumbering some modes. More recently, Haddad and Prado (2005) added 10 newly discovered reproductive modes to the list, bringing the total to 39, with some of Duellman and Trueb's modes being renumbered (table 10.2). Salthe (1969) developed a somewhat different classification of reproductive modes for urodeles. However, all of the modes of egg deposition and development found in urodeles have been described in anurans, so I will use the classification given in table 10.2 for both groups. The reproductive biology of most caecilians is so poorly known that it is impossible to determine where many species fit in this scheme, so I will discuss their reproductive modes in more general terms. Attempts to classify amphibian reproductive modes have been complicated by variation in how different authors define certain reproductive modes. For example, Lamotte and Lescure (1977) and Duellman and Trueb (1986) used the term "direct development" for species in which eggs hatch into fully formed juveniles with no feeding or nonfeeding larval stage. They included species in which the eggs develop in terrestrial or arboreal nests, on the body of a parent, or in a vocal sac or special pouch. They distinguished direct development from modes of reproduction in which eggs are retained in the oviducts for all or part of development. M. Wake (1980c, 1982, 1989b) used a broader definition of direct development to include any species that lacks a free-living, feeding larval stage, such as those with eggs that hatch into nonfeeding larvae and those that retain encapsulated eggs throughout development in the reproductive tract. I will use the more restricted definition in my discussion. Salthe and Mecham (1974) and M. Wake (1982) also used the term "ovoviviparity" to refer to any species that carries eggs that develop entirely from yolk reserves and hatch into larvae or juveniles. They included species that carry eggs on the back, in pouches, in the vocal sac, or in the stomach. I prefer the more traditional use of the term "ovoviviparity" to refer only to species that retain eggs in the oviducts, but do not provide them with any nutrition other than the yolk. "Viviparity" is used to refer only to species that retain eggs in the oviducts and provide them with additional sources of nutrition. The term "paraviviparity" has been proposed to describe development of embryos from yolk reserves in sites outside of the mother's reproductive tract, such as brood pouches (Altig and Johnston 1989; Thibaudeau and Altig 1999), but this term has not been widely used in the literature.

Most authors assume that some form of aquatic oviposition is the ancestral condition for all three living orders of amphibians, but the primitive mode of egg placement and the structure of egg clutches in ancestral amphibians are unknown. Salthe and Mecham (1974) speculated that the ancestral condition might be the deposition of eggs in rosary-like strings, with individual eggs connected by jelly strands constricted between the eggs. This type of egg mass is characteristic of some relatively primitive salamanders (*Cryptobranchus, Andrias, Amphiuma*) and several tropical plethodontids, in which it probably is secondarily derived. All of the oviparous caecilians for which eggs have been described also produce this type of egg mass, as do some relatively primitive frogs, including *Leiopelma, Ascaphus,* and *Alytes* (Salthe and Mecham 1974; Duellman and Trueb 1986; Funk et al. 2004), as well as some terrestrial-breeding microhylid frogs of the genus *Cophixalus* (Hoskin 2004). It is not clear whether clutch structure is homologous in all of these groups or simply the result of superficial similarity in appearance, because the morphology of the eggs has not been studied in detail.

The evolution of nonaquatic oviposition has long been recognized as a recurring theme in amphibian evolution (Lutz 1947; Jameson 1955a; Goin 1960a; Crump 1974; Salthe and Mecham 1974; Lamotte and Lescure 1977; McDiarmid 1978; Bogart 1981; Duellman 1985, 1989a; Duellman and Trueb 1986). In some cases, the shift to nonaquatic oviposition involves little more than placing aquatic eggs in a saturated environment where larvae eventually have access to water. In other groups, adaptation to the terrestrial environment has gone much farther, culminating in the complete loss of the aquatic larval stage and direct development of eggs. Although most authors have considered the most likely direction of evolution in reproductive modes to be from aquatic to terrestrial reproduction, there is evidence for plethodontid salamanders that evolution has gone in the opposite direction, with reacquisition of an aquatic life history from direct-developing ancestors (Titus and Larson 1996; Chippindale et al. 2004; Kozak et al. 2005; see the following further discussion).

For more than 60 years, there has been speculation about the selective pressures favoring the evolution of nonaquatic reproduction, especially in anurans. The most common explanation is that nonaquatic oviposition removes the most vulnerable life-history stages, the eggs and early larvae, from the dangers presented by a host of aquatic predators. This advantage would be most pronounced in species with direct development, a strategy that completely eliminates aquatic stages (B. Lutz 1947; Tihen 1960, 1965; Poynton 1964b;

Table 10.2 Modes of egg deposition and development in anurans

Egg deposition site	D&T mode	Tadpole development	Selected examples
Aquatic eggs			
1. Still water	1	Feeding in pond	Many *Rana, Hyla, Bufo*
2. Flowing water	2	Feeding in stream	*Ascaphus, Atelopus*
3. Subaquatic chamber in stream		Feeding in stream	*Crossodactylus, Hylodes*
4. Streamside basin	3	Feeding in stream	*Hyla boans, Hyla vasta*
5. Subterranean nest		Feeding in water after flooding	*Aplastodiscus, Hyla albofrenata* group
6. Treehole, bromeliad	4	Feeding in water	*Anotheca, Nyctimantis, Phyllodytes*
7. Water-filled depression	5	Nonfeeding in water	*Pelophryne, Eupsophus, Leiopelma hochstetteri*
8. Treehole, leaf axil	6	Nonfeeding in water	*Anodonthyla, Frostius, Platypelis*
9. On ground or in water	7	Develop in stomach	*Rheobatrachus*
10. Bubble nest on pond		Feeding in pond	*Chiasmocleis leucosticta*
11. Foam nest in pond	8	Feeding in pond	*Adelotus, Physalaemus,* some *Leptodactylus*
12. Foam nest in pool	9	Feeding in stream	*Megistolotis lignarius*
13. Foam nest in basin		Feeding in pond	*Leptodactylus labyrinthicus*
14. Foam nest in ground bromeliad		Feeding in pond	*Physalaemus spiniger*
15. Dorsum of female	10	Feeding in pond	*Pipa carvalhoi*
16. Dorsum of female	11	Direct development	*Pipa pipa*
Nonaquatic eggs			
17. Terrestrial nest	12	Feeding in pond	*Pseudophryne, Geocrinia*
18. Ground, rock, burrow, depressions, nest	13	Tadpoles move to water	*Hemisus, Leptopelis, Batrachyla,* some *Centrolene, Phrynomedusa, Paratelmatobius*
19. Humid rocks, rock crevices, tree roots above water		Feeding semiterrestrial tadpoles on rocks in water film or splash zone	*Cycloramphus, Thoropa, Petropedetes*
20. Terrestrial nest	14	Tadpoles carried to water	*Dendrobates, Colostethus*
21. Terrestrial nest	15	Nonfeeding in nest	*Thoropa, Leiopelma, Zachaenus*
22. Terrestrial nest	16	On dorsum, in vocal sac, in pouches	*Sooglossus, Rhinoderma, Assa, Cycloramphus stejnegeri*
23. Terrestrial nest	17	Direct development	*Brachycephalus, Eleutherodactylus, Myersiella, Platymantis*
24. Leaves over water	18	Feeding in pond	*Agalychnis, Phyllomedusa,* some *Hyla*
25. Leaves over water	18	Feeding in stream	*Hyalinobatrachium, Phasmahyla*
26. Walls of tree holes or hollow bamboo	19	Feeding in water	*Acanthixalus, Nyctixalus, Chirixalus*
27. Arboreal nest	20	Direct development	*Eleutherodactylus, Platymantis*
28. Foam nest on ground		Feeding in pond after flooding	*Physalaemus signifer* group
29. Foam nest in basin	21	Feeding in pond after flooding	*Heleioporus*
30. Foam nest in burrow		Feeding in pond after flooding	*Adenomera bokermanni, Leptodactylus fuscus* group
31. Foam nest in burrow		Feeding in stream after flooding	*Leptodactylus cunicularius*

(*continued*)

Egg deposition site	D&T mode	Tadpole development	Selected examples
32. Foam nest in burrow	22	Nonfeeding in burrow	Some *Adenomera, Stumpffia*
33. Foam nest in tree	23	Feeding in water	*Chiromantis, Rhacophorus, Polypedates*
34. Carried on male's legs	24	Feeding in pond	*Alytes*
35. Dorsal pouch on female	25	Feeding in pond	*Gastrotheca* (some)
36. Dorsum of female	26	In bromeliads or bamboo stems	*Flectonotus, Fritziana*
37. Dorsum of female	27	Direct development	*Gastrotheca* (some), *Stefania, Hemiphractus*
38. Eggs retained in oviducts	28	Nutrition provided by yolk	*Eleutherodactylus jasperi*
39. Eggs retained in oviducts	29	Nutrition provided by female	*Nectophrynoides occidentalis*

Sources: Modified from Haddad and Prada (2005). D&T mode indicates reproductive modes of Duellman and Trueb (1986).

A. Martin 1967; Heyer 1969; Salthe 1969; Van Dijk 1971; Crump 1974; Salthe and Mecham 1974; McDiarmid 1978; Duellman and Trueb 1986). Nevertheless, terrestrial and arboreal eggs are preyed upon by snakes, spiders, insects, and other arthropods, often at rates similar to those reported for aquatic breeders (see chapter 14). Very high survivorship often is achieved only if nonaquatic oviposition is coupled with parental care (see chapter 11). A variety of other putative benefits of nonaquatic reproduction have been proposed, including reduced larval competition (B. Lutz 1947; A. Martin 1967; Crump 1974; Duellman and Trueb 1986), escape from problems of desiccation in temporary ponds (A. Lee 1967; Crump 1974; McDiarmid 1978; Duellman and Trueb 1986), escape from low oxygen levels in tropical ponds (Van Dijk 1971), and avoidance of oviposition in streams with swift currents (Alcala 1962; Goin and Goin 1962; W. Brown and Alcala 1983).

Magnusson and Hero (1991) correlated the diversity of reproductive modes of frogs at various Amazonian sites with environmental variables thought to affect the survival of eggs and larvae, including abundance of predators, water temperature, oxygen availability, and probability of desiccation. They found a positive correlation between the proportion of species with nonaquatic reproductive modes and the abundance of invertebrate predators. Sites where fish were abundant actually had a higher proportion of species with aquatic oviposition, perhaps because fish tend to prey on invertebrate egg predators but represent only a minor threat to amphibian eggs. Physical factors such as oxygen, temperature, and chances of the habitat drying up were not clearly related to the frequency of nonaquatic reproduction. This study helps to explain why anurans with certain modes of reproduction do better than others in particular habitats, but it tells us very little about the origins of these modes.

In fact, any attempt to find a general explanation for the evolution of nonaquatic reproduction probably is a fruitless exercise, for several reasons. First, species with different reproductive modes often coexist in the same habitat, particularly in the tropics (e.g., Crump 1974), and represent equally successful alternatives for dealing with certain kinds of environments. Second, many amphibians with nonaquatic reproduction represent ancient lineages that evolved their modes of reproduction in ecological conditions quite different from those in which they are currently found. Other groups, such as centrolenid frogs that lay eggs on leaves overhanging streams, probably have remained closely associated with the habitats in which their reproductive modes evolved. In any case, an assemblage of species in a particular locality, like those included in the study by Magnusson and Hero (1991), almost certainly did not evolve together, but instead represents a diverse array of lineages with independent evolutionary histories.

Amphibians with nonaquatic oviposition are exposed to selective pressures quite different from those affecting aquatic breeders. Oxygen availability is seldom a serious problem, although under some circumstances, such as high temperature, metabolic rates and development of embryos are limited by rates of gas diffusion (Seymour and Bradford 1987; Seymour, Geiser, and Bradford 1991a, b; Seymour and Loveridge 1994; see also chapter 4). In contrast, a high rate of evaporative water loss probably is the most important constraint on successful development of terrestrial eggs (A. Martin and Cooper 1972; Taigen, Pough, and Stewart 1984; Bradford and Seymour 1988a). Consequently, adaptations for terrestrial or arboreal oviposition generally include choice of suitable wet substrates for oviposition, placement of eggs in sheltered locations, and parental attendance of eggs (Salthe and Mecham 1974; McDiarmid 1978; Wells 1981a; Taigen, Pough, and Stewart 1984; Nussbaum 1985; Townsend 1989a; N. Mitchell 2001, 2002a, b).

Reproductive Modes of Anurans

A summary of anuran reproductive modes, modified from Duellman and Trueb (1986) and Haddad and Prado (2005), is presented in table 10.2. The various features of reproductive modes need not have evolved in parallel. There are, for example, frogs with terrestrial eggs and aquatic larvae, frogs with aquatic or terrestrial eggs and nonfeeding tadpoles or direct development, and frogs that lay their eggs in foam nests placed either in the water or on land. Reproductive modes are far more diverse in the tropics than in other regions, and most of this diversity is found in wet tropical forests, especially in the New World. For example, Crump (1974) identified 10 distinct modes of reproduction at a single rainforest site in Ecuador, while the Atlantic rainforest of Brazil has 27 different modes represented (Haddad and Prado 2005). Overall, 31 of 39 modes (80%) listed by Haddad and Prado (2005) are represented in the Neotropical region. In contrast, 90% of the frogs in the United States lay eggs in permanent or temporary ponds, as do nearly all species in Europe. Africa, southern Asia, and the Australo-Papuan region have fewer reproductive modes represented than do the Neotropics, but more than in temperate regions (Duellman and Trueb 1986). Arid regions typically have relatively few reproductive modes represented, because most anurans in these regions are dependent on standing water. For example, in a semiarid region of Argentina, half of the anuran species laid eggs in ponds, and only four reproductive modes were represented (Perotti 1997).

One difficulty with the classification scheme of Duellman and Trueb (1986), as well as that of Haddad and Prado (2005), which is derived from it, is that some reproductive modes encompass a wide variety of egg-laying strategies that represent fundamental adaptive differences, while others are very specialized reproductive modes that differ only slightly from others. For example, Mode 1 (oviposition in still water with feeding aquatic larvae) includes species that lay eggs in many different types of aquatic habitats that differ in size, depth, temperature, and permanence. Variation in habitat structure results in different selective pressures shaping the evolution of oviposition behavior (see the following additional discussion). On the other hand, species with Mode 4 reproduction (oviposition in a streamside basin constructed by the frogs) do not differ in any fundamental way in their egg and larval development from many anurans with Mode 1 reproduction. Species in the genus *Pipa* all share a unique mode of egg deposition in which eggs develop in cavities in the back of the female, but some retain the eggs longer than others, giving birth to small froglets (Mode 16) rather than aquatic tadpoles (Mode 15). Other reproductive modes group together species that are only superficially similar to one another. Some anuran species exhibit considerable plasticity in oviposition behavior, resulting in a single species exhibiting several of the reproductive modes listed in table 10.2. Some frogs, for example, construct basins in which eggs are laid, but sometimes also place them in natural rock pools or streams. Other species usually are pond-breeders, but sometimes will place their eggs in quiet stream pools.

Consequently, while these classification schemes provide a useful starting point for further discussion, the various modes of reproduction should not be viewed as clearly differentiated grades of evolution or the final word on the diversity of reproductive modes in anurans. Indeed, if one were to clearly differentiate among various types of oviposition sites, larval development, and amount of parental care, the list in table 10.2 could easily be expanded to 50 or 60 distinct modes of reproduction. The list in table 10.2 also should not be interpreted as an evolutionary progression from ancestral to derived modes of reproduction, even though it begins with the most generalized mode and ends with modes generally considered to be highly derived. The numbers in table 10.2 provide a convenient shorthand for referring to reproductive modes, but I do not follow the order of reproductive modes precisely as listed in the table. Instead, I group them roughly by ecological similarity.

Oviposition in Standing Water (Mode 1)

Oviposition in standing water such as permanent and temporary ponds has long been considered the ancestral condition in anurans (Noble 1927; Goin 1960a; Salthe and Duellman 1973; Salthe and Mecham 1974; McDiarmid 1978; Duellman and Trueb 1986), although some authors have questioned this (Bogart 1981). Certainly this appears to be the most generalized reproductive mode, and is by far the most common, being found in about 80% of anuran families (Duellman and Trueb 1986). Mode 1 is a very broad category, encompassing species that lay eggs in all sorts of standing water, from permanent lakes and ponds to vernal pools, swamps, flooded fields, temporary rain forest pools, desert rain pools, and small rock pools on the shores of rivers and lakes. The physical and biological characteristics of these habitats vary considerably (table 10.3) and almost certainly have shaped the evolution of both clutch structure and oviposition behavior. Clutch sizes, egg sizes, placement of eggs, and development times all vary enormously among Mode 1 anurans. Most studies have tended to focus on a single selective pressure, such as predation or oxygen availability, but the type of oviposition found in any given species or clade probably represents a compromise among conflicting selective pressures. At present we can do little more than speculate about the adaptive significance of various types of egg clutches, because quantitative measurements of selection gradients are virtually nonexistent.

Table 10.3 Selected physical and biological features of various kinds of aquatic sites commonly used by breeding amphibians

Habitat type	Water temperature	Dissolved oxygen	Probability of drying	Food for larvae	Predation pressure
Vernal pool	Low	Moderate	Moderate	Variable	Low
Permanent pond (in summer)	High	Low	Low	High	High
Swamp (in summer)	High	Very low	Moderate	High	High
Mountain lake	Low	High	Low	Low	Variable
Desert rain pool	Very high	Variable	High	Variable	Low
Lowland stream	Variable	Variable	Low	Variable	Variable
Mountain stream	Low	High	Variable	Low	Low
Streamside basin (tropics)	High	Low	Moderate	Variable	Low
Tree hole (tropics)	Moderate	Low	Low	Low	Low
Bromeliad (tropics)	High	Low	Low	Low	Low

Eggs Laid in Compact Masses

Many ranid frogs that deposit eggs in cold ponds and lakes lay their eggs in compact jelly clumps attached to submerged vegetation in relatively deep water. Placing the eggs well below the surface presumably reduces their chances of being frozen or drying out if water levels drop (J. Moore 1939, 1940, 1949b; Licht 1971; Salthe and Mecham 1974). At the same time, clumping the eggs in a compact mass is feasible because levels of dissolved oxygen generally will be high enough in cold water to allow adequate diffusion of oxygen into the center of the mass (Burggren 1985; Seymour and Bradford 1995; Seymour 1999; see also chapter 4). Both the thick jelly layer surrounding the egg masses and the relatively tough egg capsules of these species provide protection against some types of predators, such as fishes and chewing insects, but are less effective against newts and sucking insects (Salthe 1963; Grubb 1972; Werschkul and Christensen 1977; see also chapter 14).

Eggs Laid in Floating Rafts

An alternative mode of egg deposition practiced by some cold-water breeders, such as the North American wood frog (*Rana sylvatica*) and the European common frog (*Rana temporaria*), is to lay eggs in floating jelly rafts at the surface, usually in exposed locations that receive direct sunlight. This increases rates of embryonic development by exposing them to higher temperatures than those experienced by submerged egg masses, a distinct advantage for species breeding in vernal pools or other temporary sites that undergo rapid drying. The thermal advantage of laying eggs exposed at the surface is enhanced by selecting the warmest available sites for egg deposition (Seale 1982b; Sjögren, Elmberg, and Berglind 1988) and by clumping eggs into large communal masses, sometimes composed of hundreds of clutches (fig. 10.4 A). On sunny days, temperatures inside these communal egg masses tend to be higher than in isolated clutches or the surrounding water. The communal masses also retain heat longer than do isolated masses (Heusser 1961; R. Savage 1961; Guyétant 1966; Herreid and Kinney 1967; Zweifel 1968b; Licht 1969a, 1971; Hassinger 1970; Beattie 1980; Seale 1982b; Waldman 1982a; Waldman and Ryan 1983; Caldwell 1986b; Håkansson and Loman 2004; see chapter 3 for further discussion of embryonic thermal requirements). In some cases, clustering of egg masses also may provide some defense against predators such as leeches, because isolated masses may be more vulnerable to attack from the periphery (Håkansson and Loman 2004). A clear disadvantage of placing eggs at the surface is the possibility of freezing or desiccation, but laying eggs in communal masses reduces the rate of evaporative water loss when the eggs are stranded above water and prolongs survival of the eggs (Forester and Lykens 1988).

Eggs Laid in Strings

Most toads in the genus *Bufo* and some pelobatids lay eggs in long jelly strings (10.4 B). These strings typically are draped over vegetation in the water or are deposited on the bottom of a pond. Presumably such egg masses enhance gas exchange for the embryos by ensuring that each embryo is exposed to open water (Zweifel 1968b; Duellman and Trueb 1986; Seymour 1999; see chapter 4 for a discussion of respiration by amphibian embryos). Nevertheless, toad eggs often are piled up into large aggregations in shallow water, a pattern of egg deposition that would tend to decrease oxygen availability, particularly in very warm water. In some species, such as *Bufo quercicus,* egg strings are broken into short bands of five or six eggs that are scattered on the pond bottom, and a similar pattern of oviposition is seen in some spadefoot toads (*Spea*) as well.

Egg Scattering

Many pond-breeding anurans scatter eggs individually or in small packets on the bottom of a pond. This mode of

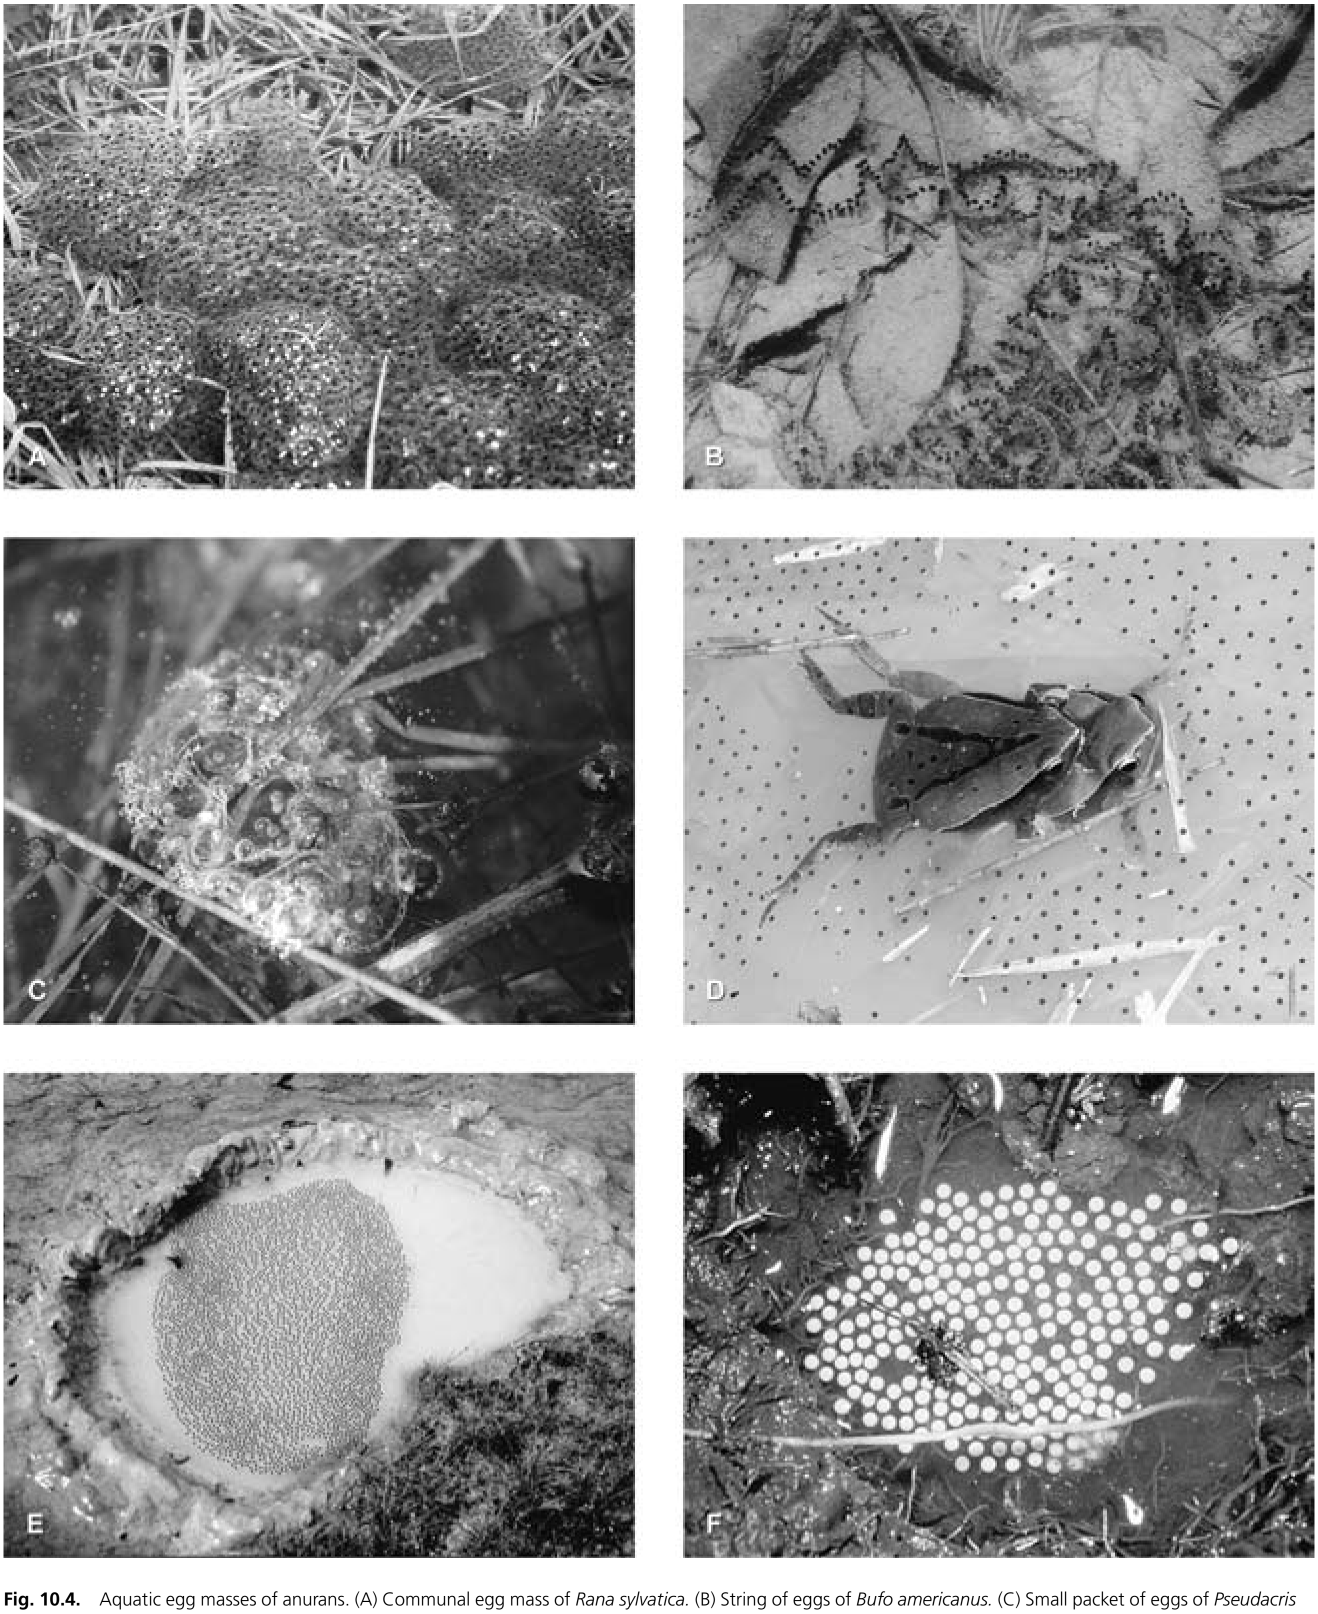

Fig. 10.4. Aquatic egg masses of anurans. (A) Communal egg mass of *Rana sylvatica.* (B) String of eggs of *Bufo americanus.* (C) Small packet of eggs of *Pseudacris feriarum* laid at the water's surface. (D) Diffuse surface film of a microhylid frog, *Kalophrynus interlineatus,* with an ovipositing pair in amplexus. (E) Tiny pigmented eggs of *Hyla wavrini* in a streamside mud basin. (F) Large unpigmented eggs of *Hyla leucopygia* in a flooded subterranean chamber. Photos by Kentwood D. Wells (A–C), Wayne van Devender (D), Walter Hödl (E), and Celio F. B. Haddad (F).

oviposition is typical of frogs in the genera *Bombina* and *Discoglossus,* some species of *Paratelmatobius* from Brazil (Pombal and Haddad 1999), some myobatrachid frogs, and many others. Eggs also are attached individually or in small groups to submerged plants, as in some species of *Pseudacris, Acris, Hyla, Spea,* and *Xenopus,* or released individually at the water's surface, as in *Hymenochirus*. The behavior of scattering eggs rather than laying them in a single mass generally is interpreted as an antipredator adaptation that makes eggs inconspicuous and therefore difficult for predators to locate (Rabb 1973; Salthe and Mecham 1974; C. Marshall, Doyle, and Kaplan 1990). Antipredator benefits of egg scattering have been demonstrated more clearly for newts than for anurans (see the following discussion). This type of oviposition also could enhance gas exchange in oxygen-poor water by maximizing the exposed surface area of the eggs (Zweifel 1968b; Seymour 1999).

Surface Films

Many anurans that breed in warm water lay eggs in films only a single egg thick on the surface of the water (fig. 10.4 C–E). Following the work of J. Moore (1940), most authors have interpreted this as an adaptation to poorly oxygenated water. The surface film allows the eggs to obtain oxygen directly from the air, even when the water is nearly anoxic (Zweifel 1968b; Van Dijk 1971; Salthe and Mecham 1974; Kluge 1981). M. Ryan (1977) and Kluge (1981) also found that surface films tend to be slightly cooler than the surrounding water, a possible advantage if high temperatures result in developmental abnormalities (R. D. Howard 1978b), but it seems unlikely that this is the principal selective advantage of such clutches. Poynton (1964a) suggested that surface films are an adaptation to reduce predation because they keep the eggs off the bottom, where most predators are found. However, this does not deter leeches, a major predator on clutches of bullfrog eggs (R. D. Howard 1978b). This explanation also does not account for the strong association of surface films with warm, poorly oxygenated breeding sites.

Oviposition in Flowing Water (Mode 2)

Many Mode 1 frogs that normally breed in ponds also breed in slow-moving streams and stagnant pools at the edges of streams. For example, pond-breeding anurans such as green frogs (*Rana clamitans*), pickeral frogs (*R. palustris*), and American toads (*Bufo americanus*) often lay eggs in the quiet backwaters of streams. There also are stream-breeding species, such as *Bufo torrenticola* in Japan, that have oviposition behavior, egg clutch structure, and larval development that are very similar to those of pond-breeding species (Tsuji and Kawamichi 1996b, 1998). Other anurans have become more specialized for breeding in flowing water from moderately fast streams to mountain torrents (Mode 2), with modifications in oviposition behavior, egg size, clutch structure, and larval morphology that enhance survival in rapidly flowing water. For example, stream-breeding bufonids in the genus *Atelopus* lay large and unpigmented eggs in double strings attached to rocks (Starrett 1967). Parallel adaptations for stream breeding are found in the bufonid genera *Werneria* from Africa and *Ansonia* from Asia (Amiet 1972; W. Brown and Alcala 1983; Lamotte and Lescure 1989b). The tailed frog (*Ascaphus truei*) lays large, unpigmented eggs in rosary-like strings attached to the undersides of rocks in streams (H. Brown 1989). Megophryids in the genus *Scutiger* from the mountains of China lay large, unpigmented eggs in clusters attached to the undersides of stones or plant roots in streams (C. Liu 1950). All of these anurans have highly modified tadpoles adapted to holding onto rocks in fast-moving water (see chapter 12).

Ranid frogs from many parts of the world breed in streams. These include species from Africa (*Conraua*), Asia (*Staurois, Amolops, Paa,* some *Rana*), Europe (*Rana graeca, R. iberica, R. italica, R. pyrenaica*), North America (*Rana subaquavocalis*), and Central America (*Rana warszewitschii, R. maculata;* C. Liu 1950; Lamotte and Perret 1968; Kuramoto 1973; Villa 1979a; Sabater-Pi 1985; Kusano and Fukuyama 1989; T. Matsui and Matsui 1990; Platz 1993; Donnelly 1994; Kam et al. 1998; Schleich and Kästle 2002). Similar stream-breeding habits have evolved independently in many other families, including mantellids from Madagascar, rhacophorids from Asia (*Buergeria*), astylosternids from Africa (*Trichobatrachus*), *Heleophryne* from southern Africa, South American leptodactylids (*Insuetophrynus, Megaelosia, Telmatobius, Hylodes,* and others), several groups of Neotropical hylids (*Plectrohyla, Ptychohyla,* several species groups of *Hyla*), some hylids from Australia and New Guinea (*Litoria booroolongensis, L. eucnemis, L. genimaculata, L. lesueri, L. pearsoniana, L. spenceri, L. subglandulosa,* and the genus *Nyctimystes*), and some Australian myobatrachids (*Taudactylus, Rheobatrachus,* some *Crinia;* Duellman 1970; Visser 1971; Boycott 1972, 1988; Formas, Diaz, and Valencia 1980; Blommers-Schlösser 1981; Sinsch 1985; Fukuyama, Kusano, and Nakane 1988; Amiet 1989; M. Davies 1989; Fukuyama and Kusano 1989, 1992; Lamotte and Lescure 1989a; McDonald and Davies 1990; Duellman and Campbell 1992; Giaretta, Bokermann, and Haddad 1993; Anstis and Littlejohn 1996; Duellman, de la Riva, and Wild 1997; Anstis, Alford, and Gillespie 1998; Cogger 2000; Andreone et al. 2002; Vences et al. 2002).

Most stream-breeding frogs lay relatively large eggs compared to closely related species that breed in standing water, often in relatively compact masses attached to rocks in relatively sheltered sites. Presumably this type of oviposition site reduces the chances of eggs being swept away in a current. A common pattern among stream-breeding frogs in the tropics is for breeding to occur mostly in the dry season, when stream flow is low and eggs are less likely to be swept away in torrential floods (Menzies 1963; C. B. Jørgensen, Shakuntala, and Vijayakumar 1986; Fukuyama and Kusano 1992; Kam et al. 1998). Eggs laid in hidden locations often are unpigmented, presumably because their exposure to ultraviolet radiation in sheltered oviposition sites is minimal (Salthe and Mecham 1974). In all of these genera, the tadpoles have special adaptations for adhering to rocks in stream currents (see chapter 12). Reproductive Mode 2 tends to grade into Mode 18 among stream-breeding frogs that lay eggs on wet rock faces, often in the splash zones of waterfalls. Tadpoles of those species either drop into streams to complete development, or remain attached to the rock faces (see the following "Non-Aquatic Eggs with Feeding Tadpoles"). In some cases, eggs of such species also are unpigmented (e.g., *Amolops cremnobatus;* Inger and Kottelat 1998). Mode 2 also grades into Mode 4 (eggs laid in streamside basins), because some basin-building frogs also place eggs directly in streams (e.g., *Smilisca sordida;* Malone 2004).

In at least some lineages, stream breeding appears to be derived from ancestral pond-breeding habits. For example, two subfamilies of mantellid frogs in Madagascar, Mantellinae and Boophinae, include extensive radiations of stream-breeding species. In both groups, stream breeders appear to form monophyletic groups that probably are derived from pond-breeding ancestors. In the genus *Boophis,* stream breeding also seems to have resulted in higher rates of speciation than pond breeding, perhaps because of lower rates of movement in stream breeders and a greater tendency for populations to become isolated from one another (Vences et al. 2002). One species, *B. occidentalis,* lays relatively large eggs attached in a single layer to rocks. Their larvae exhibit typical morphological adapations for stream life (see also chapter 12). On the other hand, this species often forms relatively large breeding aggregations and lays large clutches, features that are more characteristic of pond-breeding members of the genus (F. Andreone et al. 2002).

Aquatic Eggs in Constructed Nests, Chambers, or Basins (Modes 3, 4, and 5)

The habit of laying aquatic eggs in basins or nests constructed by a parent has evolved independently several times in the family Hylidae and probably several times in the family Ranidae as well. Presumably the main advantage to laying eggs in a nest is to remove the eggs from habitats where aquatic predators are abundant, or to avoid periodic flooding events that could sweep away eggs.

Eggs Laid in Constructed Subaquatic Nests (Mode 3)

Several stream-breeding hylodine leptodactylid frogs from the Atlantic rainforest of Brazil place their eggs in chambers constructed by the males, a reproductive mode with some similarities to that of Mode 2 species that attach their eggs to natural cavities under rocks in streams. In *Crossodactylus gaudichaudii,* males call along the edges of streams and excavate nesting chambers under submerged rocks, apparently located within defended territories (Weygoldt and Carvalho e Silva 1992). In *Hylodes asper,* males use a complex array of acoustic and visual signals, including foot-waving displays, to advertise their territories and attract females. Males periodically dive underwater to excavate nesting chambers by pushing sand between submerged rocks, and mated pairs lay their eggs in these locations (Haddad and Giaretta 1999).

Nest-Building Hylids

In several species of Neotropical gladiator frogs (*H. boans, H. circumdata, H. faber, H. pardalis, H. rosenbergi,* and *H. wavrini*), males construct large basins beside streams (Mode 4), and females are then attracted to the nest by the male's calls. In *H. boans,* however, males call mostly from trees rather than from their nests (Magnusson et al. 1999). Eggs are laid in a surface film, probably an adaptation to low oxygen levels in the nests (Breder 1946; Lutz 1960a, b, 1973; Crump 1974; Lamotte and Lescure 1977; Kluge 1981; Martins and Haddad 1988; M. Martins 1993a, b; fig. 10.4 E).

In some regions, nest building appears to be a facultative response to habitats that lack suitable natural pools for egg laying, but nest building is abandoned if oviposition sites are plentiful. In Brazil, Caldwell (1992) found that *Hyla boans* breeding in sandy areas constructed nests, while those breeding along rocky streams usually deposited their eggs in natural rock pools. In *H. wavrini,* an Amazonian species that until recently was considered conspecific with *H. boans* (Hoogmoed 1990b), males make nests by pushing debris out of natural water-filled depressions, but have not been observed making elaborate nests like those of *H. boans* (Martins and Moreira 1991; Martins 1993a). Breder (1946) reported that males of *Hyla rosenbergi* in Panama sometimes did not build complete mud nests, but instead constructed mud walls to dam up natural rock pools. In Costa Rica, this species used cattle footprints and other small puddles as nests, with less than a third of all nests being constructed by males (Höbel 1999b, 2000). *Hyla crepitans,* another member of this group, usually breeds in ponds, flooded areas, and stream pools without building nests. However, Caldwell (1992) found a single nest constructed by this species on a sandy spit in a stream in Venezuela, even though most of the frogs at this locality did not build nests. At other sites, this species is reported to make use of water-filled depressions (Martins 1993a). *Hyla faber* in Brazil normally constructs mud nests, but during periods of high water, they sometimes deposits eggs as surface films directly in ponds (Haddad and Sawaya 2000).

A large treefrog from Hispaniola, *Osteopilus vastus,* lays eggs in shallow basins at the edges of mountain torrents. Eggs are laid in clumps attached to rocks at the bottom of the nest. Whereas the newly hatched tadpoles of *H. rosenbergi* and *H. faber* have large external gills, presumably an adaptation to very low oxygen levels in their nests (Kluge 1981; Martins 1993a), those of *O. vastus* lack these gills and complete their development in well-oxygenated streams (Noble 1927). An Australian hylid in the *Litoria lesueuri* complex lays its eggs in nests at the edges of streams, but nest construction has not been observed. Eggs are laid in a globular cluster that rests on the bottom of the nest (S. Richards and Alford 1992; S. Richards 1993). Levels of dissolved oxygen in nests of this species were considerably higher than those reported for *H. rosenbergi* in Panama (Kluge 1981).

Several Brazilian treefrogs have similar breeding habits, but show some plasticity in the placement of eggs. For example, a clutch of eggs of *Hyla luctuosa* was found in a water-filled depression at the edge of a pond, while other eggs were found in a pond (Pombal and Haddad 1993). *Hyla ibitipoca* males have been observed calling in natural cavities formed by tree roots at the edges of streams (Caramaschi and Feio 1990). Martins (1993a) suggested that the use of these types of natural, water-filled cavities gave rise to the more elaborate nest-building behavior of species such as *H. boans, H. faber,* and *H. rosenbergi.* A thorough phylogenetic analysis of the entire complex is needed before the direction of evolution in reproductive modes will be clear, but unfortunately, even the species-level taxonomy of these frogs is poorly understood at this point (Kluge 1979; Cardoso 1983; Hoogmoed 1990b).

Other Brazilian hylids have somewhat similar reproductive modes, except that aquatic eggs are placed in subterranean nests that are subsequently flooded, with tadpoles completing development in temporary ponds or streams (Mode 5). These frogs (*Hyla cavicola, H. leucopygia,* other members of the *H. albosignata* group, and *Aplastodiscus perviridis*) lay aquatic eggs in burrows constructed at the edges of temporary ponds or streams (Cruz and Peixoto 1984; Haddad and Sazima 1992; Haddad and Sawaya 2000; Haddad, Faivovich, and Garcia 2005; Haddad and Prado 2005). Because the eggs of these species are laid in a covered chamber, they generally lack pigmentation (fig. 10.4 F), in contrast to eggs of hylids that construct exposed nests. After the nests of *H. leucopygia* are flooded, their roofs often collapse, and the resulting basins sometimes are used as oviposition sites by *H. luctuosa* (Haddad and Sawaya 2000).

In Costa Rica, hylids in the genus *Smilisca* exhibit a variety of reproductive modes and also exhibit some plasticity in oviposition behavior (Malone 2004). *Smilisca puma* has the most generalized mode, placing eggs in temporary ponds (Mode 1), as do other members of the genus elsewhere in Central America. These frogs tend to be explosive breeders that use temporary ponds formed by heavy rains. In contrast, *Smilisca sila* and *S. sordida* are associated with forest streams, and place their eggs in constructed nests near the water (Mode 4). Both also use natural stream pools for oviposition. *Smilisca sordida* exhibits unusually plastic oviposition behavior. They sometimes attach eggs to the substrate, bury them beneath the substrate, or deposit them in a floating film on the water's surface. This species was most likely to place constructed basins on sandbars and small islands in streams, rather than on streambanks. Basin construction was most common during the middle of the breeding season, whereas eggs were sometimes placed in natural pools at the beginning of the breeding season.

Nest-Building Ranids

Nest building also has been reported in a number of ranid frogs from Asia. In two species, *Rana holsti* and *R. subaspera* (both sometimes placed in the genus *Babina*), eggs are laid as a surface film in natural basins or mud nests constructed at the edge of a stream (Utsunomiya and Utsunomiya 1983; Utsunomiya et al. 1983). Males and females sometimes work together to build a nest of gravel along a stream in fanged frogs from Borneo (*Limnonectes leporinus*) and Vietnam (*L. blythii*). The eggs are then mixed with sand or gravel in the bottom of the nest and tadpoles develop in the stream (Dring 1979; Emerson 1992; Orlov 1997).

Oviposition in Very Small Bodies of Water (Modes 6, 7, and 8)

Frogs with reproductive Mode 6 lay eggs in very small bodies of water such as treeholes, the axils of aerial plants, and water-filled seedpods and fruit capsules (phytotelmata; Lehtinen, Lannoo, and Wassersug 2004). The eggs hatch into feeding tadpoles that subsist on organic material that accumulates in their tiny pools. Mode 6 represents a somewhat artificial grouping of unrelated frogs, with repeated independent evolution of superficially similar reproductive modes that actually encompass a wide variety of oviposition sites. A bufonid from East Africa, *Mertensophryne micranotus,* breeds in crevices in rotten trees (Grandison 1980). A toad from Brazil, *Bufo castaneoticus,* lays its eggs in water-filled, woody fruit capsules of the Brazil nut tree (*Bertholletia excelsa,* Lethycidaceae) after rodents have removed the seeds from the capsules. The tadpoles subsist on detritus that collects in the water (Caldwell 1991, 1993; Caldwell and Araújo 2004).

The Jamaican hylid frog *Calyptahyla crucialis* has been observed calling from hollow trees, but it appears to breed mainly in bromeliads. All of the other Jamaican hylids (*Hyla wilderi, H. marianae,* and *Osteopilus brunneus*) also are bromeliad-breeders (Dunn 1926a; Lynn and Grant 1940; A. Schwartz and Fowler 1973; Garrick, Sutton, and Lang 1985; Hedges 1987). Other Neotropical hylids that breed in bromeliads include *Anotheca spinosa* and members of the *Hyla bromeliacia* group from Central America (Duellman 1970) and the South American genus *Phyllodytes* (Bokermann 1966a; Weygoldt 1981a; Peixoto, Caramaschi, and Freire 2003; Lehtinen, Lannoo, and Wassersug 2004). At least some members of the South American genus *Osteocephalus* breed both in bromeliads and the water-filled leaf axils of forest palms (Zimmerman and Bogart 1988; Hödl 1990b). The tadpoles of some bromeliad-breeders, such as *Phyllodytes luteolus,* are generalist feeders on organic material, and have relatively unspecialized mouthparts (Weygoldt 1981a). The tadpole of *Phyllodytes gyrinaethes* has a bizarre enlarged oral disc, and older tadpoles eat frog eggs (Peixoto, Caramaschi, and Freire 2003). Other bromeliad breeders, such as *Osteopilus brunneus* and *Osteocephalus oophagus,* have reduced mouthparts, and subsist partly or entirely on the eggs of their own or other species of frogs (Lannoo, Townsend, and Wassersug 1987; Jungfer and Schiesari 1995; see also chapter 12).

A large hylid from lowland Amazonian forests, *Phrynohyas resinifictrix,* breeds in stagnant water in tree holes. Some of these are the abandoned nests of bees and are lined with resin, leading Goeldi (1907) to incorrectly conclude that these frogs actually lined their nests with gum (Lamotte and Lescure 1977; Zimmermann and Hödl 1983; Hödl 1990b, 1991b). Tadpoles of this species often eat conspecific eggs, but females apparently do not deliberately feed eggs to tadpoles, as occurs in some species that breed in phytotelmata (Schiesari, Gordo, and Hödl 2003). Tadpoles also lack the specialized mouth morphology typical of obligate egg-eating species (Schiesari, Grillitsch, and Vogl 1996).

Several frogs in the family Mantellidae from Madagascar also breed in phytotelmata. One species of *Mantella* breeds in bamboo stumps or treeholes (Heying 2001, 2004), whereas at least six species of *Mantidactylus* breed in *Pandanus* plants (Lehtinen, Richards, and Nussbaum 2004). All of these appear to be descended from pond-breeding ancestors, and there has been one apparent reversal to pond breeding within the clade of phytotelm-breeding *Mantidactylus.* A small West African frog, *Phrynobatrachus guineensis,* breeds in treeholes, water-filled fruit capsules, and empty snail shells (Rödel 1998; Rödel, Frohschammer, and Linsenmair 2004). Most members of this genus breed in temporary ponds, so it seems likely that *P. guineensis* had a pond-breeding ancestor. Males of a small microhylid frog from Borneo, *Metaphrynella sundana,* call from small pools in tree holes, but the placement of eggs has not been described (Inger and Stuebing 1997). Most species in another genus of Asian microhylids, *Ramanella,* breed in water-filled treeholes or buttress roots, laying eggs either in the water (Mode 6) or just above the water (Mode 26) (Manamendra-Arachchi and Pethiyagoda 2001; Krishna, Krishna, and Vijayalaxmi 2004), although some species use temporary rain pools (Dutta, Sushree, and Mohanthi-Hejmadi 1990–1991).

Because food tends to be in short supply in small bodies of water such as those found in bromeliads and tree holes, some frogs that breed in such sites provision their eggs with sufficient yolk to allow their aquatic tadpoles to develop without feeding (Mode 8). These endotrophic tadpoles typically lack mouthparts that would allow them to feed. This unusual reproductive mode is found in three genera of microhylids from Madagascar (*Anodonthyla, Platypelis, Plethodonthyla;* Blommers-Schlösser 1975a). It also has been reported in a Neotropical microhylid, *Syncope antenori,* which breeds in terrestrial or arboreal bromeliads (Hödl 1990b; Krügel and Richter 1995), and two Brazilian bufonids, *Dendrophrynicus brevipollicatus* and *Frostius pernambucensis* (Carvalho 1949; Lamotte and Lescure 1977; Lehtinen, Lannoo, and Wassersug 2004).

There also are frogs that breed in small water-filled depressions on the ground and have nonfeeding aquatic tadpoles (Mode 7). Leptodactylid frogs in the genus *Eupsophus* from southern Chile lay their eggs in cold water that collects in cavities under moss, logs, or rocks; the nonfeeding tadpoles complete development in these small pools (Formas and Pugin 1978a, b; Formas and Vera 1980; Formas 1989). A very similar reproductive mode is found in the most aquatic species of *Leiopelma* from New Zealand, *L. hochstetteri* (Archey 1922, 1935; N. Stephenson and Thomas 1945; Turbott 1949; N. Stephenson 1951, 1955; E. Stephenson and Stephenson 1957; B. Bell 1978, 1982, 1985; B. Bell and Wassersug 2003). The larvae complete most of their development in the eggs and do not feed after hatching. Indeed, they have lost all vestiges of feeding structures typically found in most free-living tadpoles and lack functional gills and lungs as well. Nonfeeding tadpoles in other species usually retain more indications of feeding structures than do those of *Leiopelma.* The tadpoles of *L. hochstetteri* do retain other morphological features typical of tadpoles, including a muscular tail that enables them to swim. The life history of this species clearly appears to be derived from one with a free-living tadpole stage, perhaps resembling the stream tadpoles found in other families of frogs (B. Bell and Wassersug 2003).

The golden toad of Costa Rica (*Bufo periglenes*), now thought to be extinct, bred in small pools on the forest floor and had tadpoles that could survive to metamorphosis without feeding, although they could feed if food was available (Crump 1989b). An Australian myobatrachid, *Crinia georgiana,* breeds in very shallow seeps where the tadpoles remain until metamorphosis. As in *B. periglenes,* they are capable of feeding, but their large yolk reserves allow them to reach metamorphosis without feeding (Doughty 2002).

Most bufonids in the genus *Pelophryne,* from high-altitude forests in the Philippines, have nonfeeding tadpoles that develop in water-filled depressions on the ground (Inger 1960; Duellman and Trueb 1986). However, the eggs and nonfeeding tadpoles of *Pelophryne brevipes* have been found three to five meters above the ground in leaf axils of screw pines (*Pandanus;* Alcala and Brown 1982) and in tree holes (Denzer 1994), a mode of reproduction closer to Mode 8 than Mode 7. Indeed, these two categories tend to grade into one another. For example, tadpoles of *Kalophrynus pleurostigma,* a microhylid from Borneo, have been found not only in water-filled holes in logs and in pitcher plants, but also in a forest-floor pool and a burrow in a stream bank (Inger 1985).

Oviposition above Water-Filled Cavities (Mode 26)

A number of arboreal frogs attach their eggs to the walls of water-filled tree holes, buttress tanks, or cavities in plants, and their tadpoles drop into the water and feed on organic material or frog eggs (Mode 26). This reproductive mode tends to grade into Mode 6 (eggs placed in the water in tree holes or bromeliads) and Modes 24 and 25 (oviposition on vegetation above water). For example, the Asian rhacophorid *Chirixalus eiffingeri* usually places its eggs on the walls of water-filled tree holes, leaf axils, or bamboo stumps. Some eggs are placed in the water, but are soon consumed, because tadpoles of this species feed mainly on conspecific eggs that are provided by the female (Kuramoto 1973; Ueda 1986; Kuramoto and Wang 1987); see also chapter 11. Wassersug, Frogner, and Inger (1981) described tadpoles of a treehole-breeding rhacophorid from Thailand, identified as a species of *Philautus.* They also are mainly egg-eaters that probably are fed by the female. Whether fertilized eggs are normally placed in the water or on the walls of the tree hole is unknown. Other Asian rhacophorids in the genera *Theloderma* and *Nyctixalus* also are thought to have Mode 26 reproduction, although egg-laying sites are not known for all species (C. Liu 1950; Inger 1966; Wassersug, Frogner, and Inger 1981; W. Brown and Alcala 1983). Most phyllomedusine hylid frogs lay arboreal eggs on vegetation above ponds or streams (Modes 24 and 25), but *Agalychnis craspedopus* in Peru placed eggs on the sides of tree buttresses above small pools, a mode of reproduction closer to Mode 26 (Block et al. 2003).

The African hyperoliid *Acanthixalus spinosus* lays its eggs on the walls of large water-filled tree holes, where the tadpoles apparently feed on algae (Perret 1962; Lamotte and Lescure 1977; Schiøtz 1999). A second recently described species, *A. sonjae,* has similar breeding habitats, but the tadpoles will eat other species of tadpoles as well as vegetation (Rödel et al. 2003). Two other hyperoliid frogs, *Hyperolius acutirostris* and *H. mosaicus,* also are treehole breeders that deposit eggs just above the water (Schiøtz 1999). Tree hole breeding also has been reported in an African petropedetid frog, *Phrynobatrachus guineensis,* but other members of this genus breed in temporary ponds (Rödel 1998). African microhylids of the genus *Hoplophryne* lay their eggs on the walls of hollow bamboo stems and rolled banana leaves; their tadpoles subsist at least in part on conspecific eggs (Noble 1929a). A microhylid from India, *Ramanella montana,* lays eggs on the walls of tree holes just above the water line, or on floating dead leaves in the water (Krishna, Krishna, and Vijayalaxmi 2004), so reproduction in this species grades between Modes 6 and 26.

Oviposition in Bubble or Foam Nests (Modes 10–14, 29–33)

The habit of laying eggs in a frothy or foamy nest on the water's surface (Modes 10, 11, and 12), in water-filled basins (Mode 13), in phytotelmata (Mode 14), on the ground (Mode 28), in burrows (Modes 29–32), or in trees (Mode 33) has evolved independently in several major clades of frogs. Duellman and Trueb (1986) and Haddad and Prado (2005) placed foam-nesting frogs in several different reproductive modes, but in many cases, these modes tend to grade into one another. For example, some frogs lay eggs in foam nests in both still (Mode 11) and slowly moving water (Mode 12), and foam nesting in ponds (Mode 11) tends to grade into foam nesting in basins or burrows (Modes 29–32). Some frogs lay eggs both on the surface or at the edge of ponds (Mode 11) and in trees (Mode 33).

Bubble Nest on Water's Surface (Mode 10)

An apparently unique mode of reproduction has been described in the Neotropical microhylid frog *Chiasmocleis leucosticta* (Haddad and Hödl 1997). Amplexed pairs laid eggs on the surface in small groups, with a total of up to 70 bouts of oviposition. After deposting the eggs, the male and female submerged together and released air bubbles from their nostrils from underneath the floating eggs, creating a frothy bubble nest floating on the water's surface. This is the only known example of an amphibian nest being constructed by exhaling air. Presumably the bubbles help to hold the eggs at the water's surface, and perhaps provide supplementary oxygen in warm water. It is somewhat reminiscent of the bubble nesting of a variety of tropical fishes that live in poorly oxygenated water, although in those cases, the males construct their bubble nests and defend them prior to ovipostion (Hostache and Mol 1998; Jaroensutasinee and Jaroensutasinee 2001). The genus *Chiasmocleis* includes 18 species, all of which breed in warm, poorly oxygenated pools, but the frequency of bubble nesting in the genus is not known.

Foam Nesting in Nonarboreal Frogs (Modes 11–14, 28–32)

Foam-nesting is characteristic of most frogs in the subfamily Leptodactylinae, including *Leptodactylus, Physalaemus, Pleurodema, Lithodytes, Edalorhina,* and *Vanzolinius* (Fernandez and Fernandez 1921; Eisentraut 1932; Breder 1946; Cei 1949a, 1980; Gallardo 1958; Heyer 1969; Rivero and Esteves 1969; Lescure 1973, 1979; M. Crump 1974; Philibosian et al. 1974; Vaz-Ferreira and Gehrau 1975; Heyer and Rand 1977; Lamotte and Lescure 1977; Cardoso 1981a; Lescure and Letellier 1983; Regös and Schlüter 1984; M. Ryan 1985b; Hödl 1986, 1990a, b, 1992; M. Martins 1988; Duellman and Morales 1990; Schlüter 1990). It also has been reported in one Neotropical hylid species (Haddad, Pombal, and Gordo 1990).

Foam nests of leptodactylids are derived from mucus secretions produced by the female as she lays her eggs (fig. 10.5). These are whipped into foam when the male kicks his legs (fig. 10.5 A). Hödl (1990a) provided a detailed description of foam nest construction in *Physalaemus ephippifer.* Construction of a complete nest takes about half an hour to an hour and involves an average of 85 individual bouts of foam beating by the male. Each bout of activity is initiated by a female laying a small number of eggs, which are then beaten into the foam by rotating movements of the male's hind legs. Individual bouts of fertilization and foam beating are very short, averaging only three to four seconds, with intervals of 20 to 30 seconds between bouts.

In *Pleurodema, Physalaemus,* and *Edalorhina,* foam nests are usually placed on the surface of the water in shallow, temporary pools (Mode 11). Often the foam nests are attached to bits of vegetation, dead leaves, or mud at the edge of the pools (Sexton and Ortleb 1966). In some species, pairs attach their eggs to previously laid foam nests, resulting in large communal egg masses of several hundred clutches (Hödl 1992; fig. 10.5 B). The smaller frogs in this group, such as *Physalaemus* and *Edalorhina,* exhibit considerable flexibility in choice of oviposition sites. They use almost anything from moderately large temporary ponds to roadside ditches, tire tracks, water-filled animal footprints on the forest floor, water-filled seed pods, and pools between tree roots (Rand 1983; Hödl 1986; Tárano 1998; Dillon and Fiaño 2000; D. Marsh and Borrell 2001). Schlüter (1990) even reported observations of *Edalorhina perezi* building a foam nest in the axil of a palm tree, and tadpoles were found in a water-filled depression on a tree trunk. More typical oviposition sites for this species are water-filled holes left by the roots of large fallen trees (P. Murphy 2003). Another member of this genus, *Physalaemus signifer,* also exhibits considerable plasticity in reproductive behavior, with foam

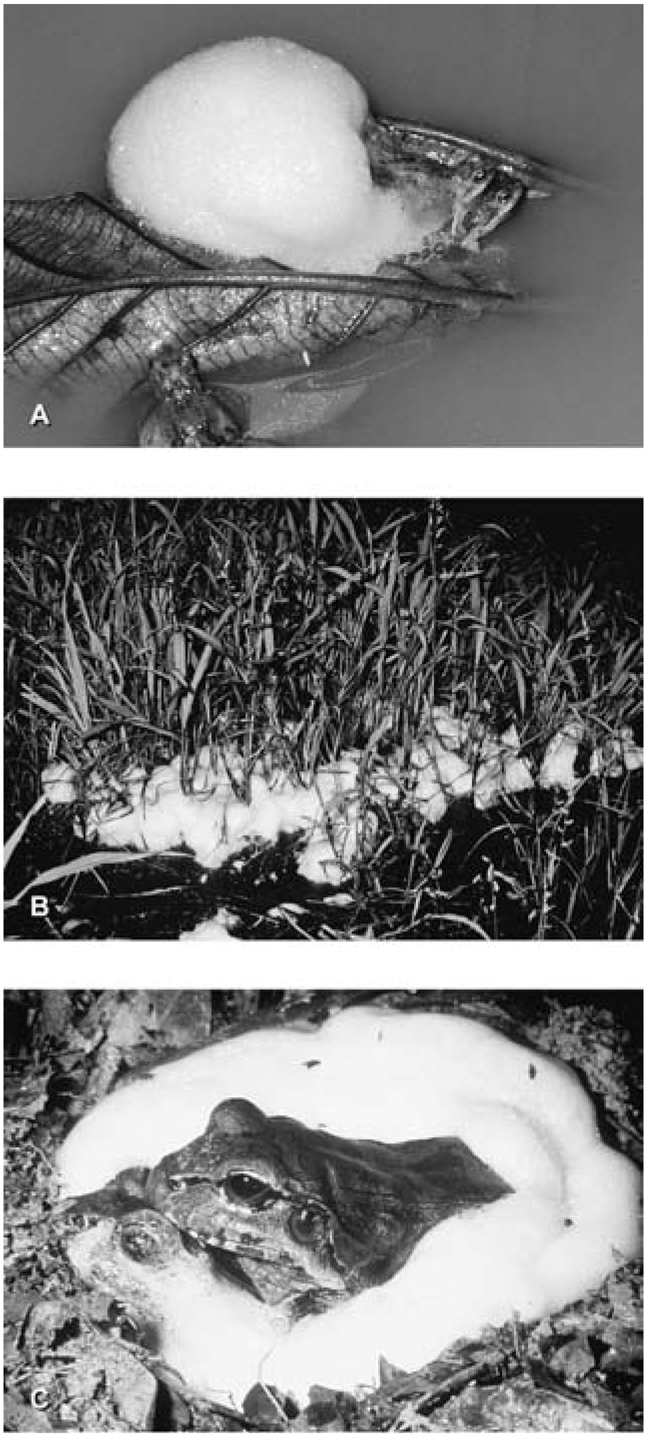

Fig. 10.5. Foam nesting in leptodactylid frogs. (A) Male and female of *Physalaemus pustulosus* laying eggs attached to a floating leaf. (B) Communal nest composed of the egg masses of many different pairs of *P. pustulosus.* (C) Pair of *Leptodactylus knudseni* in amplexus. nests being placed in shallow ponds, on moist ground, or in water accumulated in the axils of terrestrial bromeliads; tadpoles develop in water once the area is flooded (Haddad and Pombal 1998). The plasticity of behavior in this species led Haddad and Prado (2005) to place this species in three distinct reproductive modes (Modes 11, 14, and 28), but all of these clearly are variations on the same mode of reproduction. Several closely related species also place foam nests on the ground or in terrestrial bromeliads and may show similar plasticity in behavior.

Most members of the *Leptodactylus ocellatus* and *L. melanonotus* species groups deposit eggs in foam nests floating on the water's surface or at the edge of ponds (Mode 11), whereas members of the *L. pentadactylus* group deposit their large foam nests in open cavities at the edges of ponds (Mode 13; fig. 10.5 C; Breder 1946; Heyer 1969; Rivero and Esteves 1969; Hödl 1990b; Prado, Uetanabaro, and Lopes 2000). In one Brazilian member of the *L. melanonotus* group, *L. podicipinus,* males construct water-filled basins near small ponds. The frogs call from the basins, which often are covered by a roof of leaves, and attract females that lay foamy egg clutches in the basins (Prado, Uetanabaro, and Haddad 2002).

In frogs of the *Leptodactylus fuscus* group, the male builds an underground burrow in saturated soil and leads the female to the nest site, where a foam nest is produced (Heyer 1969; Lescure 1973; Martins 1988; Perotti 1997). Tadpoles remain in the nest until it is flooded, and complete development by feeding in the water (Mode 30). *Leptodactylus mystaceus,* another member of this group, places its foam nests in open mud basins under logs or other cover (Caldwell and Lopez 1989). In one species, *L. bufonius,* foam nests are constructed in an open burrow at the margin of a pond, and the nest is then covered over with soil after eggs are laid (Pisanó 1962; Philibosian et al. 1974; M. Crump 1995a; Reading and Jofré 2003). This type of nest may help protect the developing embryos from extreme temperatures in the hot, dry habitat of this species.

In *Leptodactylus fallax,* which is a member of the *L. pentadactylus* group, tadpoles remain in a foam nest in an underground burrow throughout development. Most authors have stated that the tadpoles do not feed (Lescure and Letellier 1983; Duellman and Trueb 1986) and this frog has been placed in a different reproductive mode (Mode 32) than other leptodactylids. S. Davis et al. (2000) reported that even relatively young tadpoles of this species appeared to lack substantial yolk reserves, but they were not able to determine whether the tadpoles took in supplemental food. Gibson and Buley (2004) subsequently reported that females of this species actually feed tadpoles by laying unfertilized eggs in the foam nest, a form of parental care previously known mostly for species that lay eggs in bromeliads or tree holes (see chapter 11).

A similar mode of reproduction has been reported for the genus *Adenomera,* although there is no evidence that females feed the tadpoles. These frogs typically place their foam nests in open terrestrial chambers in which the tadpoles develop without feeding (Heyer and Silverstone 1969; Lescure 1979; Heyer et al. 1990; Kokubum and Giaretta 2005). In a population of this genus in Bolivia, however, females laid eggs at the edges of temporary ponds, and tadpoles completed their development in the ponds (De la Riva 1995), and this also may be true for some other species in the genus (Kokubum and Giaretta 2005). Members of this genus therefore exhibit both Mode 11 and Mode 32 reproduction, but whether this represents species-specific differences in mode of development, or perhaps hidden taxonomic diversity within the genus, is not yet clear. Microhylid frogs of the genus *Stumpffia* from Madagascar lay eggs in foam nests in leaf litter and apparently have nonfeeding tadpoles, so this represents a completely independent evolution of this type of reproduction in another family (Glaw and Vences 1994).

Australian myobatrachids in the subfamily Limnodynastinae exhibit a striking convergence with leptodactyline frogs in their reproductive biology (A. Martin 1970). Most species of *Limnodynastes,* as well as *Adelotus* and *Lechriodus,* build foam nests on the surface of shallow pools (fig. 10.6 A, B), where tadpoles complete their development (Mode 11; Main, Littlejohn, and Lee 1959; J. Moore 1961; A. Martin 1967; Tyler 1985b). However, the way in which the nest is constructed is completely different from that seen in leptodactylines, and really should be considered a distinct mode of reproduction. As the eggs are laid, the female beats the water in front of her with flattened, paddle-shaped structures on her front toes (fig. 10.6 C). This causes bubbles to rise underneath the female, where they combine with mucus secretions produced by the female to form a mass of foam that traps the eggs (H. Parker 1940; A. Martin 1967; Tyler and Davies 1979). In some populations of *Limnodynastes tasmaniensis* in southern Australia, females do not build foam nests, but instead produce a surface film of eggs. Females in these populations lack the enlarged flanges on the front feet (J. Roberts and Seymour 1989). Some species of *Limnodynastes* are flexible in their choice of oviposition sites. For example, *L. dorsalis* is reported to place foam nests in standing water (Mode 11), flowing water (Mode 12), or even in burrows at the edges of streams (Mode 31; A. Martin 1967).

The burrowing frog *Megistolotis lignarius,* which lives around boulder fields and rocky ledges near small streams in northern Australia (Cogger 2000), also is a foam-nest builder, but it places nests in pools that become flowing streams after heavy rains (Mode 12). Females lack flanges on the front toes, and the mode of nest construction is un-

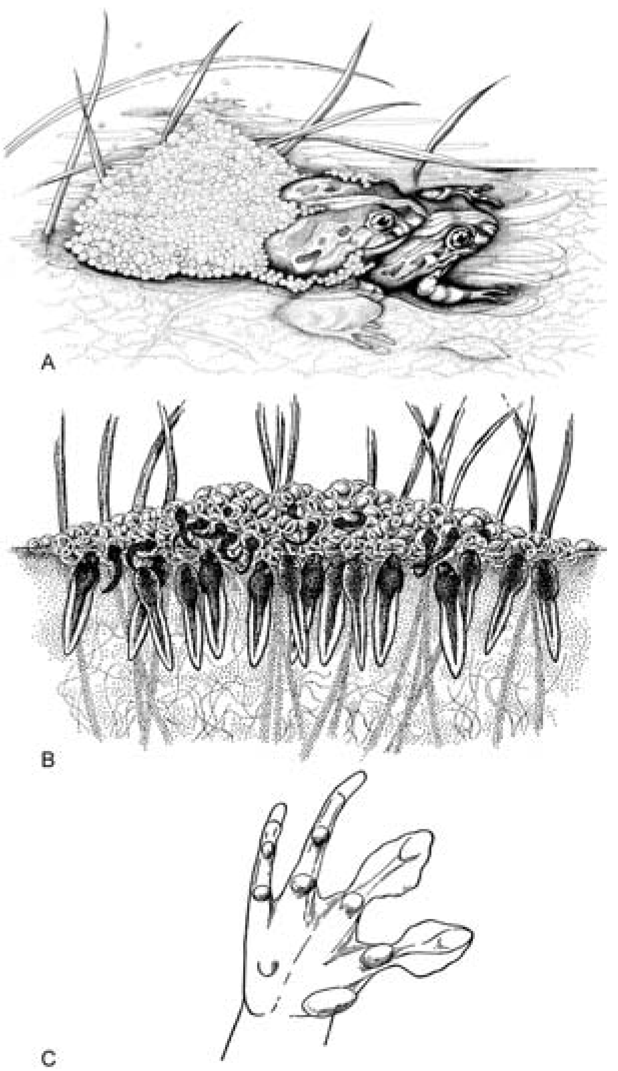

Fig. 10.6. Foam nests of limnodynastine frogs. (A) Pair of *Limnodynastes ornatus* laying eggs in a foam nest. (B) Hatched tadpoles suspended from the foam nest of *Limnodynastes tasmaniensis.* (C) Flanges on the front feet of the female of *Limnodynastes.* (A, B) from Littlejohn et al. (1993), (C) from Noble (1931).

known. Another group of foam-nesters that lacks enlarged front toes is the genus *Heleioporus*. These are frogs that usually place their eggs in burrows at the edge of standing water or in places where they are flooded after eggs are laid, allowing tadpoles to complete development in the water (Mode 31; A. K. Lee 1967; A. Martin 1967). However, some members of the genus place their foam nests in standing water (Mode 11; M. Tyler 1985b). Frogs in the limnodynastine genus *Philoria* produce foam nests that are placed in terrestrial situations such as moist depressions or sphagnum moss. The tadpoles develop completely in the nest and apparently do not feed (Mode 32; J. Moore 1961; Littlejohn 1963; A. Martin 1967; Tyler 1985b).

Construction of aquatic foam nests is characteristic mainly of species that breed in warm, poorly-oxygenated water, and many foam-nesting species utilize temporary ponds or very small bodies of water such as animal footprints. Several benefits of foam nesting have been proposed, and these are not necessarily mutually exclusive. Some authors have suggested that placing eggs in a foam nest reduces exposure to aquatic predators (A. Martin 1967; Heyer 1969; M. Ryan 1985b), while terrestrial or flying insects become entangled in the sticky foam (Villa, McDiarmid, and Gallardo 1982). Presumably species that place foam nests in burrows or depressions away from standing water would derive the greatest benefit. Nevertheless, foam nests are subject to predation by tadpoles, aquatic insects, and a variety of terrestrial arthropods (Villa, McDiarmid, and Gallardo 1982; M. Ryan 1985b; Downie 1988). Unfortunately, there are no quantitative estimates of egg survivorship in species that build foam nests and those in the same habitat that do not.

Another common suggestion is that foam nests protect the eggs from desiccation when temporary pools in which they are laid dry up, keeping the eggs viable until the next rain (Breder 1946; A. Martin 1967; Heyer 1969; Salthe and Mecham 1974; Duellman and Trueb 1986; Hödl 1986; Duellman 1989a). Downie (1988) found that some eggs in foam nests of *Physalaemus pustulosus* could survive for two or three days if stranded, although those close to the surface died quickly under dry conditions. This is not much better than the survivorship of *Rana sylvatica* eggs left out of the water in the laboratory, but the latter were not exposed to the high temperatures experienced by *Physalaemus* eggs in the field (Forester and Lykens 1988). However, aquatic foam nests probably provide enough protection to get the eggs through brief dry periods during the rainy season, an effect that probably is enhanced by grouping the eggs together in large communal masses (M. Ryan 1985b). The limited protection from desiccation provided by foam nests presumably preadapts foam-nesting species to move their eggs out of the water altogether, especially if they are placed in a relatively moist burrow (Heyer 1969). Lynch (1971) suggested that foam-nesting in leptodactylines evolved during a period of increasingly dry climate, while Heyer (1975) argued that foam-nesting originated in wet forests, but preadapted leptodactylines for later invasion of drier savanna habitats. In some species that produce foam nests in burrows, hatched tadpoles generate their own foam from mucus mixed with water from the substrate. This enables the tadpoles to survive for a number of days in a state of developmental arrest before the burrow floods and the tadpoles move into a pond (Downie 1984, 1989, 1994; Caldwell and Lopez 1989; Downie and Weir 1997; Downie and Smith 2003).

Other authors have suggested that foam nests provide some thermal advantage to the eggs, but results of several studies are inconsistent. Gorzula (1977) reported that temperatures at the center of *Physalaemus* foam nests were considerably cooler than the surrounding water on a sunny day and suggested that the foam reflects solar radiation and helps to prevent the eggs from overheating. In contrast, Dobkin and Gettinger (1985) found that *Physalaemus* foam nests reflected relatively little short-wave radiation and warmed more rapidly than the surrounding water, sometimes exceeding air temperatures by 4–8° C. They interpreted this as an advantage for species breeding in temporary pools, where rapid embryological development would be favored. Downie (1988) found little difference between nest and water temperatures in the same species. He found that foam nests usually were slightly cooler than the surrounding air, but still rose as high as 35° C without any apparent damage to the eggs. Hence, the evidence that foam nests provide any heating or cooling advantage to the eggs is weak.

A fourth possibility that seems more promising is that foam nests ensure a supply of oxygen by surrounding eggs with air-filled bubbles and elevating them above the warm, hypoxic water typical of their breeding sites (Downie 1988; Seymour 1999). This has not been thoroughly tested for New World species. However, Seymour and Roberts (1991) measured oxygen profiles of foamy and nonfoamy egg masses of an Australian frog, *Limnodynastes tasmaniensis.* The structure of the foam nest in this species, and presumably in other limnodynastine frogs, is different from that of leptodactyline frogs. In the latter, most of the eggs are held above the water's surface by the foam for most or all of development. In contrast, those of *Limnodynastes* were mostly submerged in the water, suspended under a thin layer of foam floating on the surface. Oxygen levels in the foam and near the surface, where the majority of eggs were concentrated, remained relatively high throughout development, but eggs that were a centimeter or more below the surface experienced much lower levels of oxygen, especially late in development. Nonfoamy egg masses suspended near the surface showed a similar oxygen profile, but with an even steeper decline in oxygen levels with increasing depth. When either type of egg mass was allowed to sink to the bottom, at least part of the mass became anoxic and many eggs died. The foamy egg masses of this species apparently serve mainly to keep the eggs suspended near the surface, and therefore function much like the surface films of other warm-water breeders. In fact, at high temperatures, the foam nests of limnodynastine frogs tend to break up into surface films (Tyler 1985b; Seymour and Roberts 1991). This has not been reported for leptodactyline frogs, although their nests disintegrate in heavy rains (M. Ryan 1985b).

Foam Nesting in Arboreal Frogs (Mode 33)

Some rhacophorid and hyperoliid frogs build foam nests, often in trees, but sometimes in the water or on the ground. African treefrogs in the genus *Chiromantis* live in a variety of habitats, from moist forests to savannas. They breed in the rainy season, sometimes quite explosively after heavy rains. *Chiromantis xerampelina* and *C. rufescens* typically deposit their eggs in foam nests overhanging temporary pools or slow-moving rivers and streams (fig. 10.7 A), where the tadpoles complete their development (Wager 1926, 1965; Lamotte and Perrett 1963a; Coe 1974; Jennions, Backwell, and Passmore 1992). *Chiromantis petersi,* a savanna species, often breeds in areas with very few trees, and attaches its eggs to almost any suitable object, including grass stems, logs, tree trunks, rocks, or branches of shrubs (Coe 1974). The foam nest is constructed by rapid leg movements of both the male and female, and it is not uncommon for several males to participate in building a nest with a single female (Coe 1967, 1974; Jennions, Backwell, and Passmore 1992; see chapter 8). In *C. xerampelina,* females lay eggs in bouts interrupted by periodic trips to the water to rehydrate. When a female resumes her egg laying, she does not necessarily mate with the same male or group of males. Females of this species also have been observed returning to nests on the night after egg-laying and adding an additional layer of foam (Jennions 1992). The nests of these frogs can survive prolonged exposure to hot, dry conditions. They develop a hard crust on the outside, but remain moist on the inside. The tendency of these frogs to deposit eggs in large communal nests probably helps to reduce water loss as well. The hardening of the surface of the egg mass actually increases diffusion of oxygen into the egg mass, but early in development, air trapped in the bubbles of foam provide most of the oxygen needed by the developing embryos (Seymour and Loveridge 1994; see also chapter 4).

Foam nesting also is characteristic of Asian rhacophorids in the genera *Rhacophorus* (fig. 10.7 B), *Polypedates,* and some species of *Chirixalus* (fig. 10.7 C, D). These frogs exhibit considerable plasticity in placement of foam nests, especially in disturbed habitats. Some species place their eggs in trees over water. Others place them on almost any sort of substrate, including vegetation at the surface of ponds, mud banks, or man-made walls. Eggs also are laid under stones or logs, in ditches, floating on the surface of shallow ponds, in depressions on muddy ground, or in terrestrial burrows (Ikeda 1897; Siedlecki 1909; Pope 1931; Bhaduri 1932; Liu 1950; Kato 1956; Okada 1966; Mallick and Mallick 1982; Maeda and Matsui 1989; Girish and Saidapur 1999b; Kadadevaru and Kanamadi 2000). Indeed, the distinction among reproductive modes becomes somewhat arbitrary for these frogs. For example, a large treefrog from Borneo, *Rhacophorus harrissoni,* places its foam nests on the trunks of trees over tanks formed by the fusing of buttress roots, a mode of reproduction similar to that of some treehole breeders that lay nonfoamy egg masses in much smaller bodies of

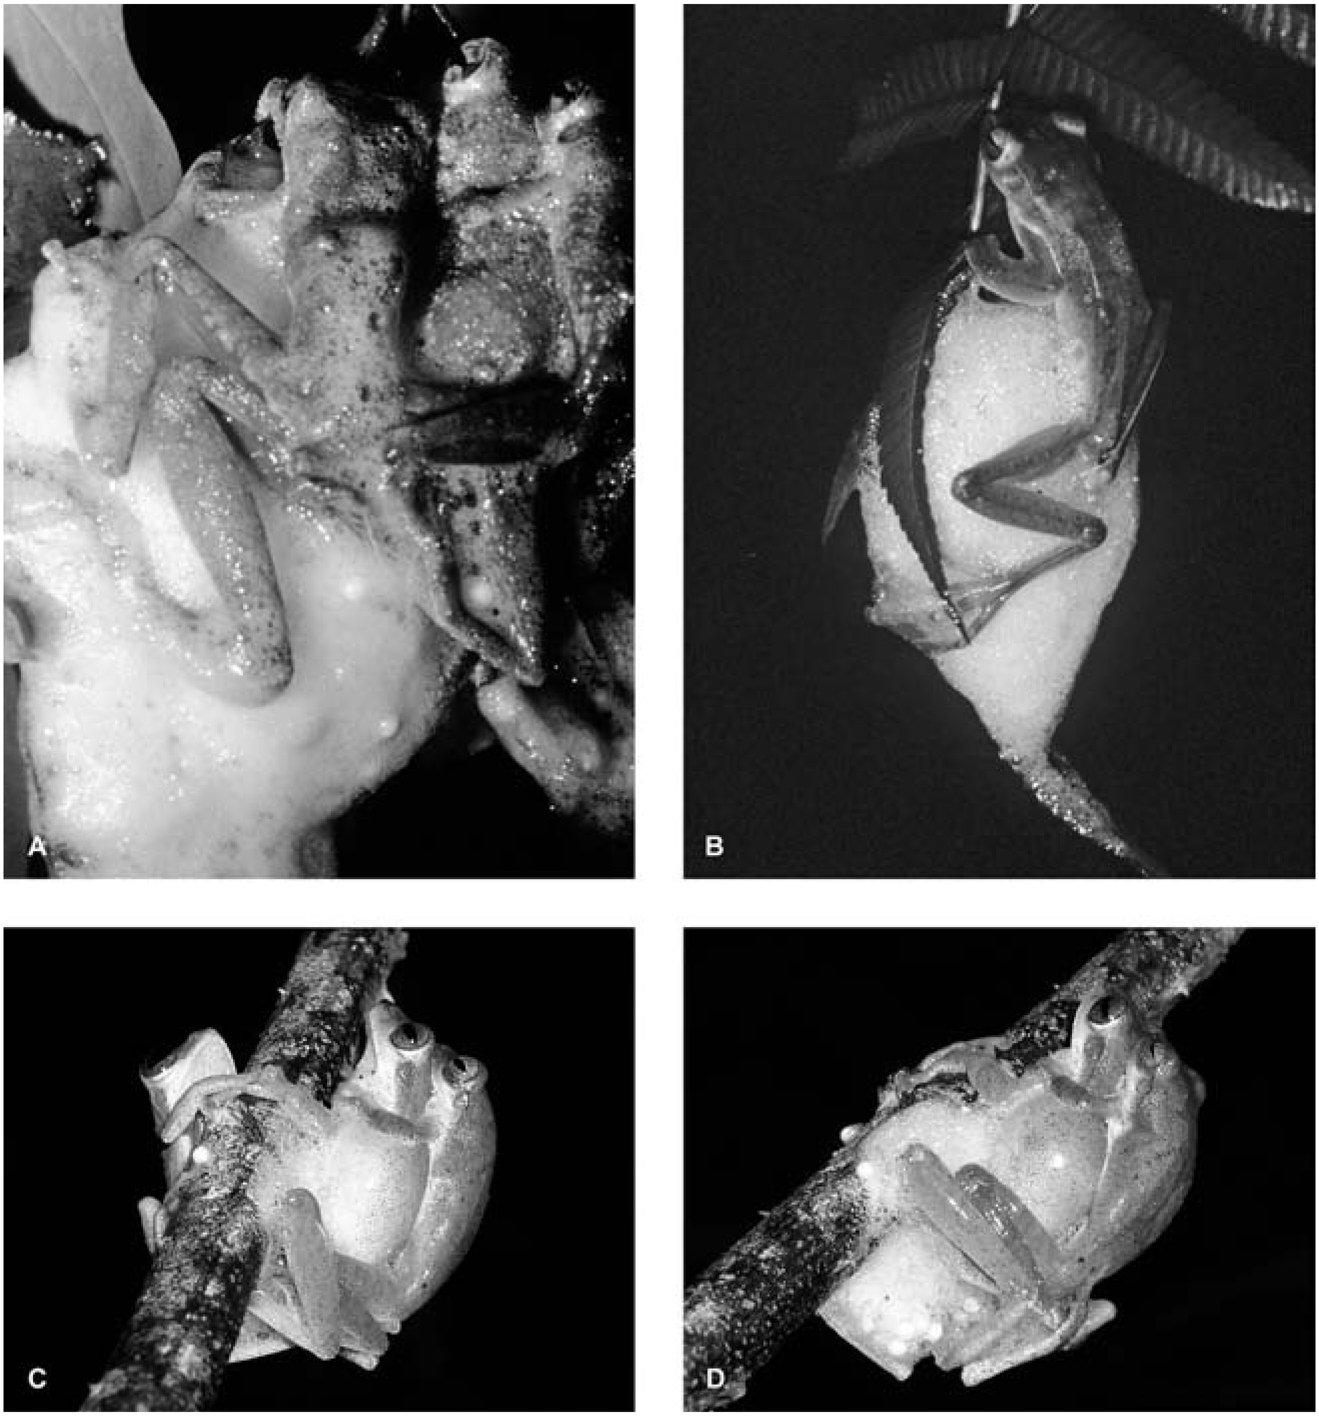

Fig. 10.7. Foam nests of arboreal rhacophorid frogs. (A) Multiple males fertilizing the eggs of a single female of *Chiromantis rufescens* from West Africa. (B) Female of *Rhacophorus dulitensis* from Borneo smoothing the outside of a foam nest. (C) Pair of *Chirixalus nonkhorenis* from Vietnam depositing a foam nest on a branch, with a satellite male nearby, possibly attempting to fertilize some eggs. water (Mode 26; Inger and Stuebing 1997). In one Japanese species, *Rhacophorus viridis,* eggs have been found several meters above the ground in trees (Mode 33), in grassy ponds (Mode 11), between rocks, on mud (Mode 28), and in terrestrial burrows (Mode 29) (Kuramoto 1973; Utsunomiya and Utsunomiya 1983). Several Asian rhacophorids build communal nests similar to those of *Chiromantis.* Simultaneous matings by several males with a single female have been observed in both arboreal and terrestrial breeders (Kasuya et al. 1987; Feng and Narins 1991; Fukuyama 1991; Kusano et al. 1991; see chapter 8 for additional discussion of the significance of group mating in these frogs).

Foam nesting also has been reported in one hyperoliid frog, *Opisthothylax immaculatus* from West Africa. It produces a foam nest folded inside a leaf overhanging a body of water (Amiet 1974b, 1989). The eggs are unusually large (4.6 mm in diameter) compared to those of most other foam-nesting species, and only a few eggs are laid. This suggests that foam nesting in this species is secondarily derived from arboreal egg-laying in nonfoamy masses, like that seen in some species of *Afrixalus* (see the following), rather than from aquatic foam nesting. The function of the foam is unknown, but it could provide a reservoir of water for the eggs or simply serve to cement the surrounding leaves together.

Arboreal Oviposition without Foam Nests (Modes 24 and 25)

In addition to arboreal foam-nesters discussed earlier, many other arboreal frogs deposit eggs on leaves, branches, or trunks of trees above water. The egg-laying adaptations in these frogs are extremely diverse and parallel those found in terrestrial breeders (see the following). The very different structure of the egg masses produced by different groups of arboreal frogs clearly reflects the repeated independent evolution of arboreal reproductive modes. As with many of the reproductive modes already discussed, Modes 24 and 25 could easily be subdivided into several distinct reproductive modes. Some Neotropical hylids, such as *Hyla ebraccata* and *H. brevifrons,* place their eggs on the upper surfaces of leaves, where they develop rapidly, and tadpoles drop into the water to complete development. Egg masses in these species are little more than aquatic egg masses attached to vegetation (fig. 10.8 A), although eggs tend to be somewhat larger than those of aquatic breeders of similar body size (Duellman 1970; Salthe and Duellman 1973; Crump and Kaplan 1979; Aichinger 1987a; Hödl 1991a). Somewhat similar egg masses are laid on leaves by some species of *Mantidactylus,* a group of mantellid frogs from Madagascar.

All of the phyllomedusine hylid frogs of South and Central America lay eggs in sites over water, and their tadpoles drop into the water to complete development, but the types of oviposition sites used vary considerably. Most members of this subfamily attach eggs to leaves overhanging ponds, but eggs also can be attached to tree trunks, stems, vines, and rocks (Caldwell 1994). Some species of *Phyllomedusa* place their eggs on vegetation over streams or attach them to rocks (A. Lutz and Lutz 1939; Cannatella 1980a; Langone, Prigioni, and Venturino 1985; Hödl 1990b). Members of the genus *Phrynomedusa,* formerly placed in the *Phyllomedusa fimbriata* group, deposit eggs in cavities, rock crevices, or hollows in fallen trees (Cruz 1982, 1990; Weygoldt 1984b, 1985, 1991; Jungfer and Weygoldt 1994). *Agalychnis craspedopus* lay eggs on vegetation over small forest pools or water-filled hollow logs (Hoogmoed and Cadle 1991), or on tree buttresses above small pools (Block et al. 2003). A closely related species, *A. calcarifer,* apparently breeds exclusively in small pools formed in cavities formed by the buttresses of large fallen trees. Eggs are deposited on vegetation over the pools or on the sides of the fallen trees just above the water (Marquis, Donnelly, and Guyer 1986; Donnelly et al. 1987; Caldwell 1994; Donnelly 1994). The reproductive modes of these species therefore grade into Mode 26 (see the following). Another species, *A. saltator,* lays eggs in huge communal masses imbedded in moss and epiphyte rootlets growing on vines over swamps (W. Roberts 1994). Egg capsules of this species are unusually hard and sticky and lack the large jelly mass typical of leaf-breeding members of the genus.

In *Pachymedusa dacnicolor,* most species of *Agalychnis, Phyllomedusa lemur,* and probably other members of the *Phyllomedusa buckleyi* group, the eggs are laid on the exposed surfaces of leaves, but the leaves are not wrapped around the eggs. Sometimes the female provides the eggs and surrounding jelly with water by periodically returning to the water with the male to rehydrate between bouts of egg deposition (Pyburn 1970; Wiewandt 1971; N. Scott and Starrett 1974; Bagnara et al. 1986; Jungfer and Weygoldt 1994; Leary and Parker 1998). This behavior does not occur in *A. saltator* (W. Roberts 1994). Many species of *Phyllomedusa* surround their eggs with one or more leaves that are wrapped around the eggs by the female, or formed into a funnel-shaped nest before eggs are laid. These frogs do not return to the water to rehydrate during oviposition. Instead, eggless jelly capsules are incorporated into the nest as water reservoirs. As the eggs develop, water passes by osmosis from the eggless capsules to the adjacent eggs (compare fig. 10.8 C and 10.8 D; Agar 1909; Kenny 1966; Pyburn 1970, 1980a; Pyburn and Glidewell 1971; Crump 1974; Lescure 1975b; Lamotte and Lescure 1977; Weygoldt 1981b; Cannatella 1982; Langone, Prigioni, and Venturino 1985; Hödl 1990b; Langone 1993; Jungfer and Weygoldt 1994; Vaira 2001).

Most centrolenid frogs deposit relatively large, unpigmented eggs on the undersides of leaves overhanging streams

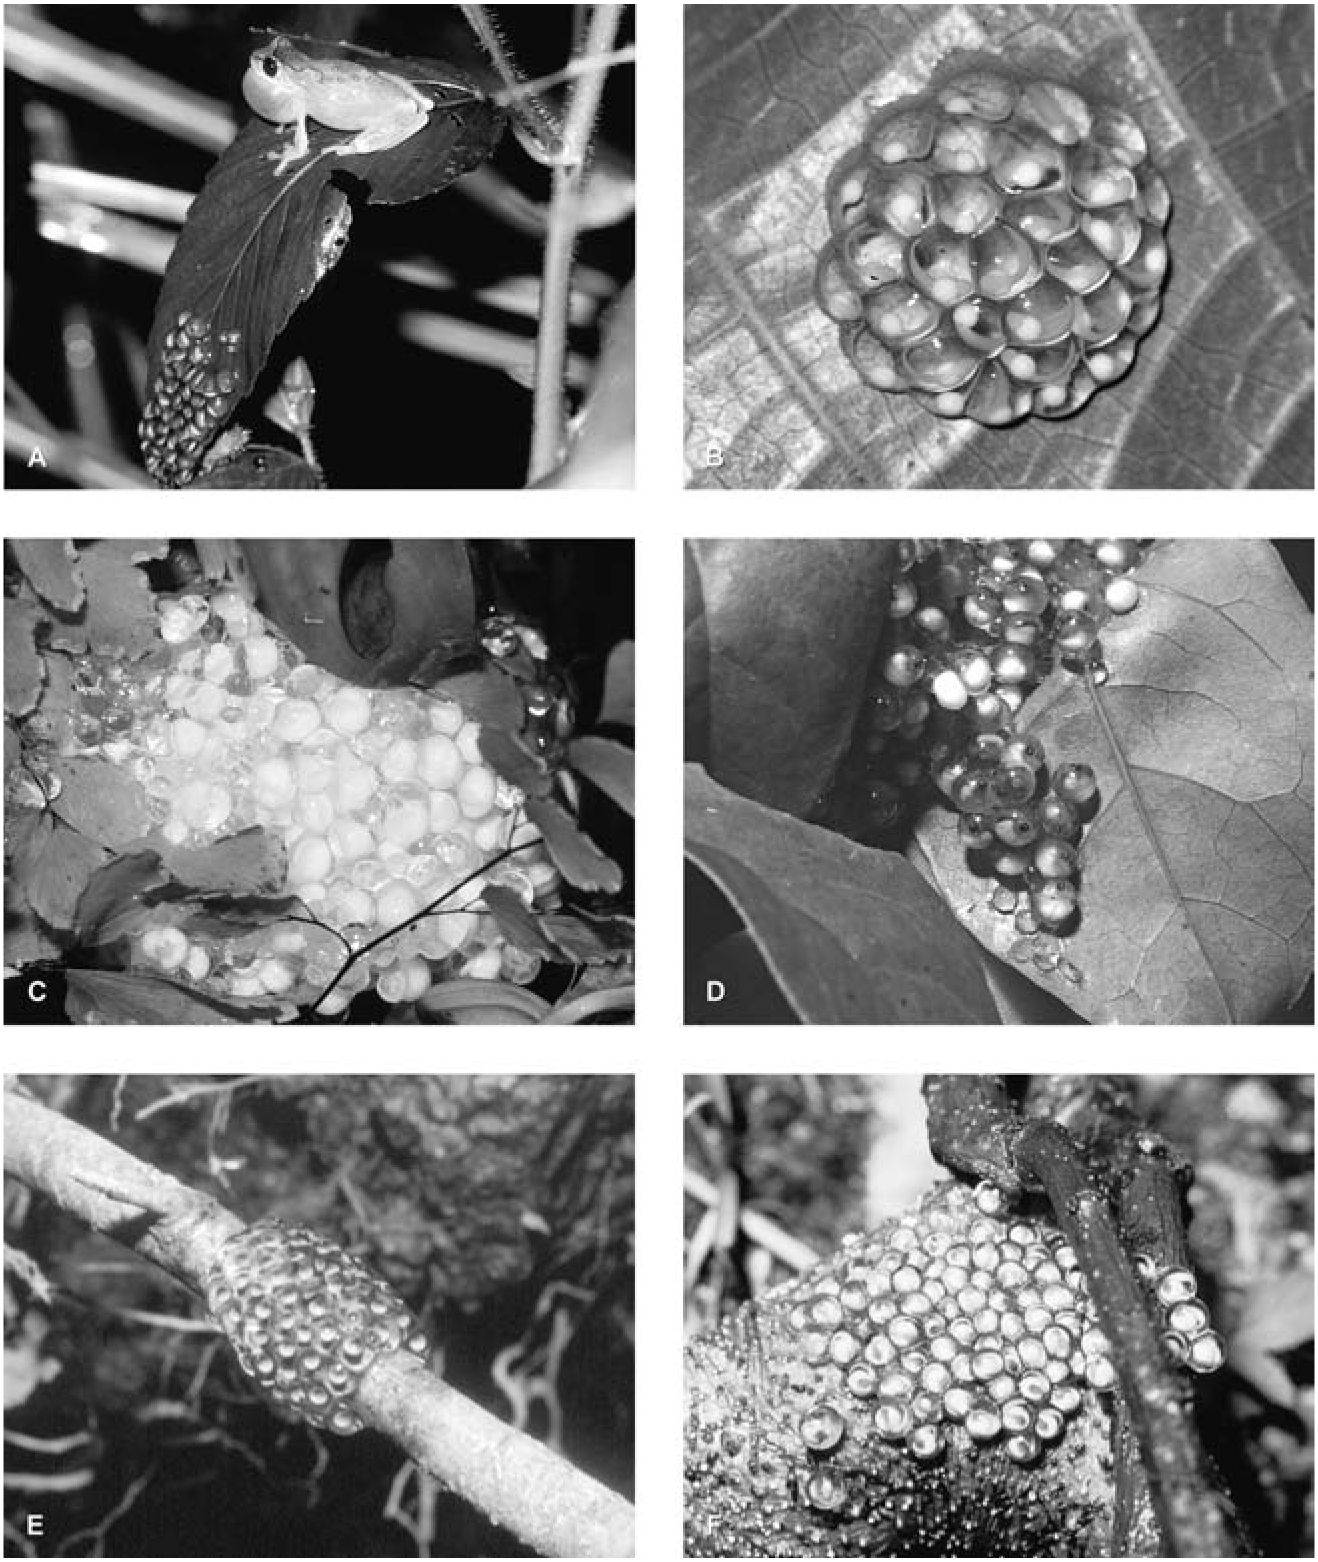

Fig. 10.8. Nonaquatic egg masses of anurans. (A) Male of a Central American treefrog, *Hyla ebraccata* (Hylidae), calling above an egg clutch on a leaf over a pond. (B) Egg mass of *Hyalinobatrachium fleischmanni* (Centrolenidae) placed on the underside of a leaf over a stream in Panama. (C) Egg mass of *Phyllomedusa trinitatis* (Hylidae) from Trinidad at an early stage of development. The embryos are wrapped in leaves and lack pigment. Empty egg capsules serve as water reservoirs. (D) Eggs of *P. trinitatis* in a later stage of development, with water-filled empty capsules largely depleted. (E) Eggs of the South African Kloof frog, *Natalobatrachus bonebergii* (Ranidae) on a branch. (F) Egg mass of *Cycloramphus dubius* (Leptodactylidae) from Brazil, placed on a tree root near the splash zone of a waterfall. Photos by Kentwood D. Wells (A–D), Alan Channing (E), and Marcio Martins (F).

(fig. 10.8 B), and in many species, a parent guards or broods the eggs (Duellman and Tulecke 1960; McDiarmid 1975, 1978; Greer and Wells 1980; Villa 1984; S. Jacobson 1985; M. Hayes 1991; see also chapter 11). Tadpoles drop into streams where they burrow into mud at the bottom (Villa and Valerio 1982). Other frogs that deposit eggs on vegetation over streams include *Hyla calypsa* and *H. thorectes* (Hylidae) from Central America (Duellman 1970; Lips 1996, 2001), *Litoria iris* (Hylidae) from the mountains of New Guinea (Zweifel and Tyler 1982), *Rana leytensis* (Ranidae) from the Philippines (Alcala 1962), and *Nyctibatrachus petreua* (Ranidae) from India (Kunte 2004).

Many hyperoliid frogs lay eggs out of water, with eggs being placed at various heights from just above the water line to four or five meters above the water (Wager 1965; Schiøtz 1967, 1999; Stewart 1967; Rödel 2000). In one species that lays eggs close to the water, *Hyperolius tuberilinguis,* pairs in amplexus return to the water after laying eggs, rehydrate, and then return to deposit additional layers of jelly on the eggs (M. Mason and Passmore 1998). This behavior is reminiscent of the behavior of some phyllomedusine frogs, which either rehydrate during egg laying or deposit empty water-filled jelly capsules in the egg masses. In another species, *H. spinigularis,* females have been observed returning for several nights after eggs have been deposited to moisten them with water (R. Stevens 1971). In most species of leaf-folding frogs in the genus *Afrixalus,* eggs are laid above water and are wrapped in leaves that are glued around the egg mass, a behavior remarkably similar to that of some phyllomedusine hylid frogs (Schiøtz 1999). A phylogenetic analysis of reproductive modes in hyperoliid frogs suggested that nonaquatic oviposition was derived from aquatic oviposition, probably more than once (fig. 10.9; Duellman 1989a).

Terrestrial Oviposition with Aquatic Tadpoles (Modes 17–21)

Many groups of frogs have evolved reproductive modes that involve deposition of eggs on land, but they nevertheless retain the aquatic larval stage. In some cases, the eggs are laid in sites that are later flooded, thereby allowing the tadpoles to complete their development in water. There also are species that lay their eggs at some distance from water, and the tadpoles either make their way to water on their own, or are carried there by a parent. Finally, there are species that lay eggs in terrestrial nests in which the tadpoles complete development without feeding at all.

Nonaquatic Eggs with Feeding Tadpoles (Modes 17, 18, and 19)

Perhaps the least specialized mode of nonaquatic oviposition is to place the eggs in a terrestrial nest or natural cavity in a saturated area that is likely to be flooded by future rains.

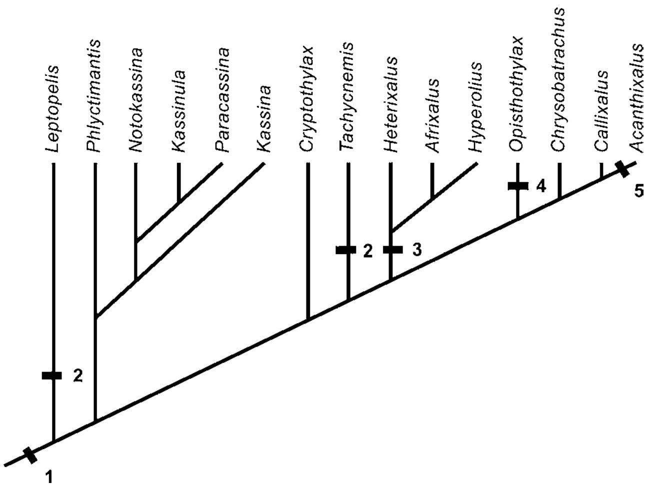

Fig. 10.9. Hypothesized phylogenetic relationships of hyperoliid frogs, based on morphological characters. Numbers show evolutionary changes in reproductive modes. 1 = aquatic eggs and larvae. 2 = terrestrial eggs and aquatic larvae. 3 = eggs on vegetation above water with aquatic larvae. 4 = arboreal foam nest with aquatic larvae. 5 = eggs and larvae in water-filled cavities in trees. After Duellman (1989a).

The tadpoles remain in the nest until it is flooded and then complete their development in temporary ponds (Mode 17). This mode of reproduction is characteristic of several Asian species of *Rana,* including *R. caldwelli* in China (described as *R. adenopleura* in C. Liu 1950) and *R. psaltes* in the Ryukyu Islands of Japan (Kuramoto 1985). In Taiwan, *R. psaltes* places eggs in small nests (about 30 mm in diameter) in very shallow water (personal observations), so the reproductive mode of this species grades into Mode 4. The eggs of these species are clearly derived from those of aquatic-breeding ancestors, being surrounded by a thick jelly mass characteristic of many pond-breeding frogs. This reproductive mode resembles that of the Brazilian hylid frog *Hyla leucopygia* and other members of the *H. albosignata* group, which was discussed earlier under Mode 4. A rhacophorid frog from Taiwan, *Chirixalis idiootocus,* lays pigmented eggs in shallow depressions or holes at the edges of temporary ponds. Hatching apparently is stimulated by heavy rain, and the tadpoles complete their development in a pond (Kuramoto and Wang 1987).

A similar reproductive mode is found in Australian myobatrachids in the genus *Geocrinia,* which lay eggs at the base of grass tussocks, and *Pseudophryne,* which lay eggs in burrows. The eggs hatch when the nests flood after heavy rains. These frogs have relatively large eggs that are not surrounded by a jelly mass. The eggs are morphologically and physiologically more similar to eggs of other terrestrial breeders than those of aquatic breeders (Jacobson 1963; A. Martin and Cooper 1972; Watson and Martin 1973; Woodruff 1976b, 1977; Bradford and Seymour 1985, 1988a, b; Seymour and Bradford 1987; Gollmann and Gollmann

1991; Seymour, Geiser, and Bradford 1991a, b). Newly hatched tadpoles of these species have considerable yolk reserves that allow them to develop rapidly in areas flooded for only a few weeks. One species, *P. australis,* has more specialized reproductive habits. It breeds throughout the year and lays eggs in terrestrial sites through which water flows after heavy rains (Thumm and Mahony 2002a). Eggs generally hatch at a more advanced stage of development than do those of other members of the genus, but there is considerable plasticity in both the timing and stage of hatching (Thumm and Mahony 2002b).

Some frogs deposit their eggs in terrestrial sites that are close enough to water to allow the tadpoles to drop into the water or wriggle to the water to complete development (Mode 18). This reproductive mode lumps together a number of unrelated anurans and does not fully capture the wide range of variation in both the types of sites used for oviposition and the way in which tadpoles reach the water. There is no doubt that Mode 18 (Mode 13 of Duellman and Trueb 1986) represents a somewhat artificial grouping of many independently evolved reproductive modes.

Some species in the genus *Leptopelis* (Hyperoliidae) from western and southern Africa lay their eggs in excavated depressions or natural cavities close to temporary savanna ponds, forest pools, or streams. When tadpoles hatch, they wriggle into the water (Lamotte and Perret 1961; Schiøtz 1963, 1967, 1999; Wager 1965; Largen 1977; Oldham 1977; Amiet 1989; Rödel 2000). Some species of the African ranid genus *Cardioglossa* apparently have a similar reproductive mode (Amiet 1989; Rödel, Schorr, and Ernst 2001). The large myobatrachid frogs of the genus *Mixophyes* are reported to lay eggs on rocks or roots above streams (Watson and Martin 1973; Duellman and Trueb 1986), although Hero, Littlejohn, and Marantelli (1991) reported that *M. balbus* lays eggs directly in streams and rock pools (Mode 2). *Paratelmatobius poecilogaster,* a small leptodactylid frog from the Atlantic forests of southeastern Brazil, lays eggs on rocks overhanging small pools on the forest floor. When the eggs hatch, the tadpoles drop into the pools, where they complete their development. The tadpoles sometimes are found in streams as well, having been washed out of the forest pools by heavy rains (Pombal and Haddad 1999). *Rana ishikawae,* a frog endemic to the Ryukyu Islands of Japan, lays unpigmented eggs in burrows in stream banks a meter or more above the water level. Tadpoles have been found in streams, but how they get from the burrow to the stream is unknown (Utsunomiya, Utsunomiya, and Katsuren 1979). Nests of an Indonesian frog, *Rana arathooni,* are located on steep banks above mountain streams, and tadpoles eventually drop into the streams to complete development (R. Brown and Iskandar 2000). Terrestrial eggs are laid in an underground chamber by African burrowing frogs in the genus *Hemisus* (Hemisotidae), sometimes with little or no water (Amiet 1991). After the eggs hatch, the female opens the burrow and constructs a channel through the mud, and the tadpoles follow her through the channel to open water (Wager 1965; Rödel et al. 1995; Spieler 1997; Kaminsky, Linsenmair, and Grafe 1999; Rödel 2000; see also chapter 11).

Many frogs with Mode 18 reproduction are inhabitants of wet, cool montane regions. For example, the three species in the leptodactylid genus *Batrachyla* are found only in the cool mountain forests and moors of southern Chile. Eggs are deposited on rocks or under rocks, logs, and leaf litter close to cold streams and moorland pools. When the tadpoles hatch, they find their way into the streams or pools (Capurro 1958; Cei and Capurro 1958; Cei 1962; Barrio 1967; Busse 1971; Formas and Pugin 1971; Formas 1976). The Philippine frog *Rana magna,* an inhabitant of cool mountain streams, lays its eggs on rock faces and moss in shaded locations, and the tadpoles complete development in streams (Alcala 1962). Duellman and Trueb (1986) classified the *Heleophryne* of the mountains of southern Africa as Mode 2 stream-breeders, but there is some evidence for at least one species, *Heleophryne purcelli,* that eggs are laid on rocks or gravel beside mountain streams and not always directly in the water (Visser 1971; Channing 2001). Two centrolenid frogs, *Centrolene geckoideum* and *C. petrophilum,* from the mountains of Colombia and Ecuador, also attach their eggs to rocks overhanging the water (Lynch, Ruiz, and Rueda 1983; Ruiz-Carranza and Lynch 1991b). Reproductive Mode 18 sometimes grades into arboreal modes of reproduction, such as Modes 24 and 25 (eggs attached to leaves over water). For example, the Kloof frog of southern Africa (*Natalobatrachus bonebergi*), a mountain stream breeder, lays eggs on vertical rock faces, leaves, or branches (fig. 10.8 E), usually about 1 m above the water, but sometimes as much as 4 m high (Wager 1965).

A number of frogs have a reproductive mode similar to those described previously, with eggs being laid on the vertical surfaces of rocks, roots, and other substrates near streams and waterfalls (fig. 10.8 F). However, instead of dropping into the water, the tadpoles of these frogs are adapted to adhering to the rock surface, where they feed on algae and bacteria growing in the thin film of water bathing the rocks (Mode 19). This mode is characteristic of South American leptodactylids in the genera *Thoropa* and *Cycloramphus* (oviposition sites of most *Cycloramphus* have not been reported). A similar reproductive mode is characteristic of African frogs in the genus *Petropedetes* (Lamotte 1954; Lamotte, Perret, and Dzieduszycka 1959; Lamotte and Lescure 1977, 1989b; Heyer and Crombie 1979; Heyer 1983; Wassersug and Heyer 1983; Cocroft and Heyer 1988; Amiet 1989, 1991). Both eggs and tadpoles of a ranid frog, *Amolops cremnobatus,* have been found adhering to rocks near a waterfall in Laos, but it is not known whether the tadpoles complete development on the rock faces (Inger and Kottelat 1998).

Nonaquatic Eggs with Larval Transport (Modes 20 and 22)

Another way of removing eggs from the water while retaining an aquatic larval stage is for a parent to carry tadpoles to water once they hatch (Mode 20). In most dendrobatid frogs, either the male or female, depending on the species, carries the tadpoles from a terrestrial oviposition site, either transporting the whole clutch of tadpoles at once or only one or two at a time. The tadpoles are placed in streams or in small bodies of water in tree holes and bromeliads, where they feed on organic matter or conspecific eggs (Weygoldt 1987). The parental behavior of these frogs is discussed in more detail in chapter 11. Males of the Bornean ranid frogs *Limnonectes finchi* and *L. palavanensis* also carry tadpoles on their backs to water (Inger 1966; Inger, Voris, and Frogner 1986; Inger and Stuebing 1997). Free-swimming tadpoles have been found in quiet stream pools, a tree buttress tank, and a water-filled hole in a log.

Frogs with Mode 22 reproduction are similar to those discussed previously, except that tadpoles complete development on the body of the parent and are not always transported far from the nest. This reproductive mode actually combines several distinct modes of tadpoles transport in unrelated clades of frogs. Tadpoles hatched from terrestrial eggs are carried on the back of a parent in *Sooglossus seychellensis,* where they develop without feeding. The three most terrestrial species of *Leiopelma* from New Zealand, *L. hamiltoni, L. archeyi,* and *L. pakeka,* lay eggs in moist terrestrial sites under rocks, logs, or vegetation. These hatch at an advanced stage and remain closely associated with the male or complete development on his back (B. Bell 1978, 1982, 1985; B. Bell and Wassersug 2003). In the myobatrachid frog *Assa darlingtoni,* tadpoles hatching from terrestrial eggs make their way into inguinal brood pouches on the sides of the male, where they complete their development (Ingram, Anstis, and Corben 1975; Ehmann and Swan 1985). Another Mode 22 frog is *Rhinoderma darwinii* from Chile, in which nonfeeding tadpoles complete development in the male's vocal sac (Cei 1962). However, in the only other species in the genus, *R. rufum,* the tadpoles are carried in the vocal sac to water (Mode 20; Formas, Pugin, and Jorquera 1975), suggesting that Mode 22 reproduction is relatively easily derived from Mode 20. All of these are discussed in more detail in chapter 11.

Nonaquatic Eggs with Nonfeeding Tadpoles (Mode 21)

Some terrestrial-breeding frogs supply their eggs with enough yolk to support larval development all the way to metamorphosis. Eggs are laid in natural cavities, excavated burrows and nests, or the surfaces of leaves and rock walls. After hatching, tadpoles remain at the nest site and develop without feeding. This mode of reproduction, termed nidicolous (= nest inhabiting) by some authors (Thibaudeau and Altig 1999), has evolved independently in a number of families. The best-studied example of this mode of development is the Tasmanian myobatrachid frog *Crinia nimbus.* Eggs are laid in small cavities in wet moss or lichens, where they undergo a prolonged development that can last up to a year. Hatched tadpoles remain in a thick soup formed by the remains of the jelly that initiatially surrounded the egg mass, apparently without feeding (N. Mitchell and Swain 1996; N. Mitchell and Seymour 2000; N. Mitchell 2002a, b). Although their development is potentially limited by lack of sufficient oxygen, the embryos and tadpoles do not normally experience hypoxic conditions because of the very low temperatures of their nests and extra oxygen supplied by photosynthesis of the plants surrounding the eggs (Mitchell and Seymour, 2003; see also chapter 4).

Terrestrial reproduction with nonfeeding tadpoles has evolved repeatedly in the family Microhylidae. One example is *Synapturanus salseri,* a burrowing microhylid from the Amazonian region of Colombia. The frogs live in burrows just below a matted layer of roots in the forest floor. Eggs are deposited in the burrow. Tadpoles apparently hatch at an advanced stage and complete development in the nest without feeding (metamorphosed froglets still had substantial yolk reserves; Pyburn 1975). Another species in the same genus, *S. rabus,* also has large terrestrial eggs, but the complete mode of development has not been observed (Pyburn 1976). The genus *Myersiella,* thought to be closely related to *Synapturanus* (Nelson and Lescure 1975; Zweifel 1986), was listed by Duellman and Trueb (1986) as having direct development (Mode 23), but in fact, it appears to have a reproductive mode similar to that of *Synapturanus* (Izecksohn et al. 1971). Several Old World microhylids have similar modes of reproduction, including the Asian frog *Calophrynus pleurostigma* and *Madecassophryne truebae* from Madagascar, but their reproduction is poorly studied (Glaw and Vences 1994; Thibaudeau and Altig 1999). Microhylid frogs in the genus *Stumpffia* from Madagascar also are believed to have nonfeeding tadpoles, but these frogs lay eggs in foam nests in leaf litter (Glaw and Vences 1994), so are more appropriately placed in Mode 32.

A burrowing leptodactylid, *Cycloramphus stejnegeri,* from the Atlantic coastal forests of Brazil, has nonfeeding terrestrial larvae. Tadpoles have been seen on the back of a female, but whether the female carries them around or simply remains with them in the nest is unknown (Heyer and Crombie 1979). Terrestrial, nonfeeding tadpoles also have been described in *Zachaenus parvulus* (Lutz 1944), a closely related species (Heyer 1983). Another Brazilian leptodactylid, *Thoropa lutzi,* which is associated with rock walls, also has terrestrial, nonfeeding tadpoles (Bokermann 1965). This mode of reproduction has recently been described in three species of *Colostethus* (Dendrobatidae) from South America (*C. degranvillei, C. stepheni,* and *C. nidicola*) and one species from the island of Martinique (*C. chalcopis;* Junca, Altig, and Gascon 1994; Kaiser and Altig 1994; Kaiser, Coloma, and Gray 1994; Caldwell and Lima 2003).

Altiphrynoides malcolmi, a bufonid from the highlands of East Africa, lays terrestrial eggs in moist locations at the bases of plants. Tadpoles hatch with large yolk reserves and complete development in the nest (Grandison 1978). Although considered by M. Wake (1980c) to be a form of direct development, it is more similar to Mode 21. Several small African petropedetid frogs also lay terrestrial eggs and have nonfeeding, terrestrial tadpoles. Two of these, *Arthroleptella hewitti* and *A. lightfooti,* lay eggs in or under wet moss near cold mountain streams. The tadpoles remain in wet mud or moss throughout development and apparently do not feed (Wager 1965). Another species, *Phrynodon sandersoni,* is unusual in laying its eggs on the surface of leaves of rainforest plants, where the eggs are attended by the female. The ecology of the tadpoles has not been studied in nature, but the location of the oviposition sites and the morphology of the tadpoles suggest that they develop on land without feeding (Amiet 1981, 1991). *Phrynobatrachus alticola* lays eggs in wet leaf litter. Tadpoles remain in the eggs until just before metamorphosis and then hatch into nonfeeding tadpoles that quickly lose their tails (Rödel and Ernst 2002).

Nonaquatic Oviposition with Direct Development (Modes 23 and 27)

The most complete form of adaptation to terrestrial life in frogs is direct development of terrestrial eggs (Mode 23). Typically these eggs are very large compared to those of frogs with other reproductive modes and are enclosed in thick capsules, but are not surrounded by a mass of jelly, which would be of little use in retarding evaporative water loss. This mode of reproduction enables frogs to sever all ties to standing water and move into habitats that otherwise might not be available to them. Several major lineages of frogs and a few minor ones have evolved direct development independently, and most of these are associated with wet tropical forests. The most successful group is the leptodactylid genus *Eleutherodactylus* (fig. 10.10 A), the largest genus of vertebrates, with over 500 named species. Direct development also is found in other members of the tribe Eleutherodactylini, including the genera *Adelophryne, Euparkerella, Ischnocnema, Holoaden, Phyllonastes, Phyzelaphryne,* and *Phrynopus.* Hedges (1989) placed several other genera with direct development in the genus *Eleutherodactylus,* including *Halactophryne, Sminthillus, Syrrhophus,*

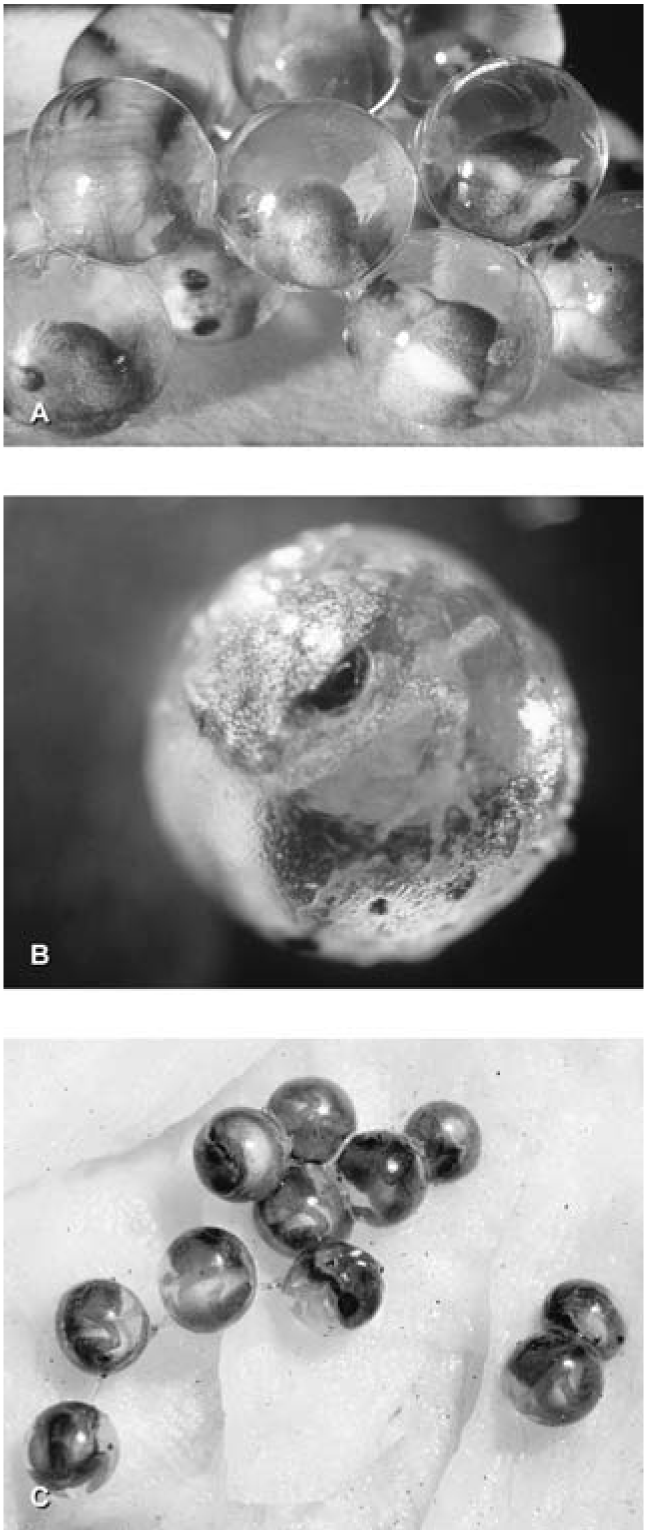

Fig. 10.10. Direct development in terrestrial frogs. (A) Developing embryos of *Eleutherodactylus coqui* (Leptodactylidae) from Puerto Rico inside their egg capsules. Light areas on the bellies of the embryos are yolk reserves. (B) Late-stage embryo of *Athroleptis stenodacylus* (Arthroleptidae) from West Africa. (C) Eggs of *Sooglossus gardineri* (Sooglossidae) from the Seychelles Islands, with developing embryos inside. Photos by James Hanken (A), Ulmar Grafe (B), and Wayne Van Devender (C).

and *Tomodactylus,* but some authors have continued to treat them as separate genera.

Species of *Eleutherodactylus* are the dominant terrestrial anurans of most tropical forests in South and Central America and the Caribbean islands, where they inhabit a variety of microhabitats, including leaf litter, piles of debris, the branches and trunks of trees and shrubs, tree holes, bromeliads, and the margins of streams. Most species of *Eleutherodactylus* use terrestrial nest sites (Mode 23), but some use arboreal nests (Mode 27). For example, *E. hedrecki* of Puerto Rico lays eggs in tree holes, sometimes up to 8 meters above the ground (Rivero 1978; Joglar 1998). *Eleutherodactylus coqui* lays eggs mostly in rolled up sierra palm leaf petioles or the curled dead leaves of *Cecropia* trees. Although most nests are on the ground, the frogs actually show a preference for arboreal sites, using suitable elevated nest sites at frequencies much higher than their occurrence in the forest (Townsend 1989a). Other species, such as *E. cochranae* of Puerto Rico, live and lay their eggs in bromeliads (Rivero 1978; Joglar 1998). Some species have elaborate parental care (e.g., *E. coqui:* Townsend, Stewart, and Pough 1984; see also chapter 11), but others simply lay their eggs in moist leaf litter, under logs, or in rock crevices and abandon them. Embryos undergo complete development within the egg capsule and emerge as tiny froglets ready for fully independent terrestrial life (Sampson 1904; Dunn 1926b; Noble 1926b, 1927; Martin del Campo 1940; Lynn 1942; Lynn and Lutz 1946a, b; Goin 1947; Jameson 1950, 1955b; Adamson, Harrison, and Bailey 1960; Chibon 1960; Heatwole 1962a; Salthe and Mecham 1974; Lamotte and Lescure 1977; Lescure 1980; Duellman and Trueb 1986; Hayes-Odum 1990; Bourne 1997, 1998).

The developmental biology of *Eleutherodactylus coqui* has been examined in more detail than that of any other frog with direct development (Elinson 1990; Hanken, Jennings, and Olsson 1997). Thibaudeau and Altig (1999) provided a detailed review of the developmental biology of *Eleutherodactylus* and other direct-developing frogs, and I will give only a brief summary here. This genus has a relatively derived type of direct development. The embryo does not simply undergo larval development inside the egg, but instead exhibits major changes in the timing and patterning of development compared to that of aquatic-breeding frogs. For example, bone appears in the developing embryo, as do paired limbs. The pattern of tissue development is like that of adult frogs, with most larval features having been lost. For example, larval mouthparts do not develop in *Eleutherodactylus,* but there are vestiges of larval mouthparts in some other direct-developing embryos, such as *Arthroleptella* (Thibaudeau and Altig 1999). Most direct-developing embryos lack gills or have only vestigial structures, but some embryos develop a tail that can serve as an accessory respiratory structure (see chapter 4). The embryos of *Eleutherodactylus* also differ from those of aquatic-breeding frogs in the timing of thyroid axis development. The mother provisions the embryos with some thyroid hormone, a pattern seen in some other frogs as well. The thyroid gland becomes active about two-thirds of the way through embryonic development in *E. coqui,* whereas this is delayed until after hatching in aquatic-breeding frogs with tadpoles (Jennings and Hanken 1998). The onset of thyroid activity corresponds with a number of morphological changes similar to those seen in metamorphosis, including regression of the tail, elongation of the limbs, remodeling of the cranium, and development of the hypaxial musculature. Thyroid hormone activity is necessary for these features of development to proceed normally (Callery and Elinson 2000).

The closest ecological equivalents of *Eleutherodactylus* in the Old World are microhylid frogs in two closely related subfamilies, the Genyophryninae (= Sphenophryninae) and the Asterophryninae of northern Australia, New Guinea, and islands in the Australo-Papuan region northward to the southern Philippines. Recent molecular systematic work by David Bickford (2001) suggests that the latter subfamily is not monophyletic, and he advocated placing all New Guinea microhylids in the subfamily Genyophryninae. As far as is presently known, all of the frogs (more than 150 species) in these subfamilies have direct development of eggs into small froglets, and most, if not all species also have parental care (Simon 1983; Bickford 2001; see also chapter 11). Like *Eleutherodactylus* in many parts of the Neotropics, these frogs are the dominant terrestrial anuran group in the Australo-Papuan region, comprising nearly 50% of the frogs of New Guinea (Zweifel and Tyler 1982). No doubt their mode of reproduction is responsible for much of their ecological success, especially in the highlands of New Guinea, where ponds are scarce.

Microhylids from New Guinea have radiated into a wide variety of ecological niches, and they use a correspondingly wide array of oviposition sites (Bickford 2001). Burrowing frogs in the genera *Callulops* place eggs in burrows as much as 140 cm deep, while other burrowing frogs (*Copiula, Xenobatrachus*) use shallower enclosed soil cavities or depressions under logs. Terrestrial frogs such as *Austrochaperina, Sphenophryne, Hylophorbus, Liophryne,* and some species of *Cophixalus,* use shallow cavities in soil, burrows near streams, or sites in leaf litter and detritus. Arboreal frogs, including other species of *Cophixalus, Albericus,* and *Oreophryne,* use cavities in tree ferns, the crotches of trees, or the surfaces of leaves. Unfortunately, little or nothing is known about the reproductive biology of most species in this group (M. Tyler 1963a; Zweifel 1972, 1985; Zweifel and Tyler 1982; W. Brown and Alcala 1983; Hoskin 2004).

Ranid frogs in the genera *Platymantis* and *Ceratobatra-*

chus overlap these terrestrial-breeding microhylids geographically, being found in New Guinea and nearby islands, the Bismark Archipelago, the Solomon Islands, the Philippines, and Fiji. They occupy similar habitats and have the same direct development mode of reproduction (W. C. Brown 1952; Zweifel 1969, 1975; W. Brown and Parker 1970; Zweifel and Tyler 1982; Thibaudeau and Altig 1999). There are both terrestrial and arboreal frogs in the genus *Platymantis,* so both Mode 17 and Mode 20 (direct development in an arboreal nest) are represented (W. Brown and Alcala 1983).

Other examples of direct development of terrestrial eggs are scattered in various unrelated groups around the world (Thibaudeau and Altig 1999). In some cases, complete development of the eggs has been observed, but in others, direct development has been inferred from the size and appearance of the eggs and site of egg deposition. Unfortunately, without complete information on egg development, it is difficult to distinguish Mode 23 (direct development into froglets) from Mode 21 (development into nonfeeding tadpoles). The large, unpigmented ovarian eggs of frogs in the small Neotropical family Brachycephalidae suggest that they have direct development (Izecksohn 1971; Duellman and Trueb 1986), and this has been confirmed for one species, *Brachycephalus ephippium.* In this species, eggs are laid in soil under leaf litter and take up to two months to develop (Pombal, Sazima, and Haddad 1994; Pombal 1999). Several genera of Neotropical bufonids (*Oreophrynella, Osornophryne,* and *Rhamphophryne*) have large terrestrial eggs and probably have direct development (Duellman and Trueb 1986), although this has been confirmed only in *Oreophrynella* (McDiarmid and Gorzula 1989). Two obscure monotypic genera of African bufonids, *Laurentophryne* and *Didynamipus,* also have direct development (Grandison 1981).

A number of other Old World frogs have direct development, including *Sooglossus gardinerii* (fig. 10.10 C) from the Seychelles Islands (Duellman and Trueb 1986), members of the rhacophorid genus *Philautus* from the Philippines (Alcala and Brown 1982), *Rhacophorus microtympanum* from Sri Lanka (Kirtisinghe 1946), the African genus *Arthroleptis* (fig. 10.10 B), and African petropedetids in the genera *Anhydrophryne* and *Arthroleptella* (Guibe and Lamotte 1958; Lamotte and Perret 1963b; Wager 1965; Amiet 1989; Thibaudeau and Altig 1999). Several Australian myobatrachids also have direct development, including *Geocrinia rosea* and *G. lutea,* possibly *Metacrinia nichollsi,* and two peculiar burrowing frogs from the western Australian deserts, *Arenophryne rotunda* and *Myobatrachus gouldii.* The two species of *Geocrinia* and *Arenophryne* all deposit their eggs in burrows. The latter is very unusual in that breeding pairs remain together in an underground burrow for many months. Burrows where eggs are deposited are deeper (80 cm) than those of most other terrestrial breeders, no doubt an adaptation to its desert environment (Roberts 1984). *Myobatrachus* is an even more peculiar frog, being highly modified for subterranean life. It has a reproductive mode very similar to that of *Arenophryne,* but it lives in drier habitats and lays its eggs even deeper (more than 1 meter; Roberts 1981).

Transport of Eggs by a Parent (Modes 9, 15, 16, 34, 35, 36, and 37)

Reproductive Modes 9, 15, 16, 34, 35, 36, and 37 all involve parental transport of eggs that either hatch into tadpoles or undergo complete development in the egg capsule (table 10.2). This type of parental care is discussed in more detail in chapter 11, so only a brief summary will be given here. Undoubtedly the most bizarre form of egg transport is found in gastric-brooding frogs of the genus *Rheobatrachus* from Australia (Mode 9). Eggs are swallowed by the female and develop entirely in her stomach (Corben, Ingram, and Tyler 1974; Tyler and Carter 1981; Tyler 1983; Leong, Tyler, and Shearman 1986). The midwife toads of the genus *Alytes* are the only frogs in which males are known to carry eggs. The eggs are wrapped around the hind legs of the male and carried for up to a month before they hatch into aquatic tadpoles (Mode 34; Boulenger 1912; Heinzmann 1970; Lopez Jurado, Caballero, and Dos-Santos Freitas 1979; Crespo 1982; König and Schlüter 1991; Márquez and Verrell 1991; Márquez 1992, 1993).

In several genera of hemiphractine frogs from South and Central America, eggs are carried on the back of the female, either attached externally (*Stefania, Cryptobatrachus, Hemiphractus*), or in partially or fully enclosed dorsal pouches (*Flectonotus, Fritziana, Gastrotheca;* see fig. 11.4 in chapter 11). Eggs undergo direct development (Mode 37) in *Cryptobatrachus, Stefania, Hemiphractus,* and some *Gastrotheca.* In *Stefania evansi,* a species that carries eggs exposed on the back, the froglets remain on the back of the female even after the egg membranes have ruptured (Gorzula, Morales, and Hernandez 1983; Jungfer and Boehme 1991). In *Flectonotus* and *Fritziana,* tadpoles are placed in water-filled leaf axils or tree holes (Mode 36). Duellman and Gray (1983) reported that these tadpoles develop to metamorphosis without feeding. However, subsequent investigations revealed that tadpoles of at least one species, *Fritziana goeldii,* do feed (Weygoldt 1989b; Weygoldt and Carvalho e Silva 1991). In some species of *Gastrotheca,* eggs hatch into feeding tadpoles that are deposited in ponds (Del Pino 1980, 1989a, b; Duellman and Maness 1980; Del Pino and Escobar 1981; Auber-Thomay and Letellier 1986; Gipouloux 1986; Duellman and Hillis 1987; Duellman 1989a; Juraske and Sinsch 1992).

The only fully aquatic frogs that carry their eggs are the bizarre South American frogs in the genus *Pipa.* In *P. parva,* *P. carvalhoi,* and *P. myersi,* eggs are carried in cavities on the back of the female and hatch into aquatic tadpoles that complete their development in a pond (Mode 15). In *P. pipa, P. arrabili,* and *P. snethlageae,* eggs hatch into froglets (Mode 16; Rabb and Rabb 1960, 1963a; Weygoldt 1976a, b; Trueb and Cannatella 1986; Duellman 1989a). While the origins of this bizarre mode of reproduction seem mysterious, some aspects of mating and oviposition in *Pipa* appear to have been inherited from ancestors with other modes of oviposition. Using a phylogeny for pipid frogs derived from morphological characters (Cannatella and Trueb 1988a), Duellman (1989a) concluded that the ancestral mode of reproduction in the family Pipidae was the deposition of small aquatic eggs on underwater plants, as seen in all species of *Xenopus* (fig. 10.11). In two genera, *Silurana* and *Hymenochirus*, small eggs are deposited on the water's surface, a process that involves elaborate mating behavior in which the pair turn upside down in the water as each egg is released. This peculiar mating behavior is retained in *Pipa,* but the eggs are pushed into spongy tissue on the female's back by the male after the eggs are fertilized (fig. 10.12).

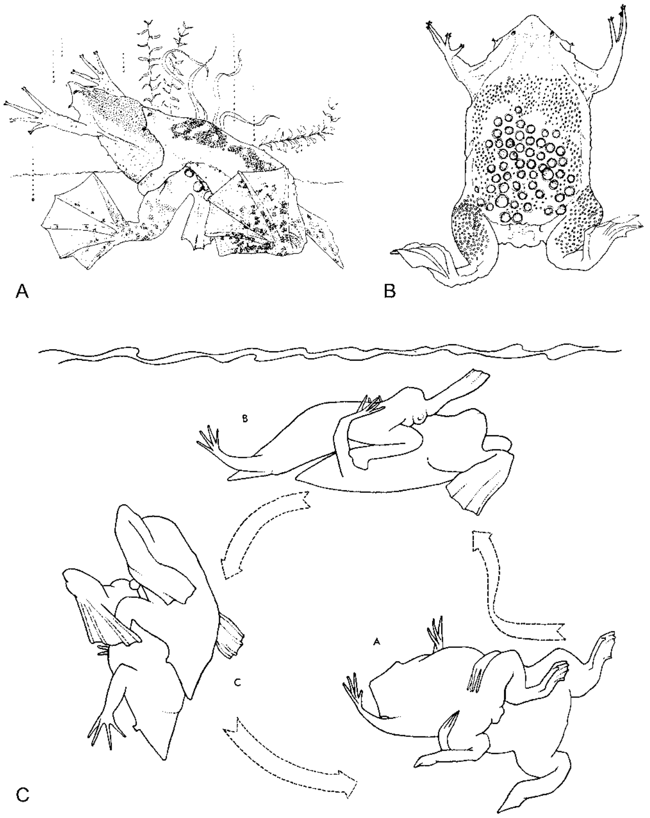

Fig. 10.12. Mating and oviposition behavior in *Pipa pipa.* (A) Male and female in amplexus. (B) Female with eggs embedded in the dorsal skin. (C) Midwater turnover that accompanies the release of each egg by the female. The released egg then catches between the male and female and is pressed into the dorsal skin of the female by the male in amplexus. Other pipids exhibit similar midwater turnovers during egglaying, but lack parental care. After Lamotte and Lescure (1977; A, B) and Rabb (1973; C).

Retention of Eggs in the Oviducts (Modes 38 and 39)

Because of the rarity of internal fertilization in anurans, it is not surprising that only a few species have evolved ovoviviparous (Mode 38) or viviparous (Mode 39) reproduction. Ovoviviparous species retain eggs in the oviducts throughout development, but nutrition to support embryonic development comes entirely from yolk reserves. This reproductive mode has been described in *Eleutherodactylus jasperi,* a bromeliad-dweller from Puerto Rico that unfortunately now appears to be extinct (Joglar 1998). This species has very large eggs typical of members of this genus and a very small clutch size (three to five eggs) that probably is due to its small body size. Development is relatively rapid, taking less than one month. Although eggs are retained in the oviducts, most features of embryonic development are very similar to that of other *Eleutherodactylus* (Drewry and Jones 1976; M. Wake 1978). It is possible that a similar reproductive mode will be discovered in other members of this genus, since the reproductive biology of most species is largely unknown.

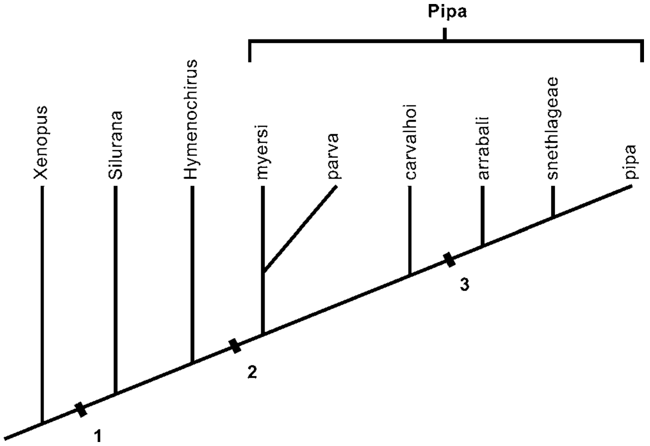

Fig. 10.11. Hypothesized phylogenetic relationships of pipid frogs, based on morphological characters. Numbers show evolutionary changes in reproductive modes. 1 = acrobatic turnovers during amplexus; eggs and larvae aquatic. 2 = acrobatic turnovers during amplexus; eggs on back of female, with aquatic larvae. 3 = acrobatic turnovers during amplexus; eggs on back of female, which undergo direct development. After Duellman (1989a).

All of the other frogs that are known to retain eggs in the oviducts are African bufonids. Traditionally all of these species were placed in a single genus, *Nectophrynoides,* along with *N. osgoodi,* an oviparous species. Dubois (1986) divided the genus into four genera on the basis of differences in reproductive mode. In his arrangement, the name *Nectophrynoides* is used only for ovoviviparous species. Currently five species are recognized—*N. viviparus, N. tornieri, N. cryptus, N. wendyi,* and *N. minutus,* but evidence for monophy of the group is weak (Graybeal and Cannatella

1995). The name *Nimbaphrynoides* was applied to two viviparous species, *N. occidentalis* and *N. liberiensis*), but other workers have continued to used the name *Nectophrynoides* for these frogs (Lamotte and Sanchez-Lamotte 1999). Dubois (1986) placed *Nectophrynoides osgoodi,* which has aquatic oviposition and free-living tadpoles, in the monotypic genus *Spinophrynoides*. He placed one species, *N. malcolmi,* in the monotypic genus *Altiphrynoides*. These frogs retain eggs in the oviducts for only a short time before being deposited on land in wet areas, where the tadpoles develop without feeding (Grandison 1978; M. Wake 1980c).

As originally conceived by Grandison (1978, 1981), these frogs were a group of closely related frogs that exhibited a graded continuum of reproductive modes, from a presumed ancestral condition of oviparity with feeding tadpoles (*N. osgoodi*) to oviparity with nonfeeding tadpoles (*N. malcomi*) to ovoviviparity and finally viviparity. M. Wake (1980c), on the other hand, suggested that the brief retention of eggs in *N. malcomi* actually is derived from an ovoviviparous ancestor that retained eggs throughout development, but did not provide them with supplemental nutrition. Unfortunately, the phylogeny of bufonids is not fully understood, and molecular data are not available for any of the African frogs with unusual reproductive modes (Graybeal 1997; some of these species are considered in the analysis of Frost et al. 2006). Morphological data suggest that all of the species with unusual reproductive modes belong to one clade, but this group also includes a number of other genera with "normal" oviparous reproduction. Thus, it is possible that the species with unusual reproductive modes are not most closely related to each other (Graybeal and Cannatella 1995; Graybeal 1997). These toads also appear to be relatively basal within the family Bufonidae, even though their reproductive modes appear to be derived.

The most derived reproductive mode appears to be that of *N. occidentalis* and *N. liberiensis,* both of which are viviparous, but it is not clear whether these evolved from oviparous or ovoviviparous ancestors (Graybeal and Cannatella 1995). The tadpoles developing inside the oviducts first use up their yolk reserves, which are less abundant than in the other species, and then feed off of "uterine milk" secretions produced by glands in the oviduct walls (Vilter and Lugand 1959; Lamotte and Xavier 1972; M. Wake 1980c; Xavier 1977, 1986). Eggs of all of the ovoviviparous and viviparous bufonids are smaller than are those of *Eleutherodactylus jasperi,* and clutch sizes are considerably larger, probably a remnant of their aquatic ancestry. Development times are long, due in part to the cold temperatures of their high-altitude habitats (M. Wake 1978, 1980c). For example, *N. occidentalis* females sometimes are pregnant during a prolonged dry season that is spent underground, and development of the young can take up to nine months (Angel and Lamotte 1944, 1948; Lamotte and Xavier 1972; Lamotte and Sanchez-Lamotte 1999).

Reproductive Modes of Urodeles

The reproductive modes of urodeles are much less diverse than those of anurans, with only 10 of the 39 modes of Haddad and Prado (2005) represented (table 10.4). In part, this reflects the much lower species diversity of urodeles, with

Table 10.4 Modes of egg deposition and development in urodeles

Egg deposition site	D&T mode	Salthe mode	Larval development	Selected examples
Aquatic eggs				
1. Still water	1	I	Feeding in ponds	*Siren, Ambystoma, Triturus*
2. Flowing water	2	II	Feeding in streams	*Dicamptodon, Eurycea, Cryptobranchus, Necturus*
Nonaquatic eggs				
17. Terrestrial nest	12	III	Feeding in ponds	*Ambystoma opacum, Ambystoma cingulatum*
18. Terrestrial nest	13	III	Larvae move to water	*Hemidactylium,* some *Desmognathus*
21. Terrestrial nest	15	III	Nonfeeding in nest	*Desmognathus aeneus*
23. Terrestrial nest	17	III	Direct development	*Desmognathus wrighti, Plethodon, Batrachoseps*
27. Arboreal nest	20	III	Direct development	*Aneides lugubris,* many Bolitoglossini
38. Eggs retained in oviducts	28		Nutrition provided by yolk	*Salamandra salamandra, Mertensiella caucasica*
39. Eggs retained in oviducts	29		Nutrition provided by mother	*Salamandra atra, Mertensiella luschani*

Sources: D&T mode indicates corresponding anuran reproductive modes from Duellman and Trueb (1986). Salthe mode indicates urodele reproductive modes of Salthe (1969).

Note: Modes are numbered as in table 10.2, but modes not found in urodeles are omitted.

only about 560 species, compared to nearly 5,300 species of anurans. Some types of reproduction, such as foam nesting, are completely absent. In addition, there are fewer arboreal species of salamanders, and they lack the diversity of reproductive modes found in arboreal frogs. All arboreal salamanders are in a single subfamily, the Plethodontinae, and most are in one tribe, the Bolitoglossini, which has undergone a large radiation in Mexico and Central America (D. Wake and Lynch 1976; D. Wake 1987; D. Wake and Elias 1983; García-Paris et al. 2000). The entire tribe is characterized by direct development of eggs laid out of water, either on land (Mode 23) or in arboreal nest sites, such as bromeliads (Mode 27). Hence, the great variety of reproductive modes seen in arboreal frogs, including hanging eggs on vegetation over water (Modes 24, 25, 26, 33) or placing them in tree holes, leaf axils, or bromeliads to hatch into feeding or nonfeeding larvae (Modes 6, 8) are simply absent in urodeles. Also not represented is any reproductive mode involving transport of eggs (Modes 9, 15, 16, 34–37) or larvae (Mode 20) on the body of a parent.

Oviposition in Still Water (Mode 1)

Oviposition in still water, such as ponds, swamps, and stream pools (Mode 1 in table 10.4; Mode I of Salthe 1969) is characteristic of many hynobiids, ambystomatids, and salamandrids, all sirenids, and a few species of plethodontids. Eggs of pond-breeding hynobiids typically are laid in paired egg sacs resembling the jelly clumps of some ambystomatid salamanders. These are laid on the pond bottom or attached to submerged logs, branches, and plant stems (Kunitomo 1910; Sasaki 1924; Thorn 1962, 1963, 1967; Kusano 1980; Saito 1987; Takahashi and Iwasawa 1988a, b, 1989b; Sato 1989; Tanaka 1989). Most pond-breeding species of *Ambystoma* have relatively short breeding seasons. Eggs are laid soon after mating, often as a single clump or several clumps attached to submerged branches and plant stems (fig. 10.13 A). Species with this mode of oviposition include *Ambystoma maculatum, A. jeffersonianum, A. texanum, A. gracile, A. annulatum* and eastern populations of *A. tigrinum* (Noble and Marshall 1929; Henry and Twitty 1940; S. Bishop 1941b, 1947; Hamilton 1948; Stebbins 1954a, 1985; Knudsen 1960; P. W. Smith 1961; Uzzell 1964; Spotila and Beumer 1970; Eagleson 1976; Petranka 1982b; Hutcherson, Peterson, and Wilkinson 1989; Kraus and Petranka 1989). As in anurans, deposition of eggs in a compact clump under water is characteristic mainly of species that breed in relatively cold water and possibly protects eggs from freezing or predators (Salthe and Mecham 1974; Ward and Sexton 1981; Morin 1983b). Thick jelly also provides some protection to eggs that are temporarily stranded in drying ponds (Marco and Blaustein 1998; Greven 2003a).

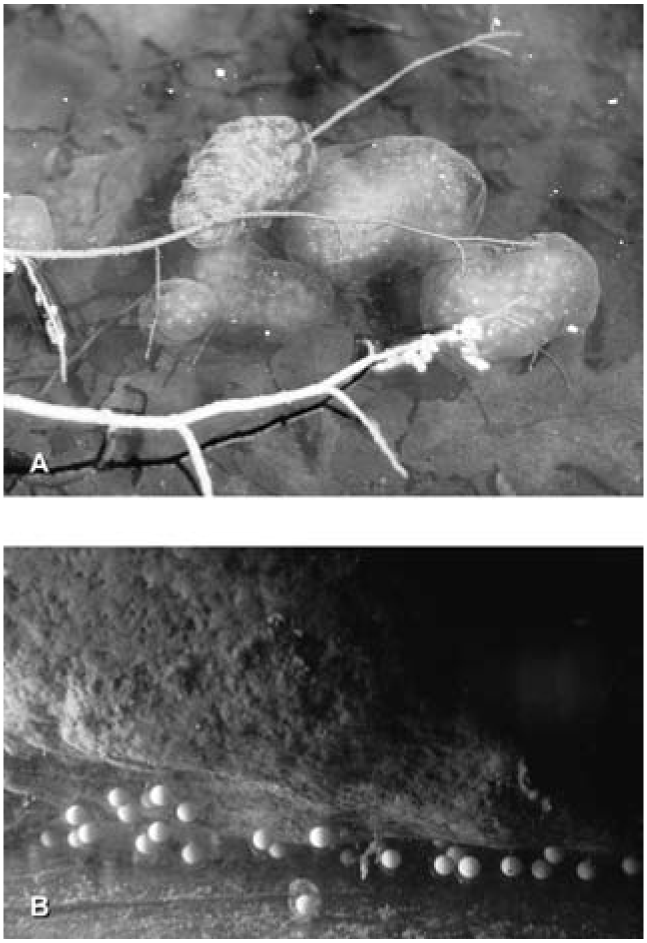

Fig. 10.13. Representative aquatic salamander eggs. (A) Eggs of *Ambystoma maculatum,* a pond-breeding salamander. Many ambystomatids produce egg masses with a thick jelly coat, usually attached to branches or other objects in the water. (B) Eggs of *Eurycea bislineata* attached to a rock. Each egg is individually attached by a short stalk. The lack of pigment is characteristic of eggs laid in hidden locations where the eggs are not exposed to direct sunlight. Photos by Kentwood D. Wells.

Other ambystomatids scatter individual eggs on the bottom of a pond or attach them to grass stems and other substrates. Species with this type of oviposition include *A. mabeei, A. laterale,* and some hybrid combinations of *A. laterale, A. jeffersonianum, A. texanum,* and *A. talpoideum.* In western North America, *A. californiense,* some populations of *A. tigrinum,* and low-altitude populations of *A. macrodactylum* also lay eggs individually (Bishop 1941b, 1947; Stebbins 1954a, 1985; H. M. Smith 1956; Uzzell 1964; J. Anderson 1967; J. Hardy 1969; Bogart et al. 1987). High-altitude populations of *A. macrodactylum* lay eggs attached in clusters to the undersides of logs, rocks, and other objects in relatively deep water, a possible adaptation to avoid late-spring freezes (J. Anderson 1967). Populations in Oregon tend to lay eggs mostly in small clumps of 5–25 eggs (Kezer and Farner 1955; Ferguson 1961; J. Anderson 1967; Walls et al. 1993). Variation in egg-laying behavior has been reported in other species as well. For example, *A. talpoideum* has been reported laying eggs either in small clumps of up to 40 eggs (Bishop 1947; Mosimann and Uzzell 1952; Shoop 1960) or scattered individually on the pond bottom (Semlitsch 1985b). Some females of *A. texanum* also lay eggs singly, even though oviposition in clumps is more common (Petranka 1982b; Kraus and Petranka 1989). Some of this variation can be attributed to differences in the availability of suitable objects such as branches to which egg masses can be attached, variation in movements of females during egg deposition, and amount of disturbance of egg-laying females by other salamanders (Bragg 1957b; Spotila and Beumer 1970). Scattering of eggs also appears to be more common in species breeding in warm water, where compact egg masses might become hypoxic.

Most pond-breeding salamandrids have relatively long breeding seasons; individual females sometimes lay eggs over a period of days or weeks, a habit that allows them to disperse their eggs in both time and space. Two species of newts from western North America, *Taricha torosa* and *T. granulosa,* breed in ponds and slow-moving streams. *Taricha torosa* lays eggs in spherical jelly clumps of about 15–20 eggs, whereas *T. granulosa* scatters individual eggs on the bottom of a pond (Twitty 1942, 1966; Stebbins 1954a; Brame 1968; Marshall, Doyle, and Kaplan 1990). The European salamandrid *Pleuodeles waltl* lays eggs either singly or in small clumps attached to plants and stones (Steward 1969). One member of the genus *Neurergus,* found in the Middle East, breeds in ponds and stagnant stream pools. The other members of the genus are all stream breeders, so pond breeding appears to be derived in this group (Steinfartz et al. 2002). Most European newts of the genus *Triturus* breed in ponds, although some, such as *T. boscai,* sometimes breed in streams as well (Orizaola and Braña 2003a).

Many pond-breeding salamandrids, including eastern North American newts (*Notophthalmus*) and Eurasian newts (*Triturus, Paramesotriton, Cynops*) attach eggs to underwater plants. They either wrap leaves around individual eggs, or place rows of eggs between two grass blades (P. H. Pope 1924; Tsutsui 1931; S. Bishop 1941b, 1947; Romer 1951; Steward 1969; Salthe and Mecham 1974; G. Bell and Lawton 1975; Sparreboom 1984c; Diaz-Paniagua 1986, 1989b; Miaud 1995; Orizaola and Braña 2003a; Norris and Hosie 2005). Experiments with *Triturus* showed that wrapped eggs enjoyed higher survivorship than unwrapped eggs. There was a reduction in predation by female newts and by one species of water beetle (*Acilius sulcatus*), but another water beetle, *Dytiscus marginalis,* fed heavily on both wrapped and unwrapped eggs (Miaud 1993, 1994). Other experiments with dragonfly naids (*Aeshna cyanea*) also showed that wrapping protects eggs from predation (Orizaola and Braña 2003a).

All sirenids breed in still or slow-flowing water and typically inhabit heavily vegetated, swampy ponds and ditches. The eggs of *Pseudobranchus* are attached individually to leaves, stems, and roots of underwater plants (Noble and Marshall 1932; Carr 1940; S. Bishop 1941b), whereas those of *Siren* are deposited in clumps in tangled mats of roots and other vegetation (Noble and Marshall 1932; Godley 1983). A few species of plethodontid salamanders also are found mainly in swampy habitats. One example is *Eurycea quadridigitata,* which is unusual for members of this genus, because it migrates seasonally to ponds and swamps to breed (Semlitsch and McMillan 1980). Eggs have been found attached to the undersides of a submerged log in a pond (Carr 1940), among leaves and debris in seepage areas (Brimley 1923), and on wet logs several centimeters above the water (Goin 1951). Hence, both reproductive Mode 1 and Mode 18 have been observed in this species. The same is true for *Stereochilus marginatus,* another inhabitant of swamps and ditches. Noble and Richards (1932) reported that eggs of this species are attached to logs, bark, or other objects in the water (Mode 1). Both A. Schwartz and Etheridge (1954) and Rabb (1956) found eggs under logs at the edges of ponds and above the water line (Mode 18), and J. Wood and Rageot (1963) found eggs both in the water and above the water line. Another plethodontid, *Pseudotriton montanus,* is found mainly in swampy bottomlands, sluggish streams, and ponds at low elevations in the southeastern United States (Bruce 1975). Eggs have been found attached to rootlets, dead leaves, and other objects in muddy seepage areas (Fowler 1946; S. Bishop 1947).

Oviposition in Flowing Water (Mode 2)

Most other salamanders with aquatic eggs breed in some sort of flowing water, from mountain torrents to large rivers (Mode 2 in table 10.4; Mode II of Salthe 1969). These include all cryptobranchids, proteids, dicamptodontids, and rhyacotritonids, and some hynobiids, ambystomatids, salamandrids, and plethodontids. In contrast to many pond-breeding urodeles that lay their eggs in exposed locations (some newts being an exception), most Mode 2 species hide their eggs, usually under rocks (Salthe 1969). Cryptobranchids lay eggs in rosary-like strings in cavities under rocks in rivers and large streams (Kerbert 1904; B. G. Smith 1907; Tago 1929; Bishop 1941b; Nickerson and Mays 1973b). Eggs of stream-breeding hynobiids are similar to those of pond-breeding species, being laid in large jelly sacs attached to rocks or lying in quiet stream pools (Oyama 1929; Liu 1950; Sparreboom 1979; Steward 1969; Akita 1989; Griffin and Solkin 1995; Serbinova and Solkin 1995).

Other large-bodied stream-breeding salamanders typically attach individual eggs in clusters to the undersides of flat stones, logs, branches, or roots. Species with this type of oviposition behavior include *Necturus, Proteus, Ambystoma barbouri, A. ordinarium, A. rosaceum, A. rivularis,* and several other species of *Ambystoma* from the mountains of Mexico (S. Bishop 1926, 1941b, 1947; K. Fitch 1959; Briegleb 1962; H. Campbell and Simmons 1962; Shoop 1965; J. D. Anderson and Worthington 1971; Brandon and Altig 1973; J. D. Anderson and Webb 1978; Ashton and Braswell 1979; Durand 1986; Kraus and Petranka 1989; Sih and Maurer 1992). Some small stream-breeders also attach their eggs in clusters to the undersides of rocks, roots, or dead vegetation. These include *Eurycea* (fig. 10.13 B), *Gyrinophilus, Pseudotriton, Desmognathus marmoratus, Desmognathus quadramaculatus,* and *Taricha rivularis* (C. H. Pope 1924; Wilder 1924; Bishop 1941b, 1947; Twitty 1942, 1966; Mohr 1943; J. Wood 1950, 1953a; J. Wood and McCutcheon 1954; Organ 1961a; Franz 1964; Spotila and Ireland 1970; Ireland 1974, 1976).

Other stream-breeding salamanders lay their eggs in even more cryptic locations. For example, some Old World salamandrids, including *Paramesotriton caudopunctatus, Euproctus,* and *Calotriton,* attach their eggs individually to the undersides of rocks or place them in crevices, inserting them with a protruding cloaca that the female develops in the breeding season (Sparreboom 1983; Thiesmeier and Hornberg 1986, 1990). Two genera of salamanders found only in streams in the Pacific Northwest region of North America, *Dicamptodon* and *Rhyacotriton,* often lay eggs in holes and crevices well underground in springs and seepage areas, often several meters from the main streams where the larvae complete their development (Nussbaum 1969a, b; Nussbaum and Tait 1977). Some species of *Rhyacotriton* also lay eggs under rocks in the main channels of streams (Karraker 1999; MacCracken 2002; Russell et al. 2002). Small *Dicampton* larvae are very cryptic, sometimes living in the spaces between rocks 30 centimeters or more below the beds of streams (Feral, Camann, and Welsh 2005). In at least some populations of the Japanese hynobiid salamander *Hynobius naevius,* large yolky eggs are laid in underground streams, where larvae develop without feeding (Tanabe 2002, cited in Tominaga, Nishikawa, and Sato 2003).

The antipredator advantages of cryptic oviposition in stream-breeding salamanders seem clear (Nussbaum 1985), but other factors, such as current velocity or silt formation, also might be important. In experimental studies with stream-breeding populations of *Ambystoma barbouri,* Sih and Maurer (1992) exposed some clusters of eggs by overturning rocks and left others in cryptic locations on the undersides of rocks. About 93% of the hidden eggs survived to hatching, whereas almost 98% of the exposed eggs died, mostly because of desiccation or being washed away in the current. Accumulation of silt on exposed egg clutches did not appear to have much effect on survivorship, and the effects of predation were not considered.

Nonaquatic Oviposition with Aquatic Larvae (Modes 17, 18, and 21)

Salamanders in several families have independently evolved nonaquatic modes of oviposition, although some retain an aquatic larval stage. Presumably, the selective pressures favoring this shift are the same as those already discussed for anurans. Salthe (1969) had difficulty placing species with terrestrial eggs and aquatic larvae in his scheme of reproductive modes, but generally assigned them to either Mode I (pond-breeders) or Mode II (stream-breeders) on the basis of larval adaptations, regardless of where their eggs are laid. Several urodeles lay eggs in nests that are later flooded, allowing larvae to complete their development in the water (Mode 17). These include *Ambystoma opacum, A. cingulatum,* and probably all three species of *Amphiuma.* The two ambystomatids resemble Australian frogs in the genus *Pseudophryne* in that eggs are laid during the fall in low-lying areas that will later be flooded by winter rains. *Ambystoma opacum* females remain with the eggs until they are flooded (Noble and Brady 1933; Petranka and Petranka 1980; M. Jackson, Scott, and Estes 1989), whereas *A. cingulatum* females scatter their eggs under logs, leaf litter, sphagnum mats, or on the bare ground and desert them (J. Anderson and Williamson 1976). In *Amphiuma,* eggs are laid in depressions in dried-up swamps, holes under logs near ponds, and similar locations that are flooded by spring and summer rains. The female apparently stays with the eggs until they are flooded, sometimes for several months (J. A. Weber 1944; Bishop 1947; C. Baker 1945; Fontenot 1999). Larvae hatch at an advanced stage of development once the eggs are flooded, and retain their gills for only about two weeks before undergoing metamorphosis (Ultsch and Arceneaux 1988; Gunzburger 2001, 2003).

A somewhat similar mode of reproduction (Mode 18) is found in several species that lay their eggs just above the water line or at the edges of ponds or streams. The larvae hatch in the terrestrial nest and wriggle or flip themselves into the water to complete development. In addition to *Stereochilus marginatus* and *Eurycea quadridigitata,* which appear to exhibit both Mode 1 and Mode 18 reproduction (see the previous discussion), this mode is found in *Hemidactylium scutatum,* which lays eggs in sphagnum moss over or adjacent to standing water (see fig. 11.12 C in chapter 11). Larvae hatch at a relatively early stage (with only the front legs well developed) and drop into the water to complete development (Blanchard 1933b, 1936; Bishop 1941b; P. Gilbert 1941; J. Wood 1953a; R. Harris and Gill 1980).

Mode 18 reproduction also is found in *Echinotriton andersoni,* a salamandrid from the Ryukyu Islands of Japan. Eggs are laid under leaf litter at the edges of ponds, puddles, and springs. The larvae creep about in the mud until they are able to make their way into the water, where they undergo typical aquatic larval development (Utsunomiya and Utsunomiya 1977; Utsunomiya, Utsunomiya, and Kawachi 1978; Nussbaum and Brodie 1982). In the only other member of this genus, *E. chinhaiensis* from China, eggs are laid in moist detritus up to 180 cm from the edges of ponds. The larvae apparently complete development on land, although it is possible that some larvae make their way into the ponds or are washed into the water by rain (Xie et al. 2000).

This mode of reproduction also is characteristic of species of *Desmognathus* that lay their eggs in seepage areas or cavities under rocks, moss, roots, or leaf litter at the edges of streams and swamps. These include *D. fuscus, D. ochrophaeus, D. ocoee, D. orestes, D. monticola,* and several other species. The larvae hatch at a relatively advanced stage (all four legs well developed) and remain with the mother in the nest for several days before eventually moving to water (Bishop 1941b, 1947; Hairston 1949; Organ 1961c; Petranka 1998). Another species, *D. aeneus,* is even less dependent on standing water, and lays eggs that hatch into advanced larvae that complete development in the nest without feeding or moving to water (Mode 15; Valentine 1963; J. R. Harrison 1967).

Nonaquatic Oviposition with Direct Development (Modes 23 and 27)

Complete emancipation from standing water has been achieved by salamanders that lay nonaquatic eggs that undergo direct development within the egg capsule (Mode III of Salthe 1969). Direct development occurs only in plethodontids. It has been reported in one desmognathine species (*Desmognathus wrighti;* Organ 1961b) and is presumed to occur in a fossorial desmognathine, *Phaeognathus hubrichti,* although complete egg development has not been observed in this species (Brandon 1965a; Petranka 1998). All of the other salamanders with direct development are members of the plethodontine tribes Plethodontini and Bolitoglossini, and all members of these tribes have this mode of reproduction. This probably accounts for their ecological success in invading a variety of habitats, from relatively dry regions to tropical cloud forests (Wake and Hanken 1996). Indeed, more than 300 of the approximately 377 species of plethodontid salamanders are members of these two tribes, and the proportion is sure to increase as additional tropical species are described.

All salamanders with direct development lay large, unpigmented eggs in hidden locations. The large size of eggs, along with a very large genome size, especially in bolitoglossines (Jockusch 1997), results in prolonged periods of embryological development and probably favors the evolution of parental care (see chapter 11). Females remain with the eggs in most species, but some species of *Batrachoseps* and some Neotropical bolitoglossines apparently lack parental care. In terrestrial breeders (Mode 23), eggs usually are laid in small clusters in underground cavities, rock crevices, or inside hollow logs (Bishop 1941b, 1947; Kessel and Kessel 1942; L. Miller 1944; Stebbins 1949, 1954a; J. Davis 1952; R. Gordon 1952; Dumas 1955; A. Schwartz 1955; Highton 1956, 1962; Johnston and Schad 1959; Livezey 1959; Organ 1960b; McDiarmid and Worthington 1970; Houck 1977a, b).

Arboreal species (Mode 27), which are found mostly in Mexico and Central America, deposit their eggs under mats of mosses and liverworts on tree limbs, in bromeliads, and other cryptic sites, but the oviposition sites of most tropical salamanders remain unknown (Robinson 1976; Houck 1977b; D. Wake 1987). Some species, such as *Nototriton picadoi,* deposit eggs in mats of moss in both terrestrial and arboreal sites (Bruce 1998). Clutches of *N. barbouri* eggs have even been found in abandoned hummingbird nests, which were lined with moss like that normally used as oviposition sites by these salamanders (McCranie and Wilson 1992). At least some species of *Nototriton* and perhaps some other Neotropical salamanders appear to lack parental care (Bruce 1998). *Aneides lugubris,* an arboreal salamander from western North America, lays eggs in terrestrial sites, decaying logs, or hollow trees as much as 10 meters above the ground (Bishop 1947; L. Miller 1944; Stebbins 1954a), while the eggs of *A. vagrans* have been found in hollow spaces in fallen logs (T. Davis 2003).

It is not entirely clear how many times plethodontid salamanders have evolved reproductive modes that lack an aquatic larval stage. It has long been assumed that aquatic reproduction represents the ancestral condition for all plethodontids (Dunn 1926c). Most plethodontids with fully aquatic reproduction breed in streams, and it has been proposed that the relatively large eggs of stream breeders is a prerequisite for the eventual evolution of fully terrestrial reproduction (Collazo and Marks 1994; D. Wake and Hanken 1996). Nevertheless, phylogenetic analyses suggest that nonaquatic reproduction could have evolved more than once in the family, and indeed, there could have been some reversals from direct development back to reproductive modes with an aquatic larval stage.

The subfamily Desmognathinae is especially problematic. Traditionally, most authors have followed Dunn (1926c) and Organ (1961c) in assuming that aquatic oviposition and aquatic larvae, as exhibited by *Desmognathus marmoratus* and *D. quadramaculatus,* represent the ancestral condition for the entire subfamily. Most members of the genus *Desmognathus* lay eggs in wet seeps or along the sides of streams, but retain aquatic larvae. This has been considered the next step toward fully terrestrial reproduction. Nonaquatic oviposition and loss of aquatic larvae would then represent the most derived condition, perhaps having evolved independently in two species of *Desmognathus* (*D. wrighti* and *D. aeneus*) and in *Phaeognathus hubrichti.*

Molecular phylogenetic studies of the subfamily by Titus and Larson (1996) and Chippindale et al. (2004) suggested that this view of the evolution of reproductive modes is incorrect. Titus and Larson (1996) found that *Phaeognathus* is a basal desmognathine, and both *D. wrighti* and *D. aeneus,* the two species in the genus *Desmognathus* that lack aquatic larvae, are basal species within that genus, not the most derived species as often assumed (see also Kozak et al. 2005). One implication of this phylogeny is that nonaquatic reproduction is ancestral for the entire desmognathine clade, with metamorphosis and aquatic larvae having re-evolved secondarily. The analysis of Chippindale et al. (2004) also supported the idea of an aquatic life history having re-evolved in *Desmognathus,* because the entire desmognathine clade appears to have been derived from within a clade of direct-developing plethodontines (fig. 10.14). Traditionally the tribes Plethodontini and Bolitoglossini have been considered closely related, with a single origin of direct development (D. Wake and Hanken 1996), but the analysis of Chippindale et al. (2004) suggests direct development could have evolved independently in these two clades. An alternative is that a reversal to an aquatic life history occurred more than once, with most of the hemidactyline salamanders having reverted to this type of life history from a direct-developing ancestor.

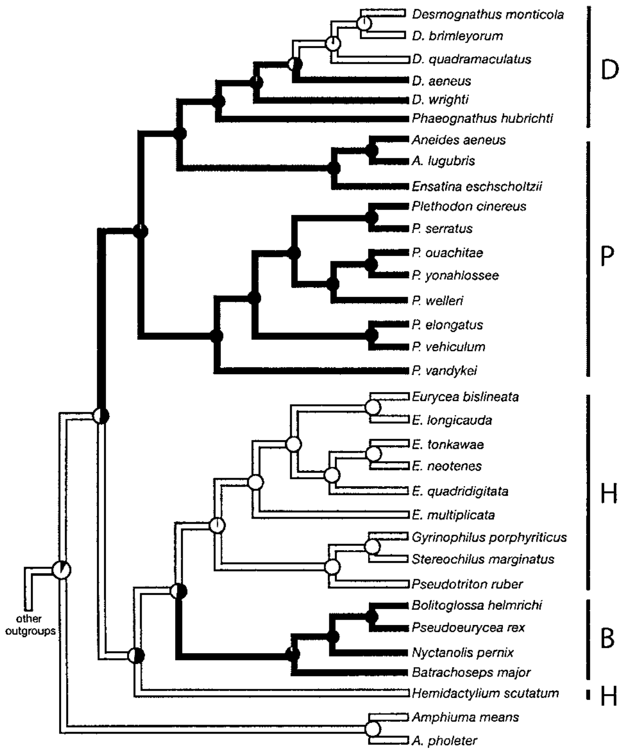

Fig. 10.14. Phylogeny of plethodontid salamanders, based on the single most parsimonious tree dervived from both nonmolecular characters and mitochondrial and nuclear DNA sequences. Branch shading shows modes of development (light = free-living aquatic larvae; dark = direct development). This phylogeny suggests the reevolution of an aquatic life history in desmognathines, which appear to be derived from within a clade of direct-developing salamanders. Abbreviations indicate traditional subfamilies and tribes, some of which appear not to be monophyletic. D = Subfamily Desmognathinae; P = Tribe Plethodontini; H = Tribe Hemidactyliini; B = Tribe Bolitoglossini. From Chippindale et al. (2004).

Additional phylogenetic analyses and comparative studies of embryological development are needed to resolve the question of how many times direct development and aquatic larval development have evolved in the plethodontids. There are major differences in patterns of development in the Desmognathinae, Plethodontini, and Bolitoglossini that suggest the possibility of independent origins of direct development in these three clades. In general, desmognathines show much greater retention of some features of larval development in direct-developing embryos than do the other two clades (Marks and Collazo 1998). The bolitoglossines exhibit the most fully derived pattern of development and the greatest loss of larval structures, including the hyobranchial apparatus (D. Wake and Hanken 1996).

The loss of larval structures has, in turn, led to extensive repatterning of development. For example, the loss of larval hyobranchial structures involved in larval feeding in bolitoglossines has resulted in extensive repatterning of the entire hyobranchial skeleton and the precocious development of the tongue well before hatching occurs. It also has allowed for the evolution of a freely projectile tongue and increased reliance on the tongue for prey capture (Lombard and Wake 1977; D. Wake 1982; see also chapter 1). There have been major changes in patterns of development of the nervous and sensory systems as well, and these changes are associated with the evolution of enhanced visual acuity and changes in motor performance associated with prey capture (G. Roth and Wake 1985b; D. Wake and Hanken 1996). Finally, there have been changes in patterns of limb development associated with loss of free-living larvae. Specifically, direct-developing salamanders exhibit accelerated hind limb development, with hind limb buds appearing at about the same time as forelimb buds (D. Wake and Marks 1993; D. Wake and Shubin 1994; D. Wake and Hanken 1996).

Retention of Embryos in the Oviducts (Modes 38 and 39)

Despite the nearly universal occurrence of internal fertilization in urodeles, only a few species have evolved reproductive modes in which embryos are retained in the lower part of the oviduct (uterus) for most or all of development. Indeed, all of these species are members of a single clade consisting of two genera of terrestrial salamandrids, *Salamandra* and *Mertensiella* (Griffiths 1996; Greven 2003b). Nevertheless, ovoviviparous and viviparous reproduction apparently has evolved independently a number of times within this clade, because there is considerable variation in reproductive modes even within a single species. The distinction between ovoviviparous and viviparous reproduction becomes somewhat blurred in these salamanders, because the two modes tend to grade into one another because of the unusual number of ways in which developing embryos receive nutrients.

Mertensiella caucasica exhibits the least specialized mode of reproduction because it retains the oviparous habits of most salamanders. Eggs are deposited in sheltered locations in streams and hatch into larvae that complete development in the water (Muskhelishvili 1964; Schultschik 1994). The other species traditionally placed in this genus, *M. luschani,* is considered by recent authors to be a member of the genus *Salamandra* (Weisrock et al. 2001). This species is viviparous, so placement of this species in *Salamandra* means that viviparity occurs only in that genus. Only two fertilized eggs develop inside the female, one in each oviduct, where the embryos remain for 5–12 months before emerging as fully metamorphosed young (Özeti 1973, 1979). The mode of nutrient provisioning has not been studied in detail, but the developing young presumably rely mainly on yolk reserves early in development. Later, the larvae are known to feed on the remains of unfertilized eggs in the oviducts (Guex 1994).

The genus *Salamandra* currently includes six species, *S. salamandra, S. atra, S. lanzai, S. algira, S. corsica,* and *S. luschani,* but there is considerable debate about the taxonomic status of many described subspecies (Griffiths 1996). *Salamandra salamandra* exhibits considerable geographic variation in size, color pattern, and mode of reproduction. Over much of its range, this species is ovoviviparous. Females retain relatively large numbers of developing embryos in an enlarged portion of the oviduct (the uterus) that serves as little more than a brood chamber. The embryos are surrounded by jelly like that of aquatic-breeding salamanders and derive all of their nutrition from yolk reserves. Once these reserves are exhausted, the larvae are born and complete their development in a pond or stream (Joly 1968, 1971, 1986; Greven and Guex 1994; Joly, Chesnel, and Boujard 1994; Warburg 1994; Degani and Warburg 1995; Greven 1998, 2003b; Dopazo and Korenblum 2000; Rebelo and Leclair 2003a; Weitere et al. 2004).

Some populations of *S. salamandra* have evolved a more derived form of viviparous reproduction. Females retain much smaller numbers of embryos in the uterus and give birth to nearly or fully metamorphosed young (Joly 1968, 1971, 1986; Fachbach 1969, 1976; Greven 1976, 1977, 1998, 2003b; Depazo and Korenblum 2000). As in ovoviviparous populations of this species, the developing embryos initially depend on yolk reserves, but after these are exhausted, the larvae hatch and remain in the uterus. There they feed on the remains of unfertilized eggs, as in *S. luschani,* or on smaller siblings (Joly 1968, 1986; Fachbach 1969, 1976; Dopazo and Alberch 1994; Greven 1998, 2003b). Some authors have argued that viviparity in this species is found mostly in high-altitude populations, and the production of a few large young is thought to be an adaptation to relatively harsh terrestrial environments (Gasser and Joly 1972; Joly, Chesnel, and Boujard 1994; Veith et al. 1998). In Spain, however, both modes of reproduction occur in populations of *Salamandra salamandra* that are genetically similar and geographically close to one another, and viviparity does not appear to be associated with altitude (Alcobendas, Dopazo, and Alberch 1996; Dopazo, Boto, and Alberch 1998; Dopazo and Korenblum 2000; García-París et al. 2003).

Salamandra atra and *S. lanzai* are viviparous and give birth to fully metamorphosed terrestrial juveniles. Both of these species are inhabitants of cool montane habitats and have an extraordinarily long gestation period (up to five years in some populations). In *S. atra,* only a single egg is fertilized in each oviduct. The remaining unfertilized eggs break apart and are fed upon by the two developing larvae. Eventually, additional nutrition is provided by secretions of the oviduct walls. The larvae use specialized teeth to scrape material from the epithelium of the uterus (Vilter and Vilter 1960, 1962, 1964; Häfeli 1971; Guex and Chen 1986; Vilter 1986; Guex 1994; Guex and Greven 1994; Greven 1998, 2003b).

Reproductive Modes of Caecilians

The reproductive biology of caecilians is poorly understood because most species are fossorial and seldom encountered in the field. The basic reproductive mode of many species is unknown. Most information on caecilian reproduction comes from studies of captive individuals, and the eggs, larvae, and juveniles of most species have never been seen in the field. However, there is enough information to suggest general distributions of reproductive modes in the group (M. Wake 1977b, 1992; Wilkinson and Nussbaum 1998). The Rhinatrematidae of South America are generally considered the most basal living caecilians (Duellman and Trueb 1986; Nussbaum and Wilkinson 1989; Frost et al. 2006), and all appear to be oviparous. Free-living larvae of several species in the genus *Epicrionops* have been found in streams, and *Rhinatrema* is assumed to have aquatic larvae as well. However, oviposition sites have not been reported for any members of this family. The family Ichthyophiidae of southeastern Asia is also considered to be a relatively basal group and appears to be exclusively oviparous with aquatic larvae. Eggs are not laid in the water, but most commonly are placed in burrows or under mats of vegetation at the margins of bodies of water, where they are attended by the female. Larvae eventually make their way to water after hatching (Sarasin and Sarasin 1887–1890; M. Wake 1977b; Kupfer, Nabhitabhata, and Himstedt 2004). Hence, reproduction in these species most closely resembles reproductive Mode 18. The largest family of caecilians is the Caeciliidae, a largely terrestrial and fossorial group. This family exhibits the widest range of reproductive modes, with both oviparous and viviparous species. Larval stages have been reported for a few species in this family, but many others apparently lay terrestrial eggs that undergo direct development (Mode 23). Genera known or assumed to have direct development include *Idiocranium, Grandisonia, Hypogeophis, Siphonops* (Goeldi 1899; Gans 1961; M. Wake 1977b, 1989b; Delsol 1986), and at least some species of *Caecilia* (Funk et al. 2004).

Viviparity (Mode 39) apparently has evolved independently several times in caecilians, but the details are hard to unravel because of major gaps in our knowledge of reproductive modes and uncertainty about the phylogenetic relationships of the major caecilian clades (Nussbaum and Wilkinson 1989; Hass, Nussbaum, and Maxson 1993; M. Wake 1993b; Frost et al. 2006). Viviparity is known in some caeciliids, and one species, *Dermophis mexicanus,* has been the subject of detailed studies of reproduction and embryological development (M. Wake 1977a, b, 1980a, b, 1992; M. Wake and Hanken 1982). Viviparity is thought to be characteristic of all typhlonectids as well, a group of aquatic caecilians found only in South America, as well as members of the small African family Scolecomorphidae, a terrestrial group (M. Wake 1977a, b; both typhlonectids and scolecomorphids were placed in the family Caeciliidae by Frost et al. 2006). In all of these viviparous species, early embryological development is supported by yolk reserves, but these are soon exhausted. Lipid-rich secretions produced by the walls of the oviducts (uterus) provide additional nutrition. These secretions are directly ingested by the developing larvae, which scrape cells from the oviduct wall with special fetal teeth. The teeth become fully developed at about the same time that the oviduct begins secreting nutrients (M. Wake 1977a, 1980a, b, 1989b, 1992; Welsch, Muller, and Schubert 1977; M. Wake and Hanken 1982; Exbrayat, Delsol, and Lescure 1983). Gestation lasts for many months, and the newborn young typically are very large relative to the size of the female, indicating a considerable energetic investment by the mother (M. Wake 1977a; Exbrayat, Delsol, and Flatin 1981, 1982). *Typhlonectus* larvae develop enormous, highly-vascularized, sac-like gills that probably are used for gas exchange across the mother's uterine wall and possibly is used for uptake of nutrients as well (Delsol, Flatin, Exbrayat, and Bons 1981, 1983; Delsol, Exbrayat, Flatin, and Gueydan-Baconnier 1986; M. Wake 1992). In contrast to viviparous salamandrids, developing caecilian larvae are not known to consume undeveloped eggs in the oviducts (M. Wake 1989b).

Interspecific Variation in Egg Size, Clutch Size, and Reproductive Effort

Since the nineteenth century, biologists have recognized that different reproductive modes in amphibians are associated with different numbers and sizes of eggs. Boulenger (1886) noted that aquatic egg-layers typically have smaller eggs and lay more of them than do terrestrial egg-layers. Several later workers attempted to synthesize information on variation in egg and clutch size, most notably Salthe (1969) and Kaplan and Salthe (1979) on urodeles, Crump (1974) and Duellman (1978) on Neotropical anurans, and Salthe and Duellman (1973) and Duellman and Trueb (1986) on all anurans. Hödl (1990b) tabulated data for 130 species of lowland Amazonian anurans, but did not attempt a detailed analysis of the data. Tilley (1968) examined both intra- and interspecific size-fecundity relationships in desmognathine salamanders, while Kuramoto (1978a) did the same for 12 species of Japanese urodeles and anurans. M. Wake (1978) analyzed the relationship of egg size and clutch size to body size in the genus *Eleutherodactylus.* Barbault (1984) presented an interspecific analysis for 17 species of anurans from West Africa, contrasting aquatic breeders with species that lay eggs out of water. Lang (1995) examined the relationship of body size to egg size and clutch size in several genera of stream-breeding hylids from Middle America. Many other studies have examined size-fecundity relationships in individual species (see the following citations). The following discussion reexamines some of the patterns revealed by these studies and presents some new statistical analyses of egg and clutch sizes for a limited number of reproductive modes.

Duellman and Trueb (1986) summarized several conclusions about the relationship of body size, egg size, and clutch size that emerged from the studies cited previously: (1) Within a given reproductive mode, there is a positive correlation between clutch size and female body size. (2) Within a given reproductive mode, there is a positive correlation between ovum size and female body size. (3) Regardless of reproductive mode, there is a negative correlation between clutch size and ovum size. (4) Regardless of reproductive mode, there is a positive correlation between ovum size and size of hatchlings. In addition, total clutch volume does not appear to be related to reproductive mode, but is tightly correlated with body size for all modes.

While these generalizations probably are correct in some instances, most of the studies from which these conclusions have been drawn are flawed in one way or another. None of the papers presents a statistical analysis of differences in egg size and clutch size within or among reproductive modes. Some of the studies, including the major reviews by Salthe (1969) and Salthe and Duellman (1973), do not present either the original data or regression equations relating egg and clutch size to body size. Instead, conclusions are drawn from visual inspection of scatter plots. Some studies have not accounted for variation in body size in comparisons among reproductive modes. For example, Duellman (1978) and Hödl (1990b) presented a comparison of mean egg size and clutch size for anurans with several different reproductive modes. However, since both of these variables covary with body size, such comparisons are not very informative.

Finally, all of these studies grouped together amphibians with similar reproductive modes without regard to phylogeny, making it impossible to discern patterns of evolutionary change within particular clades. In Kuramoto's (1978a) study, for example, urodeles and anurans were combined into one regression analysis, obscuring any differences between the two orders. In other studies, apparent differences among reproductive modes could simply reflect the influence of a single family or genus on the data set. I have attempted to partially control for taxonomic differences by presenting analyses both for individual families or genera and for several families or genera combined. This procedure cannot be considered a true phylogenetic analysis (P. Harvey and Pagel 1991), because it simply uses a hierarchical classification of families, genera, and species as currently accepted by taxonomists. This classification does not necessarily reflect true phylogenetic relationships, which are constantly being revised (see Frost et al. 2006). For example, several of the largest anuran families that are well represented in the data set, including the ranids and leptodactylids, probably are not monophyletic groups, and the relationship of genera within these groups is uncertain (Ford and Cannatella 1993; Frost et al. 2006). The analysis presented here should be treated as a descriptive summary of the data, not a definitive analysis of evolutionary trends. My hope is that these patterns will provide raw material for more detailed phylogenetic analyses of life-history traits, something that is not yet possible for most groups because of incomplete information on reproductive modes, or uncertainties about phylogenetic relationships. Once we have more robust phylogenies of large families such as Hylidae, Ranidae, and Leptodactylidae, these data should be reanalyzed using modern comparative methods (see further discussion in the last section of the chapter).

Interspecific Variation in Egg and Clutch Size in Anurans

The data used in my analyses are heavily weighted toward Neotropical species, because these have been studied in more detail than other groups (Crump 1974; Duellman 1978; Hödl 1990b) and North American anurans, taken mainly from A. Wright and Wright (1949). Since this book did not give mean snout-vent lengths, I used the midpoint of the body size range to approximate the mean. Most measurements of egg diameters are based on mature ovarian eggs and do not include jelly capsules surrounding the eggs. In some cases, only diameters of deposited eggs were available, but data were used only when the diameter of the egg itself, without the jelly capsules, was given. Some of the variation among species probably is due to differences in measurement procedures in the original studies. Certain common genera such as *Bufo, Hyla, Rana,* and *Eleutherodactylus* tend to be overrepresented in the data set, whereas little information is available for many other taxa. I have focused on several of the most common reproductive modes: pond-breeding species (Mode 1), species with terrestrial or arboreal eggs that undergo direct development (Modes 23 and 27), and species that lay nonaquatic eggs that hatch into tadpoles (Modes 18–21 and 24–25), because these are the only reproductive modes with sample sizes large enough for statistical analysis. In all of the regression analyses in the following discussions, I used natural logarithms of snout-vent length, egg size, and clutch size to improve the fit to a linear model (data tables and statistical analyses are available from the author).

For some reproductive modes, both egg size and clutch size are positively correlated with body size among species. For Mode 1 anurans as a group and for three families individually (Bufonidae, Hylidae, and Ranidae), clutch size was much more strongly correlated with body size than was egg size (fig. 10.15). The same was true for anurans with direct development (Modes 23 and 27). There were significant differences among families in both egg size and clutch size after adjusting for differences in body size. Bufonids have smaller eggs than do hylids, hyperoliids, and ranids (fig. 10.15 top), but the other families did not differ from each other statistically. This pattern reflects a general tendency for egg size to vary much less than clutch size among species of anurans. This suggests that the evolution of egg size is constrained within fairly narrow limits within reproductive modes, whereas clutch size is free to vary with changes in body size.

Mode 4 hylids were not analyzed separately because only

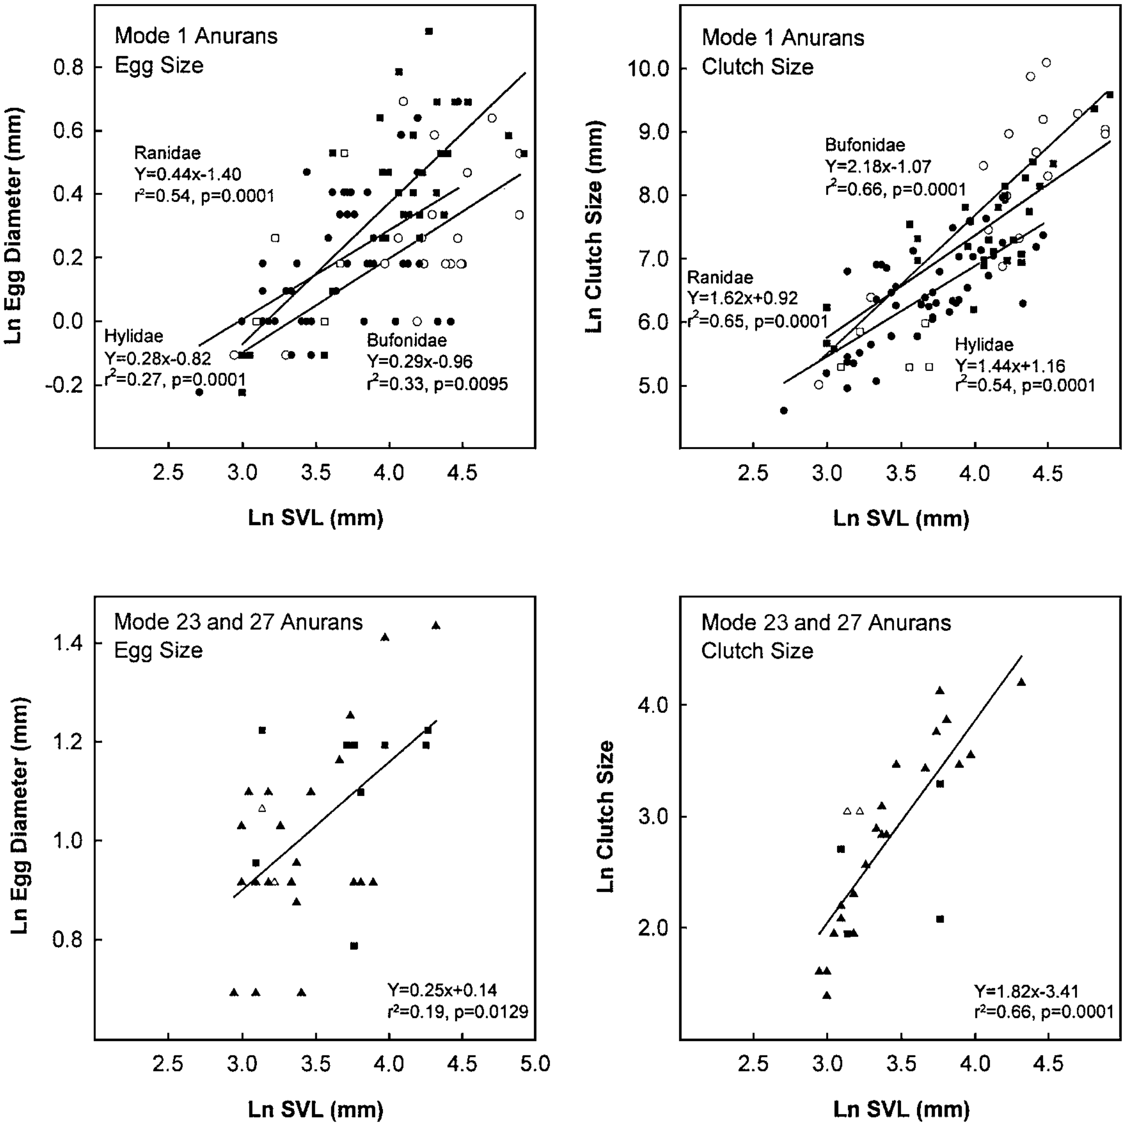

Fig. 10.15. Relationship of egg size and clutch size to body size for pond-breeding anurans (Mode 1) and those with direct development (Modes 23 and 27), plotted as natural logarithms. Mode 1 anurans include Bufonidae (open circles), Hylidae (closed circles), Hyperoliidae (open squares), and Ranidae (closed squares). Regression lines are not shown for Hyperoliidae. Mode 23 and 27 anurans include Arthroleptidae (open triangles), Leptodactylidae (closed triangles), and Ranidae (closed squares). Regression lines are for combined data. This analysis is not corrected for phylogenetic relationships.

three species were available, but egg and clutch sizes in these frogs are similar to those of Mode 1 hylids of the same size (fig. 10.16). Clutch size was not related to body size in hylids that lay eggs out of water (Modes 24 and 25; all squares in fig. 10.16). Hylids with these reproductive modes include two distinct groups that have quite different egg-laying strategies. Species of *Hyla,* such as *H. brevifrons, H. leucophyllata,* and *H. ebraccata,* lay relatively large clutches of small eggs on the surfaces of leaves (fig. 10.8 A), and these eggs hatch very quickly. These are little more than aquatic egg masses transferred to terrestrial oviposition sites. In contrast, the phyllomedusines (*Agalychnis, Phyllomedusa*) generally are larger species, and have larger eggs (fig. 10.8 C, D) with longer development times, but proportionately smaller clutches (hence, the lack of correlation between clutch size and body size when the two groups are pooled). An analysis of covariance for the Mode 24–25 hylids revealed a significant effect of taxonomic group on both egg size and clutch size. The phyllomedusines also have much larger eggs and smaller clutches than do Mode 1 hylids of similar body size (see closed squares in fig. 10.16), whereas Mode 24–25 *Hyla* have only slightly larger eggs and slightly smaller clutches (open squares in fig. 10.16). Although often considered to have the same reproductive mode, these groups clearly represent multiple independent origins of nonaquatic oviposition and quite different life-history strategies.

For all reproductive modes combined, egg size was negatively correlated with clutch size, but this is not true for any reproductive mode alone or for individual families. In fact, for Mode 1 hylids and ranids, egg size and clutch size were positively correlated, reflecting the positive correlation of each variable with body size. To eliminate the effect of body size, I used the residuals of regressions of both egg and clutch size on body size. When this was done for all frogs combined, there was a negative relationship between size-adjusted egg and clutch size (fig. 10.17). Within reproductive modes, only Mode 24–25 hylids exhibited a negative relationship, which reflects the dichotomy between the small egg/ large clutch strategy of the genus *Hyla* and the large egg/ small clutch strategy of the phyllomedusines. Hence, it appears that the negative relationship between egg size and clutch size reported by Salthe and Duellman (1973), Duellman and Trueb (1986), and others is largely a result of combining frogs of many different reproductive modes. Within reproductive modes, egg size varies relatively little among species, and there is not necessarily a direct tradeoff between these two life-history traits.

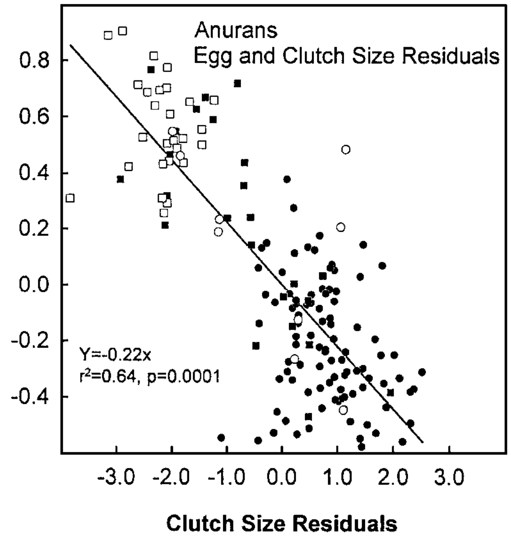

Fig. 10.17. Relationship of egg size to clutch size in anurans, after accounting for the effect of body size on both egg and clutch size. Data include pond breeders (Mode 1; closed circles), pond-breeding foam nesters (Mode 11; open circles), frogs that place eggs on vegetation over water (Mode 25; close squares), and those with direct development of terrestrial or arboreal eggs (Modes 23 and 27; open squares). Regression is for all reproductive modes combined and is not corrected for phylogenetic relationships.

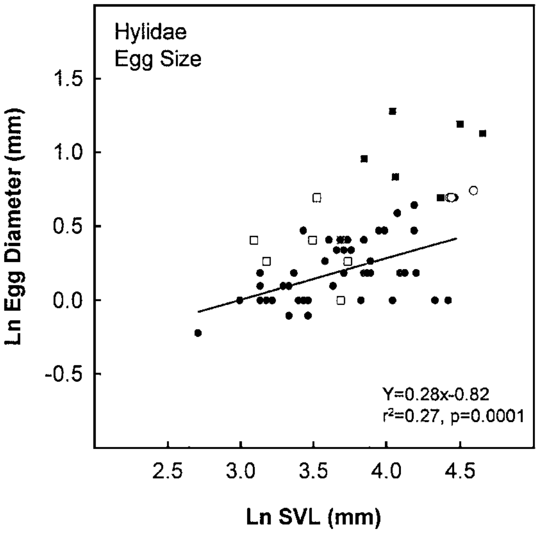

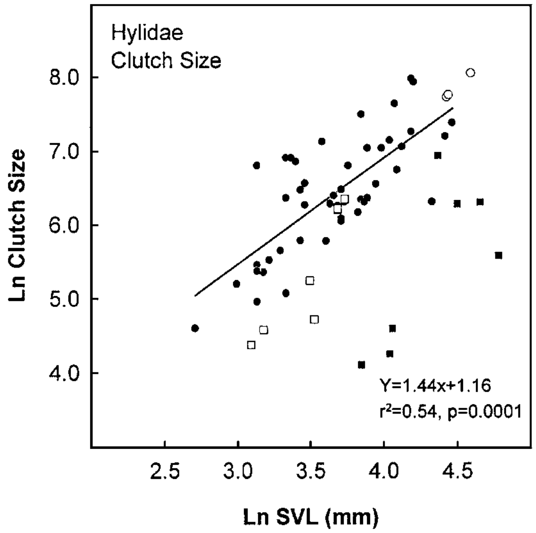

Fig. 10.16. Relationship of egg size and clutch size to body size for anurans in the family Hylidae, plotted as natural logarithms. Data include hylids that place eggs in ponds (Mode 1; closed circles), streamside nest-builders (Mode 4; open circles), *Hyla* that place eggs on vegetation over water (Mode 24; open squares), and Mode 24 phyllomedusines (closed squares). Regression lines are for Mode 1 hylids only. This analysis is not corrected for phylogenetic relationships.

Interspecific Variation in Egg and Clutch Size in Urodeles

Kaplan and Salthe (1979) provided the most detailed analysis of the relationship of egg and clutch size to body size and reproductive mode in urodeles. However, they did not present regression equations for all analyses, nor did they attempt to account statistically for family differences. Therefore, I have done a new analysis, using original data kindly supplied by Robert Kaplan. In this data set, both body size and egg size were expressed as volumes, which were calculated from linear dimensions. I used natural logarithms rather than the base-10 logarithms used by Kaplan and Salthe (1979); all statistical results are identical for the two types of transformed data. I also made some modifications to the data set. Kaplan and Salthe (1979) grouped all species

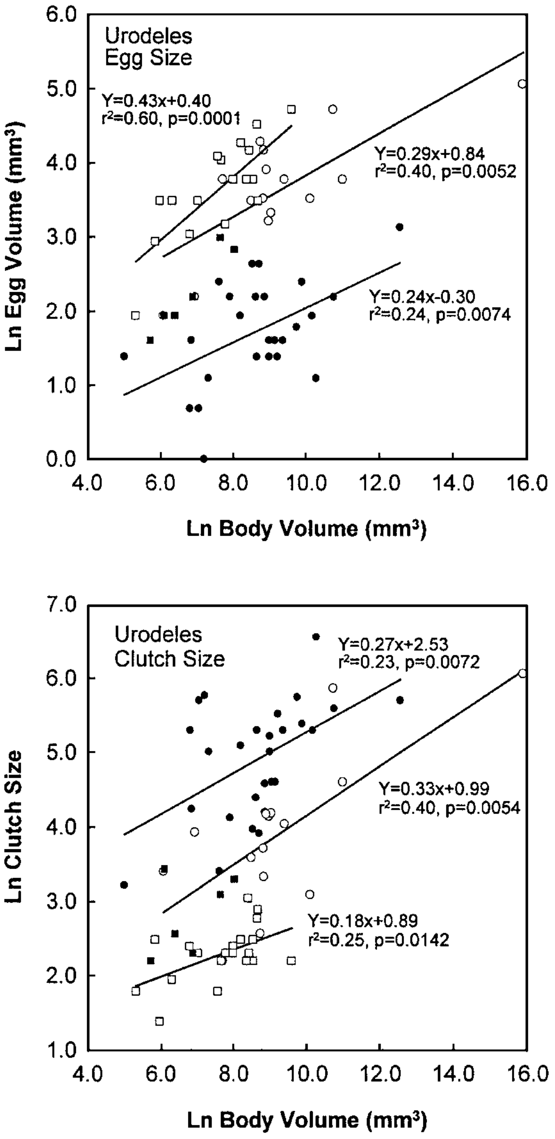

Fig. 10.18. Relationship of egg size and clutch size to body size in salamanders, plotted as natural logarithms. Data include pond breeders (Mode 1; close circles), stream breeders (Mode 2; open circles), species with terrestrial eggs and aquatic larvae (Mode 18; closed squares), and those with terrestrial eggs and direct development (Mode 23; open squares). Regression lines are not shown for Mode 18 species.

of *Desmognathus* except *D. wrighti* with the Mode 2 stream breeders because of their larval adaptations. However, I have removed all of the species that have terrestrial eggs and aquatic larvae from Mode 2 and placed them in Mode 18, leaving only *D. quadramaculatus* and *D. marmoratus* in Mode 2. For the analysis, the Mode 18 desmognathines were combined with *Hemidactylium scutatum,* which also has Mode 18 reproduction, and *D. aeneus,* which has Mode 21 reproduction (terrestrial eggs with nonfeeding larvae). *Stereochilus* and *Eurycea quadridigitata,* which were included in Mode 2 by Kaplan and Salthe, are placed in Mode 1 because they are commonly associated with ponds and swamps. Although data on egg size and clutch size are now available for some species not included in Kaplan and Salthe's analysis, I have used only the original data set, because the new information is unlikely to affect the results.

All of Kaplan and Salthe's major conclusions are supported by the reanalysis of the data. Both egg size and clutch size were positively correlated with body size for Mode 1, 2, and 23 urodeles (fig. 10.18). For plethodontids that have terrestrial eggs that hatch into larvae (Modes 18 and 21), egg size was positively related to body size, but clutch size was not. The lack of correlation between clutch size and body size could be a result of small sample size, but the relationship of egg size and body size was very robust despite the sample size. In general, plethodontids with terrestrial eggs (Modes 18, 21, 23) exhibited a stronger correlation between body size and egg size than between body size and clutch size. This generally was not the case in aquatic egg layers (Modes 1 and 2), where egg size appears to be more conservative. An analysis of covariance for all urodeles combined revealed a significant effect of both body size and reproductive mode on both egg size and clutch size. Mode 1 species had the smallest eggs and the largest clutches, while Mode 23 species had the largest eggs and the smallest clutches (fig. 10.18).

Regressions of egg size residuals on clutch size residuals revealed a strong negative relationship between size-adjusted egg size and size-adjusted clutch size for all urodeles combined (fig. 10.19) and for Mode 1, Mode 2, and Mode 23 spe-

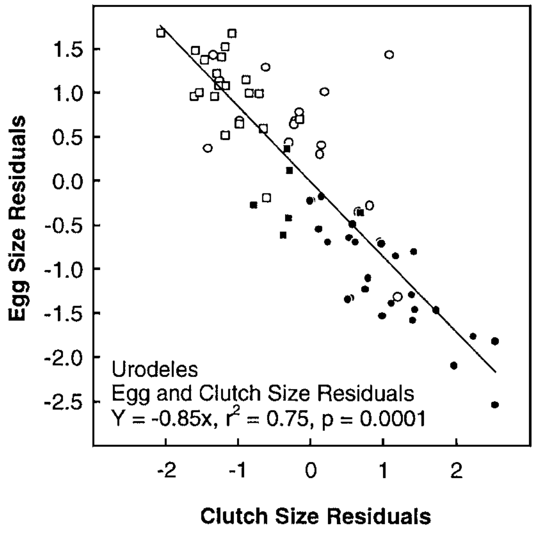

Fig. 10.19. Relationship of egg size to clutch size for salamanders, after accounting for the effect of body size on both egg and clutch size. Data include pond breeders (Mode 1; closed circles), stream breeders (Mode 2; open circles), species with terrestrial eggs and aquatic larvae (Mode 18; closed squares), and those with terrestrial eggs and direct development (Mode 23; open squares). Regression is for all reproductive modes combined and is not corrected for phylogenetic relationships.

cies. Within the Mode 1 species, only salamandrids showed a significant tradeoff between egg and clutch size after adjusting for body size, but sample sizes for all within-family comparisons were small (six to eight species per family). Mode 2 plethodontids exhibited a near perfect negative correlation between egg size and clutch size residuals, even though only six species were included in the analysis.

Egg Size, Hatchling Size, and Development Rate

I did not attempt a new analysis of the relationship between egg size and hatchling size, but in general, species with large eggs have larger hatchlings than species with small eggs in both anurans and urodeles (fig. 10.20). Large eggs also take longer to develop and usually hatch at a more advanced stage than small eggs, but both rate and length of development are affected by temperature and phylogenetic differences as well (Bradford 1990). Rate of development was positively correlated with temperature when the effects of egg size and phylogeny (urodeles or anurans) were removed, and negatively correlated with egg size when the effects of temperature and phylogeny were removed (fig. 10.21). In

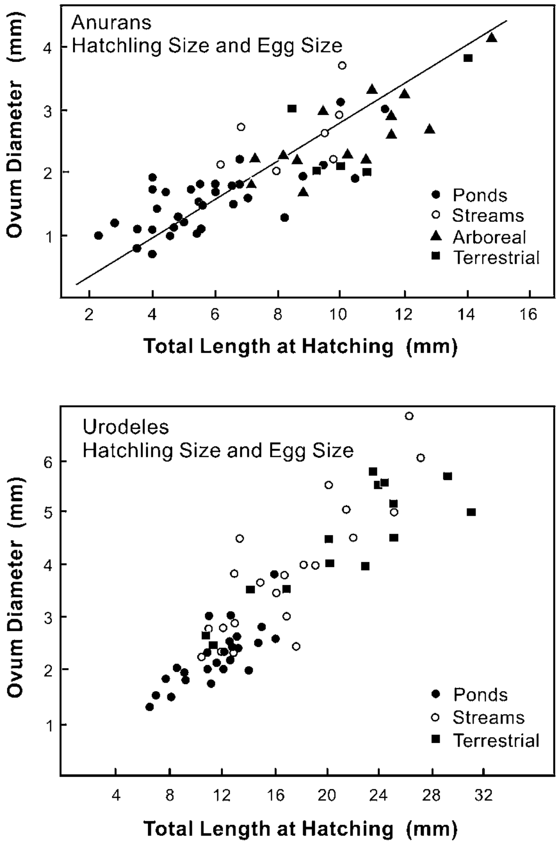

Fig. 10.20. Relationship of hatchling size and egg size for anurans (top) and urodeles (bottom) with different reproductive modes. Anuran data after Duellman and Trueb (1986). Urodele data after Salthe (1969).

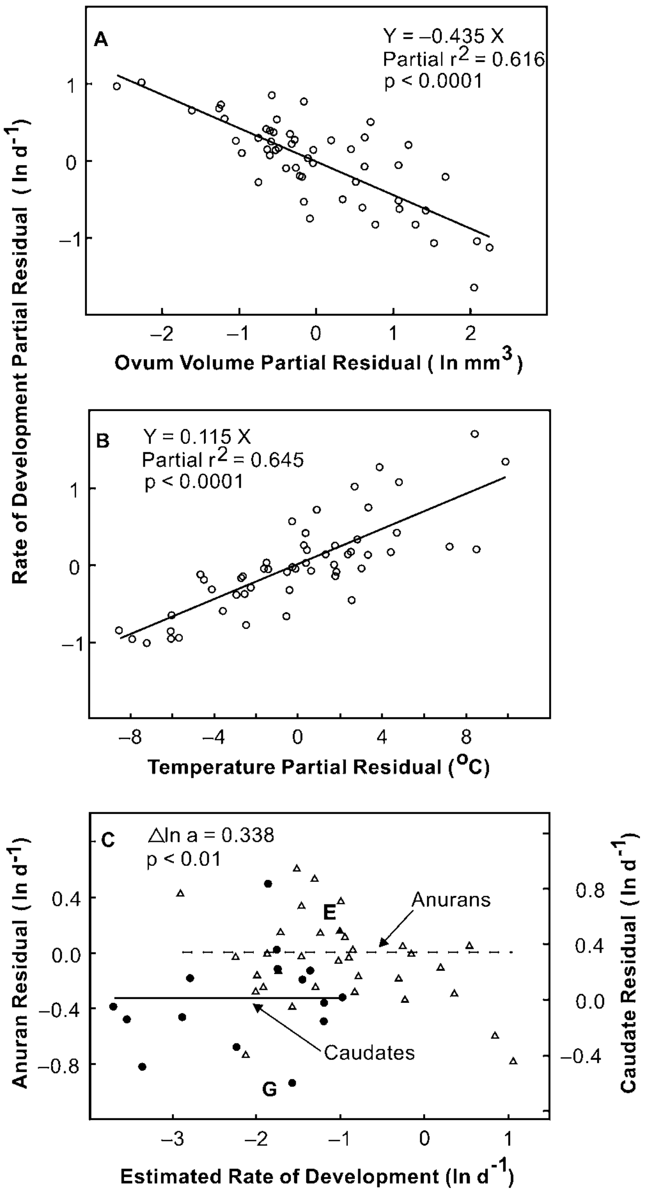

Fig. 10.21. The effect of egg size, temperature, and phylogeny on rate of egg development for anurans and urodeles. (A) Partial residual plot for rate of development as a function of egg volume, with effects of temperature and taxonomic group removed. This shows that large eggs develop more slowly than small eggs. (B) Partial residual plot for rate of development as a function of temperature, with the effects of egg volume and taxonomic group removed. This shows that eggs develop more rapidly with increasing temperature. (C) Partial residual plot showing difference in rate of development of anurans and urodeles as a function of predicted rate of development for both groups. This shows that anuran eggs develop more rapidly than urodele eggs of the same size and at the same temperature. Two species, *Eleutherodactylus coqui* (E), a tropical frog with direct development, and *Gastrotheca riobambae* (G), a "marsupial" frog, were outliers that were not included in the analysis. After Bradford (1990).

addition, urodele eggs have slower embryonic development than anuran eggs, take longer to hatch, and hatch at a more advanced stage, even when egg size and temperature are the same. The slower development times of urodele eggs probably are due at least in part to larger genome size, which tends to be negatively correlated with development rate (see chapter 1). Indeed, within plethodontid salamanders, which have the largest genomes of any vertebrates, development rate is negatively correlated with genome size, but is not related to egg size after accounting for genome size and temperature (Jockusch 1997).

In both anurans and urodeles, species that lay terrestrial eggs have longer development times, larger hatchlings, and more advanced hatchlings than aquatic egg-layers. Differences in development time generally have been attributed to differences in the size of the eggs, but differences in genome size could be more important. This has not been examined for anurans, but in plethodontid salamanders, species that lay terrestrial eggs with direct development generally have larger genomes than do aquatic-breeding species (Jockusch 1997). Egg size undoubtedly does influence hatchling size because of the much greater yolk reserves in terrestrial eggs, which allow for more prolonged development inside the egg. The disadvantage of having a long incubation period is the increased exposure of the eggs to predators and other sources of mortality. Hence, it is not surprising that many species that lay terrestrial eggs also have parental care, and survivorship of eggs often is poor if the attending parent is removed (see chapter 11).

Reproductive Mode and Energetic Investment

Reproductive mode does not appear to have much effect on the energetic investment that females make in each clutch of eggs, but instead alters the way in which energy is partitioned. In urodeles (Kaplan and Salthe 1979) and anurans (Crump 1974; Barbault 1984; Duellman and Trueb 1986), total clutch volume is tightly correlated with body size, regardless of reproductive mode (fig. 10.22). This relationship does not appear to be strongly affected by phylogeny, but this has not been explicitly tested using phylogenetically-based comparative methods. Because of the allometric relationship between clutch volume and body size, smaller species tend to have proportionately larger clutch volumes than large species, regardless of reproductive mode (Crump 1974; Kaplan and Salthe 1979). Many species of anurans and urodeles with nonaquatic reproductive modes are smaller than species with fully aquatic reproduction, so these relationships can give the impression that terrestrial-breeders invest more heavily in reproduction than do aquatic-breeders (e.g., Tilley 1968). When related species of similar size are compared, however, total energetic investment per clutch is similar, but aquatic egg-layers divide their investment into a large number of small packages, while terrestrial egg-layers divide theirs into a small number of large packages (M. Crump and Kaplan 1979). Unfortunately, without knowing something about rates of energy intake and energy expenditure, it is impossible to determine whether species allocate different proportions of their total energy budget to reproduction, the most accurate measure of reproductive effort (Seale 1987; Stearns 1992).

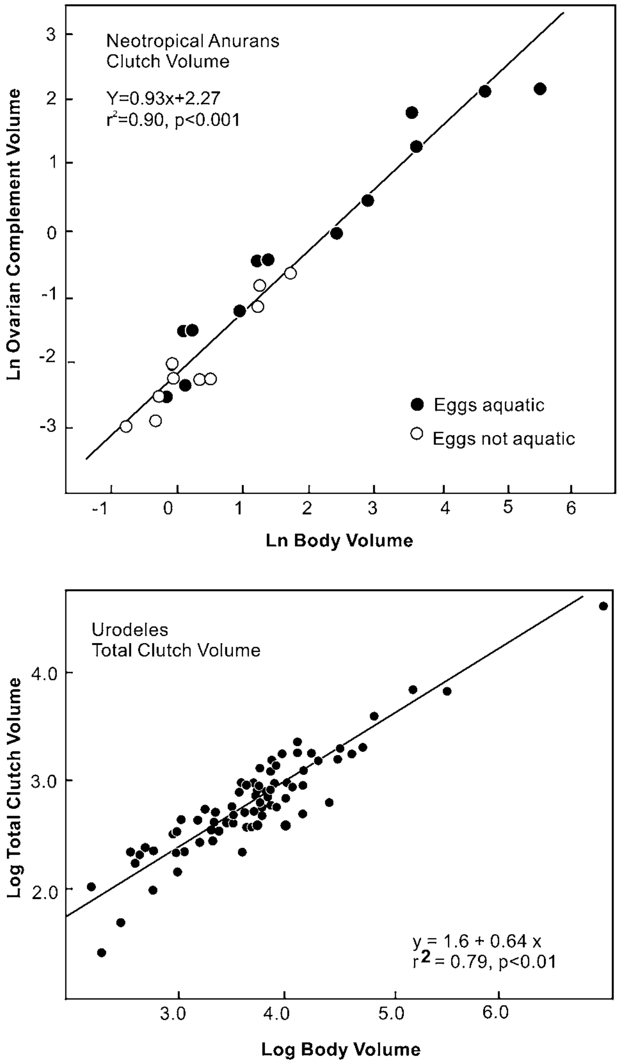

Fig. 10.22. Relationship of total clutch volume to body size for anurans (top) and urodeles (bottom). Anuran data after Duellman and Trueb (1986). Urodele data after Kaplan and Salthe (1979), with regression equation calculated from original data supplied by Robert Kaplan (personal communication).

Total annual reproductive effort is even more difficult to estimate, because in most cases we have inadequate information on the number of clutches a female lays each year. Most urodeles probably produce only a single clutch per year, and females of some temperate-zone species do not breed every year (R. Harris and Ludwig 2004). Some tropical salamanders probably produce several clutches per year, but information on these species is limited (Houck 1977a; Tilley and Bernardo 1993). In anurans, cold-weather breeders reproduce only once a year at best, but some warm-weather breeders in both the tropics and temperate zone produce multiple clutches per year (table 10.5). Unfortunately, most of the species for which quantitative information is available are Mode 1 pond-breeders, so the effect of reproductive mode on frequency of reproduction is unknown. However, two lines of evidence suggest that production of multiple clutches is common in both aquatic and

Table 10.5 Examples of multiple egg clutch production by anuran females in a single breeding season

Note: N_f = number of females.

[a] Some *Crinia signifera* females produced a small second clutch 1–3 months after the first; others produced larger clutches at longer intervals.

[b] Based on sightings of gravid females.

[c] Based on frogs breeding in laboratory.

[d] Some *Hyperolius marmoratus* females produced a second clutch within 30 days; others produced second clutches after more than 60 days due to differences in rainfall. Mean for all females was 57 days (range 18–103).

terrestrial-breeding frogs with prolonged breeding seasons: the simultaneous occurrence of more than one size of oöcytes in the ovaries (Church 1960b; Crump 1974; Barbault and Trefaut Rodrigues 1978a, b, 1979a, b; Barbault and Pilorge 1980; Rastogi et al. 1983; Shimoyama 1986; Donnelly 1989c; Kyriakopoulou-Sklavounou and Loumbourdis 1990; Silverin and Andren 1992) and observations of individual females breeding at frequent intervals in captivity (Senfft 1936; Chibon 1962; Davidson and Hough 1969; Grow 1977; Richards 1977; Schülte 1981a; Weygoldt 1982, 1984a; E. Zimmermann and Zimmermann 1982; Jungfer 1985; Lüddecke 1995a; Thumm and Mahony 2002a). In the field, intervals between clutches can be affected by a variety of environmental variables, including temperature, patterns of rainfall, and availability of food (Telford and Dyson 1990; Townsend and Stewart 1994; Harris and Ludwig 2004). While different species vary considerably in total annual reproductive output, it is not clear that this variation is related in any systematic way to differences in reproductive mode.

Adaptive Explanations for Interspecific Variation in Egg and Clutch Size

How can we explain the differences in egg size and clutch size in different reproductive modes? Many discussions of this problem published in the 1970s and 1980s were framed explicitly or implicitly in terms of r-and-K selection (M. Crump 1974, 1981b; Barbault and Trefaut Rodrigues 1978a, b, 1979a, b; Duellman 1978; Barbault and Pilorge 1980; Barbault 1984; Duellman and Trueb 1986). Aquatic habitats, especially temporary ponds, generally have been characterized as unstable, unpredictable, or fluctuating environments where eggs and larvae are subjected to high levels of mortality from predation or other causes. In contrast, terrestrial habitats, particularly in the wet tropics, have been characterized as stable, equable, or predictable environments where mortality of eggs and larvae is lower. Amphibians with large clutches of small eggs have been viewed as classic examples of "r-selected" species that produce large numbers of offspring, each at relatively low energetic cost. Terrestrial breeders, particularly those with direct development and various forms of parental care, have been viewed as "K-selected" species that invest heavily in each individual to enhance its competitive ability, but at a cost in reduced numbers of offspring. In some cases, r-and-K selection has been invoked as an explanation for the evolution of egg size and clutch size, even when other life-history traits, such as age at maturity, frequency of reproduction, age-specific mortality, and length of reproductive life were unknown (Crump 1974; Duellman 1978). In other studies, some of these variables were measured as well (Barbault and Trefaut Rodrigues 1978a, b, 1979a, b; Barbault and Pilorge 1980).

The use of r-and-K selection as an explanatory framework in studies of life-history evolution has now been largely abandoned. The scheme fails to account for the range of variation in life-history strategies seen in nature and does not make precise predictions about the types of life-history traits to be expected in r- and K-selected species (Stearns 1992). It is now clear that the evolution of life-history strategies is far more complex than originally thought. We need several kinds of data to fully understand the evolution of life-history traits in any group, including amphibians. We need detailed information not only on egg size and clutch size, but also on demographic features of populations (age at first reproduction, age-specific reproduction and mortality, reproductive life span), the genetic correlation between life-history traits, physiological costs, and the effects of phylogeny of specific life-history traits (Stearns 1992). These data are simply not available for most amphibian species, so a comprehensive discussion of the evolution of reproductive strategies is not possible at this point. Nevertheless, it is possible to identify some selective pressures that are likely to affect the evolution of egg size and clutch size in predictable ways.

All of the environmental variables listed in table 10.3 that affect the evolution of clutch structure and oviposition behavior probably also affect the evolution of egg and clutch size. Clearly these variables are not completely independent, but covary in different habitats. For example, aquatic environments with low temperatures typically have high levels of dissolved oxygen, while warm habitats have low oxygen levels. Physical factors such as water temperature, dissolved oxygen content, and probability of the habitat drying do not necessarily select for specific egg or clutch sizes, but they could act as constraints that limit the range of variation possible in a given habitat, particularly variation in egg size. In general, small eggs have high surface-to-volume ratios, short development times, and hatch into relatively small, poorly developed larvae. Large eggs have low surface-to-volume ratios, longer development times, and hatch into larger, more fully developed larvae. These differences are magnified by differences in water temperature. Species with the shortest development times and the most underdeveloped hatchlings typically are those that lay small eggs in warm aquatic environments, such as desert pools, whereas those with the longest development times and most fully developed hatchlings lay large eggs in cool aquatic or terrestrial habitats.

Small eggs probably are necessary for successful reproduction in any aquatic habitat that combines warm temperatures with low oxygen availability, such as warm ponds, swamps, desert pools, streamside basins in the tropics, or water-filled bromeliads. Oxygen demand increases with temperature, but diffusion of oxygen into the egg decreases as egg size increases (Bradford 1990; Seymour 1999). Hence, metabolic demands and oxygen availability set upper limits on the size of eggs that can survive in these types of habitats (see also chapter 4). This probably accounts in part for the small range of interspecific variation in egg size among Mode 1 anurans. In addition, the relatively large clutch sizes of most warm-water Mode 1 amphibians probably are indirect consequences of selection for small egg size, and not necessarily the result of selection on clutch size per se.

Small eggs would be particularly advantageous in warm, ephemeral habitats such as desert rain pools and shallow tropical ponds, where very rapid development should be favored because of rapid drying of the habitat (Zweifel 1968b). This is consistent with the smaller eggs of Mode 1 *Bufo,* which tend to breed in ephemeral habitats, compared to Mode 1 hylids or ranids, which usually breed in larger temporary or permanent ponds. Even within the genus *Rana,* species that breed in warm water have smaller eggs than do cold-water species with the same reproductive mode. The advantage of small eggs in warm, ephemeral habitats is enhanced by physiological changes that result in increased development rates at a given temperature (see also chapter 3). For example, spadefoot toads (*Scaphiopus* and *Spea*) from North American deserts not only have very small eggs, but they have faster rates of development at any given temperature than do other anurans from the same region (Zweifel 1968b; Bradford 1990).

In cooler, well-oxygenated aquatic environments, such as cold ponds, lakes, and mountain streams, egg size would be less constrained by oxygen availability, particularly because embryonic metabolic rates would be lower at cold temperatures (H. Brown 1977; Bradford 1990; Seymour 1999). This would allow cold-water breeders to produce larger eggs than do warm-water breeders. In fact, this is the pattern seen in both urodeles and anurans, particularly in stream-breeding species (Salthe 1969; Salthe and Duellman 1973; Kaplan and Salthe 1979; Nussbaum 1985; Bradford 1990). However, greater oxygen availability and lower metabolic demands would not necessarily select for larger eggs, since this is accompanied by a decrease in clutch size.

Nussbaum (1985, 2003) provided a thorough review of the various adaptive explanations for the correlation between cold aquatic environments and large eggs that have been proposed for urodeles, anurans, and fishes. Many authors have simply noted the correlation and have argued that large eggs are an adaptation for breeding in cold environments, without specifying the selective advantage of large eggs (J. Moore 1949b; Salthe 1969; Licht 1971). Others have argued that cold environments favor the production of large, relatively advanced larvae, and this can be achieved only by having large eggs. Large larvae might be advantageous if competition for food were particularly severe in cold environments with low productivity (an argument made mainly by ichthyologists cited in Nussbaum 1985). Large, yolky eggs also might provide sufficient energy reserves for larvae to survive for a considerable period of time without food, until they reach a size that allows them to feed effectively (H. Brown 1977, 1989). In flowing water, large size enhances the ability of larvae to hold their position in a current (Dunn1923; Noble 1927; Salthe 1969; Salthe and Duellman 1973; Salthe and Mecham 1974; S. Richards 2002). This idea was tested experimentally by Petranka, Kats, and Sih 1987), who compared the eggs and larvae of a stream-breeding ambystomatid, *Ambystoma barbouri,* with those of a closely related pond-breeder, *A. texanum* (originally the stream- and pond-breeders were thought to be two different races of *A. texanum*). *Ambystoma barbouri* has larger eggs and larger larvae, which were displaced shorter distances in the stream current than were those of *A. texanum.*

Nussbaum (1985) argued that the correlation between large eggs and cold environments is largely spurious, at least for urodeles, with the real correlation being between large eggs and flowing-water habitats, most of which also happen to be relatively cold. He proposed that large eggs in stream-breeding salamanders are favored mainly because of the types of food available for their larvae. Most pond-dwelling salamander larvae feed on small, relatively abundant prey, such as zooplankton, which tend to be evenly distributed in the environment. In contrast, stream-dwelling salamander larvae eat mostly larger prey, such as aquatic insects, that are more patchily distributed and less abundant, because zooplankton is not available. Consequently, large, relatively advanced hatchlings that can handle large prey would have an advantage over smaller, less advanced hatchlings that can eat only small prey. This argument does not seem applicable to stream-breeding anurans, because these have completely herbivorous larvae that usually scrape algae off of rocks or intercept small particles in the current (see chapter 12). Nevertheless, a simulation study of reproductive strategies in fishes concluded that production of a few large larvae was superior to production of many small larvae in all environments with low food abundance at all levels of small-scale prey patchiness (Winemiller and Rose 1993). Because productivity generally is lower in streams than in ponds, large larvae are favored in stream-breeding anurans as well.

Indeed, large eggs are likely to be favored in any aquatic environment that provides poor food resources for the larvae. For example, frogs that place their eggs in small bodies of water, such as bromeliads, tree holes, water-filled bamboo, and water-filled depressions on the ground often have larger eggs than do close relatives that breed in larger bodies of water. These types of sites generally provide little food for developing larvae. In some species, the tadpoles have become obligate or facultative egg-eaters, subsisting on eggs deliberately or accidentally deposited by females in the same bodies of water (Lannoo, Townsend, and Wassersug 1987). Others supply their eggs with enough yolk to allow the tadpoles to develop without feeding (e.g., *Eupsophus, Pelophryne, Kalophrynus, Syncope, Platypelis, Plethodonthyla, Anodonthyla*).

Several species of toads that breed in small bodies of water with low larval food supplies have much larger eggs than more typical pond-breeding toads. One such species is *Bufo periglenes,* from montane cloud forests of Costa Rica (unfortunately, now thought to be extinct), which bred in small water-filled depressions on the forest floor. These sites can be very crowded and are largely devoid of suitable food for the tadpoles. Eggs of this species were about 3 mm in diameter, larger than those of two other Costa Rican species that breed in ponds (both < 2 mm in diameter). These eggs are about twice the size expected for a toad with a body size of *B. periglenes* (SVL = 160 mm; predicted egg diameter from bufonid regression in fig. 10.15 = 1.7 mm). Tadpoles were able to feed if provided with suitable food, but also could complete metamorphosis without feeding if deprived of food (Crump 1989b). In contrast, tadpoles of the two pond-breeding species with small eggs, *B. marinus* and *B. coniferous,* could not survive to metamorphosis without food.

Another species that is closely related to *B. periglenes,* and has similar habits, is *B. holdridgei.* This toad also has much larger eggs (2.8 mm) than do congenerics of similar size (SVL = 46 mm; predicted egg diameter from regression in fig. 10.15 = 1.2 mm). Tadpoles probably can reach metamorphosis without feeding (Novak and Robinson 1975). Yet another Neotropical species with unusually large eggs is *B. castaneoticus,* which lays eggs in water-filled fruit capsules of the Brazil nut tree, a microhabitat likely to be poorly supplied with food (Caldwell 1991, 1993). The Cape Mountain toad of southern Africa, *B. rosei,* has exceptionally large eggs (2.6 mm) for its body size (37 mm; predicted egg diameter from regression in fig. 10.15 = 1.1 mm). These are laid in rosary-like strings similar to those of *B. holdridgei* in shallow, water-filled depressions. The tadpoles hatch at an advanced stage of development, with rear leg buds already visible. Wager (1965) characterized the mouth as "feebly developed," suggesting the tadpoles do little or no feeding before metamorphosis. Presumably the habit of laying unusually large eggs has evolved independently several times in the genus *Bufo,* but a detailed phylogenetic analysis of the genus is needed to test this hypothesis rigorously. Unfortunately, none of these species was included in the most recent phylogenetic analysis of bufonids, so their relationships to other species of *Bufo* with smaller eggs are unclear, as are their relationships to each other (Graybeal 1997). Similar arguments have been advanced to explain unusually large egg size in *Crinia georgiana* compared to other members of the genus. Tadpoles of this species also can reach metamorphosis without feeding (Doughty 2002).

Nonaquatic egg-layers, particularly those with direct development, have the largest eggs in relation to body size in both anurans and urodeles. Most authors have argued that the principal advantage of large eggs in these species is the production of large, advanced larvae or juveniles that can cope with the rigors of the terrestrial environment. Usually predation and competition for food are invoked as the major selective pressures favoring large, advanced hatchlings (Salthe 1969; Salthe and Duellman 1973; Crump 1974; Salthe and Mecham 1974; Duellman and Trueb 1986), but the selective pressures that favor particular sizes of eggs are varied and complex (Bernardo 1996a, b). In fact, terrestrial microhabitats do not provide any suitable food for aquatic larvae. Consequently, unless the larvae are carried to water by the parent, terrestrial eggs must be provided with large yolk reserves. In some cases, large yolk reserves allow for prolonged development until the nest site is flooded (Mode 17). In others, large eggs develop into larvae large enough to make their way to water independently (Modes 18, 24, 25, and 26), or complete development without feeding, either inside the egg capsule (Modes 23 and 27) or in the nest (Modes 18 and 32). In addition, problems of desiccation set a lower limit on egg size in terrestrial environments. Large eggs lose water more slowly than do small eggs because of their more favorable surface-to-volume ratios. Nonaquatic egg-layers must select relatively saturated oviposition sites, or provide water to the eggs in some other way. Some species surround their eggs with water-filled jelly (a strategy seen in many anurans that lay eggs on leaves overhanging water). In others, parental attendance of the eggs provides the necessary moisture (Taigen, Pough, and Stewart 1984; see also chapter 11).

In general, oxygen is readily available to terrestrial eggs, so problems of gas diffusion probably would not place an upper limit on their size, within the range of sizes normally seen in amphibians (see also chapter 4). Nevertheless, an adequate rate of oxygen diffusion depends on adequate hydration of the eggs (Seymour and Bradford 1987; Bradford and Seymour 1988a; Seymour 1999). Furthermore, under some circumstances, such as high temperatures or flooding, oxygen can become limiting even for terrestrial eggs (Bradford and Seymour 1988b; Seymour, Geiser, and Bradford 1991a). Most nonaquatic eggs are laid in relatively wet, sheltered locations that would reduce exposure to extreme conditions that might limit the availability of oxygen. However, the arboreal foam nests produced by some tropical rhacophorids often are placed in direct sunlight, and temperatures inside the nest can reach levels higher than those tolerated by many amphibian eggs. These high temperatures would increase metabolic demands of the embryos and tend to favor relatively small eggs. In one such species, *Chiromantis xerampelina,* the eggs are about 1.7 mm in diameter, smaller than those of many arboreal or terrestrial egg-layers of similar size. The wet foam surrounding the eggs actually impedes diffusion of oxygen into the nest, but as the outer surface of the nest dries, gas conductance increases. The air-filled bubbles making up the nest supply most of the oxygen needed by the embryos. As metabolic rates of the embryos increase during development, oxygen demand can exceed rates of oxygen uptake, and this serves as a stimulus for the larvae to hatch and drop out of the nest (Seymour and Loveridge 1994).

Intraspecific Variation in Egg and Clutch Size

Studies of interspecific variation in egg size and clutch size have revealed clear differences among reproductive modes that appear to be consistent across different clades of amphibians. For example, terrestrial egg-layers in many families have larger eggs and smaller clutches than do closely related aquatic egg-layers. Within aquatic egg-layers, stream-breeders consistently have larger eggs and smaller clutches than their pond-breeding relatives. All of these analyses are based on species averages for body size, egg size, and clutch size, and therefore mask a considerable amount of intraspecific variation in life-history traits. Such variation is evident in comparisons among populations, among individual females in the same populations, and even within clutches of eggs produced by individual females. Intraspecific variation in egg size and clutch size provides a potentially rich source of information on adaptation of life histories to local conditions, as well as the relative contribution of genotype and environment to variation in life-history traits.

Variation within Populations

Many investigators have reported a positive correlation between body size and clutch size within populations in both anurans and urodeles (table 10. 6), and none has reported a significant negative correlation. Not all species exhibit this type of relationship, however. For example, Crump (1974) reported that only 11 of 41 species of tropical frogs for which she had adequate data showed a positive correlation between body size and clutch size, despite robust sample sizes for many of the species. Lips (2001) did not find any correlation between clutch size and body size in the Neotropical treefrog *Hyla calypsa,* which lays eggs on vegetation over water. Kuramoto (1978a) examined intraspecific relationships for 12 species of Japanese amphibians. In four of these (two frogs and two salamanders), clutch size was not related to body size, but in two cases, this could have been due to small sample sizes ($N = 10$). Many authors have cited interspecific relationships between body size and clutch size, such as those reported by Salthe and Duellman (1973), as evidence that within species, larger females should produce larger clutches. While this certainly is true for many species, one cannot simply assume that it is true for all amphibians. There have been fewer attempts to document variation in egg size, but a positive correlation has been reported in anurans and urodeles from several different families (table 10. 6). Other species show no relationship between body size and egg size (e.g., Lips 2001), while a few exhibit negative relationships (Crump 1974; Kuramoto 1978a).

There are several reasons why a positive intraspecific correlation between body size, clutch size, and egg size is not always apparent. Several studies have shown a significant effect of female age on clutch size, independent of body size (table 10. 6). For example, Berven (1988) reported that both clutch size and egg size were positively correlated with body size within three age classes of female wood frogs (*Rana sylvatica*), but one-year-old females produced larger clutches of smaller eggs than did two- or three-year-olds, after adjusting for differences in body size. He also found a slightly higher total investment in egg production (total egg volume) by two-year-old females than by one- or three-year-olds (fig. 10.23). M. Gibbons and McCarthy (1986) reported a similar increase in relative egg size with age in *Rana temporaria,* while Elmberg (1991) reported an increase in relative clutch size (adjusted for body size) with increasing age in the same species. In a West African frog, *Hyperolius nitidulus,* some individuals became sexually mature within a few weeks of metamorphosis and reproduced in the same season. These rapidly maturing individuals were smaller than those breeding earlier in the year, and females produced smaller eggs. They also laid smaller egg clutches than first clutches of later breeding females (Lampert and Linsenmair 2002). In a facultatively paedomorphic salamander, *Ambystoma talpoideum,* egg size, adjusted for body size, increased with age, but clutch size did not (Semlitsch 1985b). Fully metamorphosed terrestrial adults, which included females that were one to five years old, produced larger eggs than did paedomorphic individuals, but the latter were all only a year old. Among one-year-olds, egg size was similar in the two types of morphs, but terrestrial females produced more eggs for their body size.

Another factor that influences the relationship between body size and both clutch and egg size is the number of clutches produced by an individual female in one season. In *Rana catesbeiana,* second clutches were smaller and had smaller eggs than first clutches (R. D. Howard 1978b, 1988a). Second clutches also were smaller in *Hyla rosenbergi* (Kluge 1981), but not in *Hyperolius marmoratus* (Telford and Dyson 1990). In the Australian frog *Crinia signifera,* which has a very long breeding season, some females produced a second, smaller clutch within three months of laying their

[a] Hatchling size positively correlated with female body size; egg size was not measured.

first clutch, whereas other individuals produced a relatively large second clutch after a much longer interval (five to six months; Lemckert and Shine 1993). Egg clutches of *Hyla calypsa* laid early in the breeding season were larger than those produced later in the season, but data were not presented for different clutches of individual females (Lips 2001). In *Bufo canorus,* a toad that breeds at high altitudes in the mountains of California, many females do not breed every year. Kagarise Sherman (1980) found that females that laid eggs at intervals of one or two years produced significantly smaller clutches than did females that reproduced every three or four years, even though the former were larger individuals.

The tendency for second clutches to be smaller than first clutches suggests that females are under considerable energy stress and do not have sufficient energy reserves, or have not been able to consume sufficient food, to produce a full complement of eggs shortly after producing their first clutches. Seasonal variation in clutch sizes in some tropical frogs supports this interpretation as well. For example, Donnelly (1989c) found that clutch sizes in *Dendrobates pumilio* varied seasonally, apparently in response to changes in food availability. Townsend and Stewart (1994) reported that clutches produced by female *Eleutherodactylus coqui* in the dry season were significantly smaller than were clutches produced in the wet season, even though clutch size generally was positively correlated with body size, and the females in the wet season sample were slightly smaller. Seasonal variation in clutch size also has been documented in some tropical African frogs (Barbault and Trefaut Rodrigues 1978b, 1979a). In one of these species, *Arthroleptis poecilonotus,* clutch size was not related to body size, but clutches were much larger in a wet year than in a dry year.

Some temperate-zone anurans, such as *Rana temporaria, R. sylvatica, Bufo bufo,* and *Bombina orientalis* also exhibit year-to-year variation in egg size, clutch size, or both, that sometimes equals or exceeds variation among populations (C. B. Jørgensen, Larsen, and Lofts 1979; Cummins 1986; Berven 1988; Kaplan and King 1997). All of these species breed in the spring and depend at least in part on stored energy reserves accumulated during the previous year to support egg production and maturation. This makes it difficult

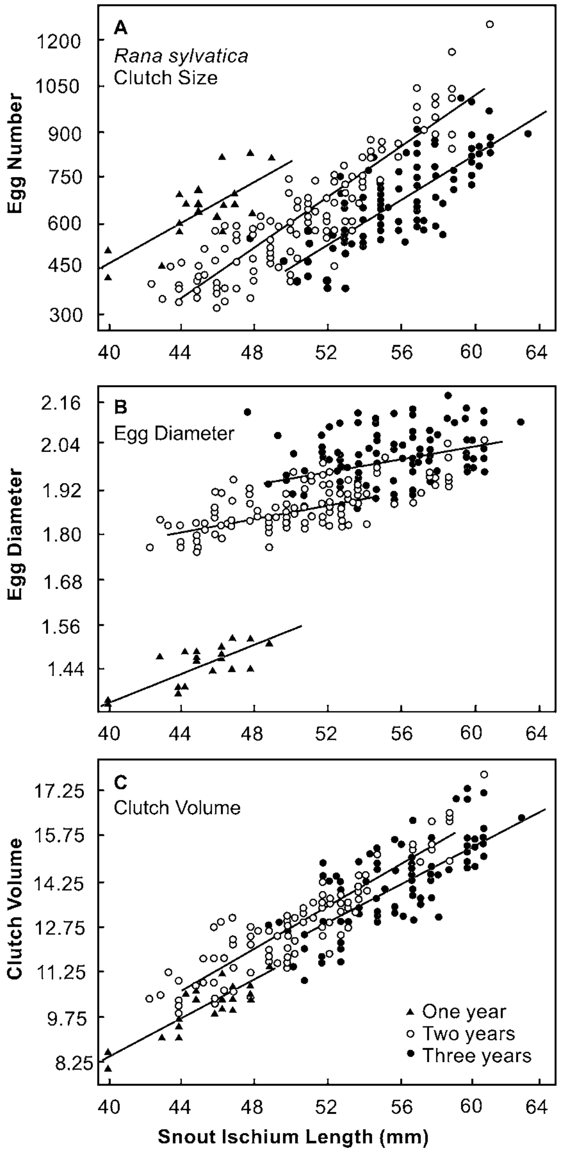

Fig. 10.23. Relationship of clutch size, egg size (mm), and total clutch volume (mm) to body size for *Rana sylvatica* females at one, two, and three years of age. Second- and third-year females have smaller clutches and larger eggs than do first-year females. After Berven (1988).

to identify the causes of year-to-year variation in egg and clutch size, but presumably these would include variation in food abundance, length of the activity season, temperature, and rainfall, which might affect time available for foraging.

Laboratory studies of several species of amphibians have shown that food availability can affect both the number and size of eggs produced by a female. The number of eggs is determined relatively early in the ovarian cycle and is a function of the number of small oöcytes available for recruitment. The nutritional condition of the female at this stage of the cycle can affect the number of oöcytes recruited, but once this is set, clutch size does not undergo any further increase. Yolk is deposited later, in the vitellogenic growth period, which generally corresponds to the main period of feeding and body growth. The nutritional condition of the female during this period has a profound effect on egg size and probably accounts for much of the variation observed in natural populations (C. B. Jørgensen 1973a, b, 1974a, 1975, 1981, 1982, 1984a, b, 1992b; C. B. Jørgensen, Larsen, and Lofts 1979; Fraser 1980; Smalley and Nace 1983; R. Kaplan 1987; Kaplan and King 1997). Any effect on clutch size, such as that observed by Kaplan (1987; clutch size was smaller in females provided with small amounts of food), probably is due to loss of oöcytes in energetically stressed females, rather than recruitment of new oöcytes in well-fed individuals (C. B. Jørgensen 1992b).

Many authors have assumed that egg size and clutch size are inversely related to each other within populations. Indeed, this type of trade-off between offspring size and number is a central assumption of much recent work on life-history evolution (G. Bell and Koufopanou 1986; Stearns 1989, 1992; Roff 1992). Evidence for an intraspecific trade-off of egg size and number is mixed. A number of studies have reported a positive correlation between egg size and clutch size (e.g., Sofianidou and Kyriakopoulou-Sklavounou 1983; Semlitsch 1985b; Matsui 1989; Kyriakopoulou-Sklavounou and Loumbourdis 1990), a pattern to be expected when both egg and clutch size increase with body size. However, some investigators have found a negative correlation between egg and clutch size after eliminating the effect of body size, indicating that females with relatively large clutches for their body size produce relatively small eggs (e.g., *Ambystoma jeffersonianum* complex: Wilbur 1977c; *A. tigrinum:* Kaplan and Salthe 1979; *Bufo bufo:* Reading 1986; *Bufo viridis:* Castellano, Cucco, and Giacoma 2004; *Rana temporaria:* Cummins 1986; Gibbons and McCarthy 1986; *Hyla calypsa:* Lips 2001; *Hyla labialis:* Lüddecke 2002b). Other studies have failed to show such a relationship (e.g., *Ambystoma opacum* and *A. maculatum:* Kaplan and Salthe 1979; *Bombina orientalis:* Kaplan 1987; *Bufo calamita:* Tejedo 1992b; five species of *Litoria:* Morrison and Hero 2002). Rico et al. (2004) reported a negative correlation between egg size and clutch size in field-deposited clutches of *Scinax trapicheiroi,* but they did not know the body sizes of the females that laid the eggs.

Presumably a trade-off between egg size and clutch size is most likely to be observed when most females in a population have been able to recruit near-maximum numbers of oöcytes and abundant food has enabled them to fully supply them with yolk. Because the number of oöcytes is determined first, females that have large clutch sizes relative to body size will face constraints imposed by the total space available for developing eggs. Consequently, they will be able to allocate less yolk to each egg than will females with smaller clutches relative to body size. For example, Kaplan and Salthe (1979) observed a trade-off between egg and clutch size only in a population of *Ambystoma tigrinum* that had a larger total clutch volume than predicted from an interspecific regression for several species in the genus. They suggested that this population was more constrained by available body space than were populations of other species that did not exhibit such a trade-off. Gibbons and McCarthy (1986) attributed the negative relationship between size-adjusted egg and clutch size in *Rana temporaria* in Ireland to an unusually large total investment in eggs compared to populations of the same species in other parts of Europe.

Lüddecke (2002b) reported that females of a tropical treefrog, *Hyla labialis,* that were supplied with unlimited food in the laboratory showed a significant trade-off between clutch size and egg size. Females in the best condition tended to produce larger clutches of smaller eggs than did those in poorer condition. Nevertheless, there was not a tendency for females with the largest total volume of eggs to have the strongest trade-off between egg and clutch size. Studies of repeated spawnings by the same females in captivity also suggested that certain females are simply more physiologically efficient at converting energy into eggs. Some females consistently had higher total volumes of eggs than did other females, yet these females often returned to a better body condition than did females that laid smaller egg clutches (Lüddecke 1995a).

Variation within Clutches

In addition to variation in egg size among females in the same population, egg size also varies within a single clutch. Such intraclutch variation has been documented in a number of anurans and urodeles, including tropical hylids (Crump 1981b; Lips 2001), *Pseudacris crucifer* (Crump 1984b), *Crinia signifera* (Williamson and Bull 1989), *Pseudophryne australis* (Thumm and Mahony 2005), *Bufo calamita* (Tejedo and Reques 1992), *Bombina orientalis* (Kaplan and King 1997), two species of *Hynobius* (Takahashi and Iwasawa 1988b), and several ambystomatid and plethodontid salamanders (Beachy 1993a). Several authors have suggested that such variation is an adaptation to fluctuating or unstable environments, where the relative advantage of large and small eggs is unpredictable. The hypothesis has been variously referred to as "adaptive coin flipping" (Cooper and Kaplan 1982; Kaplan and Cooper 1984) or "bet hedging" (Crump 1981b, 1984b; Lips 2001; Thumm and Mahony 2005). It suggests that females produce a variety of egg sizes within a single clutch to ensure that at least some are well adapted to the prevailing conditions encountered that year. This model has been questioned on theoretical grounds, mainly because fluctuating environments alone are not sufficient to result in selection for variable egg size (McGinley, Temme, and Geber 1987). Others have disagreed, arguing that variation in egg size is a widespread if not yet fully understood phenomenon that could have an adaptive explanation (Bernardo 1996b).

Consequences of Variation in Egg Size

The hypothesis that within-clutch variation in egg size represents an adaptive response to fluctuating environments was invoked to account for ranges of variation that are larger than expected if there is a single optimum egg size for a given species or population. To test this idea, it is first necessary to examine fitness consequences of variation in egg size among and within clutches. Attempts to do so have produced mixed results. Some of the differences in results reported for different species probably reflect differences in experimental techniques, sample sizes, or methods of measuring larval performance, while others reflect real differences among species. In most studies, variation in egg size among clutches in the same population has been correlated with variation in larval life-history traits, particularly the time required to reach hatching, feeding, and metamorphosis, and the sizes of larvae at each of those stages. Only two studies have examined relationships within individual egg clutches (Crump 1984b; Williamson and Bull 1989). Unfortunately, most authors have not measured all of these indicators of larval performance, making interspecific comparisons difficult.

In most species, egg size appears to have little or no effect on time until hatching or metamorphosis (table 10. 7). Loman (2002a) reported that tadpoles of *Rana temporaria* hatching from large eggs developed faster and metamorphosed earlier than did those from small eggs raised in the same conditions. Most other studies have not found such effects. The most consistent effect of large egg size is on the size of larvae at hatching and at the first feeding stage. Whenever a significant effect has been detected, it has been positive (table 10. 7), indicating that large eggs tend to give rise to large hatchlings. It is not clear that this effect always carries over to metamorphosis, however. Only a few workers have examined size at metamorphosis as a function of egg size, but positive effects were found in only two species, *Taricha torosa* (R. Kaplan 1985) and *Rana sylvatica* (Berven and Chadra 1988). In *Taricha,* the correlation was measured indirectly; size at metamorphosis was positively correlated with size at first feeding, which in turn was positively correlated with egg size. In *Rana sylvatica,* the positive effect was seen only when larvae were raised at high densities; at low densities, the pattern was reversed, with smaller eggs actually producing larger metamorphs than did large eggs, particularly at high food levels (Berven and Chadra 1988).

Table 10.7 Effect of egg size on larval life-history traits in amphibians

Notes: Effects of increasing egg size can be positive (+), negative (–), or nonsignificant (0). Blank cells indicate effects that were not measured. H = hatching; F = feeding; M = metamorphosis.

[a] Time to hatching was positively correlated with egg size in only one of three experimental temperature regimes for *Ambystoma maculatum*.

[b] Time to metamorphosis was negatively correlated with feeding size in *Taricha torosa* when larvae were provided with unlimited food, but was positively correlated when food was limited.

[c] Egg size affected time to metamorphosis in one study of *Rana temporaria* and size at metamorphosis in another.

The reasons for this are unclear, but it points up the complex nature of relationships between egg size and other measures of offspring fitness (Bernardo 1996b). Most studies have examined this relationship under ideal laboratory conditions with larvae kept at relatively low densities and supplied with abundant food. In the field, these conditions are likely to vary considerably from year to year and among ponds. This makes predictions about exactly what size of egg will yield the highest fitness difficult. The only attempt to test the prediction that egg size should be more variable in species that experience unpredictable environments was M. Crump's (1981b) study of five Neotropical treefrogs. She predicted that frogs breeding in temporary ponds, which were more variable in several ways, should have greater intraclutch variation in egg size than permanent-pond breeders, but this was not the case. However, temporary-pond breeders exhibited a somewhat more even distribution of egg sizes, which Crump interpreted as partial support for the hypothesis.

Variation among Populations

Variation among populations in both egg size and clutch size has been documented for both anurans and urodeles (Pettus and Angleton 1967; Kozlowska 1971; Koskela and Pasanen 1975; Berven 1982a, 1987; Berven and Gill 1983; Banks and Beebee 1986b; Cummins 1986; Reading 1986; Beattie 1987; Takahashi and Iwasawa 1988a, 1989a; Matsui 1989; Bruce and Hairston 1990; Elmberg 1991; Lai, Kam, and Lin 2003). Usually differences among populations have been attributed to differences in temperature, altitude, or latitude (Morrison and Hero 2003b). Populations from cool regions, high altitudes, or high latitudes often have larger eggs and smaller clutches than do populations from warmer environments. This trend is not universal, however (Berven and Gill 1983; Elmberg 1991), and in some cases simply reflects differences in female body size (Laugen, Laurila, and Merilä 2002). Furthermore, the populations in question often differ in other respects as well, such as the nature of the breeding site. Year-to year variation within populations has seldom been compared with variation among populations, but in some cases, it is nearly as great (e.g., Cummins 1986; Kaplan and King 1997), raising questions about adaptive interpretations of differences among populations. Studies of geographic variation in life-history traits frequently suffer from a lack of statistical replication, with comparisons made between single populations or pooled samples from different altitudes or latitudes (e.g., Pettus and Angleton 1967; Banks and Beebee 1986a; Beattie 1987; Laugen, Laurila, and Merilä 2002; Lai, Kam, and Lin 2003). Studies comparing egg size or clutch size along a gradient of altitude, latitude, or temperature (e.g., Matsui 1989; Takahashi and Iwasawa 1989a; Elmberg 1991) provide more convincing evidence of a relationship between life-history traits and environmental variables. At best, even these studies simply reveal a pattern of correlation, but not the underlying causes of the relationship. Only experimental studies can reveal whether geographic variation is due mainly to direct environmental effects on life-history traits or genetic differences among populations.

The most comprehensive experimental analysis of geographic variation in egg and clutch size for any amphibian is Keith Berven's work on North American wood frogs (*Rana sylvatica*). He initially studied wood frogs from nine ponds along an altitudinal gradient from near sea level to over 1000 m (Berven 1982a). Females from montane populations reached sexual maturity at a later age and at a larger size than lowland females. Both egg and clutch size were positively correlated with body size within and between populations, resulting in larger absolute egg and clutch sizes in montane populations. However, relative to body size, montane females produced larger eggs and smaller clutches than did lowland females, reflecting a trend reported in other frogs. In an experiment that ran for several years, Berven reciprocally transferred thousands of newly metamorphosed juveniles between lowland and montane ponds and then monitored their survival, age, and size at sexual maturity, and the size of eggs and clutches laid by females.

The experiment showed that both genetics and the environment in which the juveniles grew up influenced age and size at first reproduction. For example, lowland females that remained in their home ponds reached sexual maturity in two years, whereas individuals from the same population transferred to the mountains matured in three years. However, this was still faster than montane females reared in mountain ponds, which usually took three to four years to reach maturity (montane females transferred to the lowlands took two to three years). Age at first reproduction was more sensitive to environmental influences in montane females, resulting in considerable variation among individuals. Size at first reproduction for montane females was less plastic and was similar in both environments, although there was considerable year-to-year variation in both environments as well. These results suggest that the cooler temperatures and shorter growing season in the mountains are largely responsible for the later maturity of montane females, but there are genetic differences among populations that reinforce this trend.

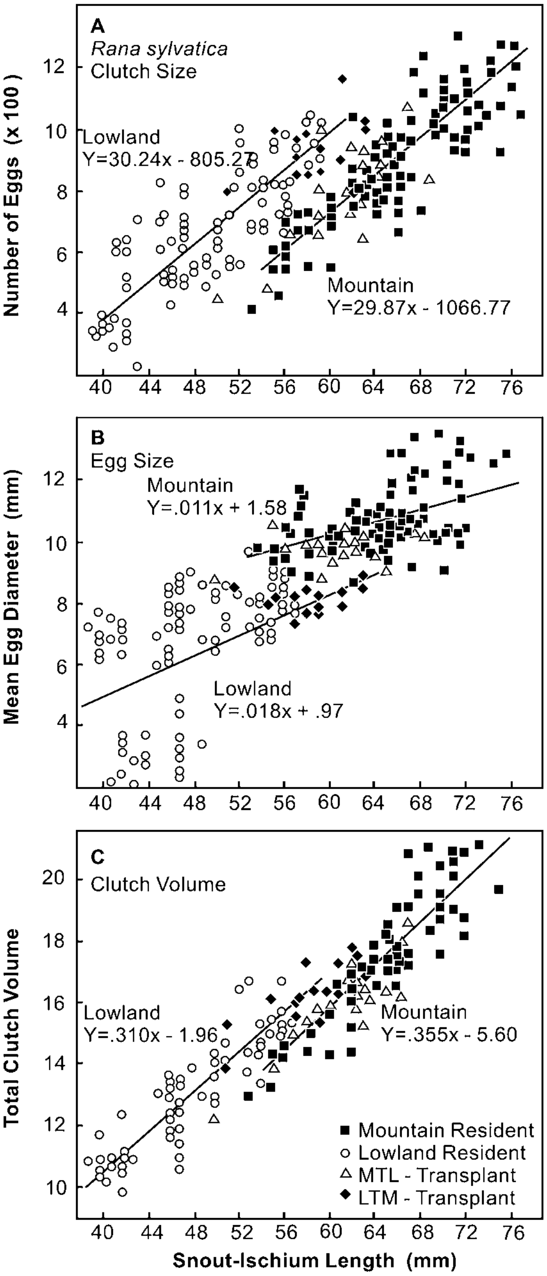

Fig. 10.24. Relationship of clutch size, egg size (mm) and total clutch volume (mm^3) to body size for *Rana sylvatica* females from lowland and mountain populations. Also shown are data for females transplanted as juveniles from mountain to lowland habitats (MTL) and lowland to mountain habitats (LTM). Mountain females are larger, on average, than lowland females. Mountain females also have larger eggs and smaller clutches than do lowland females of the same body size. After Berven (1982a).

In contrast to the strong environmental effect on age and size at maturity, egg size and clutch size were entirely determined by the population of origin, indicating genetic differences between populations that presumably result from differential selection in the two environments. Montane females had larger eggs and smaller clutches, relative to body size, than lowland females, regardless of which environment they were in (fig. 10.24). Berven speculated that selection acts mainly on egg size, with other life-history traits changing secondarily. He suggested that large eggs, and the large energy reserves associated with them, would be advantageous in cool montane environments, where larval periods are relatively long and pond productivity is low. Presumably, the additional energy provided by large eggs should enable the larvae to reach metamorphosis more rapidly or at a larger size under the adverse conditions of high-altitude ponds than larvae hatched from small eggs. In fact, experiments on larval growth and development showed that rate of development was largely determined by environmental temperature, regardless of where the eggs came from, whereas growth rate and size at metamorphosis were affected by both the environment and genetic differences between populations (Berven 1982b). Montane larvae grew faster and were larger at all developmental stages than lowland larvae. Reciprocal matings between lowland and montane males and females also revealed a significant nongenetic maternal effect on length of the larval period and size at metamorphosis. Larvae derived from montane mothers had shorter larval periods and larger size at metamorphosis than larvae derived from lowland mothers when they were reared under the same conditions in the laboratory. Presumably this maternal effect was due mainly to larger eggs being produced by montane females.

In contrast to the general expectation that latitudinal variation should parallel altitudinal variation, wood frogs from the far northern parts of their range tend to be smaller than are those from lower latitudes, and they lay smaller eggs. High latitudes resemble high altitudes in having short growing seasons, but they also have longer days, and both pond temperatures and productivity often are higher than in high-altitude ponds. In this type of environment, rapid development is favored over large size at metamorphosis, and the advantage of having large eggs is reduced because of relatively high larval food availability (Berven 1982a; Berven and Gill 1983). It is difficult to determine precisely the fitness advantages of large and small eggs in different environments because of the large effect of larval density and food availability (Berven and Chadra 1988). These do not vary in predictable ways among habitats, and indeed, year-to-year variation within one habitat can equal or exceed differences among habitats.

Summary and Conclusions

Amphibians exhibit some of the most varied modes of reproduction of any group of vertebrates. All three major clades of living amphibians have species with internal and external fertilization, but the distribution of modes of fertilization varies from nearly all external in anurans to mostly or entirely internal in urodeles and caecilians, respectively. In all three clades, external fertilization is considered an ancestral trait, although the morphologically primitive frog *Ascaphus* is one of the few anurans with internal fertilization. In most anurans, external fertilization occurs while the male and female are in amplexus, but amplexus has been secondarily lost a number of times in anuran evolution, mostly in species with nonaquatic reproduction. Early in anuran evolution, there was a shift from inguinal amplexus to axillary amplexus, with the latter being far more common today. The adaptive significance of this shift in amplexus position is not entirely clear, but it has major implications for the evolution of oviposition behavior and anuran mating systems. One important development in the oviposition behavior of anurans with axillary amplexus is a tendency for egg-laying times to be reduced and for eggs to be laid in compact masses. This in turn may have set the stage for the evolution of resource-based mating systems, in which males defend oviposition sites (see chapter 8).

In urodeles, the ancestral external mode of fertilization is retained only in the most primitive families, the cryptobranchids, hynobiids, and sirenids, and sometimes is accompanied by male defense of oviposition sites, a type of mating sytem that is not known in salamanders with internal fertilization. The evolution of the spermatophore was a key event in the evolution of urodeles, because it allows mating and oviposition to be separated in time. This in turn makes parental care by males unlikely; parental care by females is the rule in urodeles (see chapter 11). Internal fertilization by means of spermatophores, coupled with a capacity of females to store sperm, reduces the effectiveness of male mate guarding and allows for multiple paternity of egg clutches. The length of time that sperm remains viable inside the female varies among salamanders from a few days to several years, but the reasons for this variation are largely unknown. All caecilians have internal fertilization, accomplished by means of a special copulatory organ and not by means of spermatophores. In contrast to both anurans and urodeles, in which viviparous reproduction is rare, the evolution of internal fertilization has been followed by the evolution of viviparity in many caecilian lineages.

Reproductive modes, defined in terms of egg deposition sites and mode of embryonic and larval development, are extremely diverse among anurans. Currently nearly 40 different reproductive modes have been described for anurans, but these could easily be subdivided into many more distinct modes of reproduction. The most common modes, deposition of eggs in either still or flowing water with an aquatic larval stage, are found throughout the world in many different families. These reproductive modes acutally encompass a wide range of variation in the location of oviposition sites, the structure of egg masses, and the details of embryonic and larval development. The significance of this variation is just beginning to be explored.

The large number of more specialized and apparently more derived modes of reproduction, often involving partial or complete removal of the embryos and larvae from the water, are found almost exclusively in the wet tropics. It is striking how much still remains to be learned about the basic features of anuran reprodutive biology, with as many as ten new modes of reproduction having been described in recent years just from one area, the Atlantic rainforest of Brazil, a hotspot for endemic species of frogs. It seems likely that many more unusual modes of reproduction eventually will be discovered in tropical forests around the world. One feature of anuran reproductive modes that deserves more attention from researchers is the high degree of plasticity in choice of oviposition sites in many species. Some tropical frogs use a wide range of temporary pools, sites on or near the ground, or elevated sites to lay eggs, resulting in some species exhibiting several different modes of reproduction even in the same population. In other species, males build nests in some locations, but not in others. The fitness consequences of such extreme variation in oviposition site choice have scarcely been addressed.

One widespread evolutionary theme among frogs in the humid tropics is the evolution of various mechanisms to avoid placing eggs directly in oxygen-poor environments, such as warm, swampy pools, or to mediate the effects of such environments on embryonic development. These mechanisms include production of very small eggs with rapid development, placement of eggs in surface films in contact with the air, placement of eggs in bubble or foam nests that provide supplemental oxygen supplies, placement of eggs in well-oxygenated streams, or placement of eggs out of water altogether. Each of these diverse modes of oviposition entails unique costs and benefits that have yet to be studied in detail for most species.

The reproductive modes of urodeles and caecilians are much less diverse than are those of anurans, in part because both of these clades contain only a small fraction of the number of species of anurans. Furthermore, the urodele clade is dominated by a single family, the Plethodontidae, most of which exhibit direct development of nonaquatic eggs. Indeed, this mode of reproduction, and the lack of dependence on standing water, may have allowed this one lineage to colonize a variety of temperate and tropical habitats. There is evidence from phylogenetic studies, however, for one or more reversals of life-history evolution, with a reacquisition of an aquatic larval stage in some desmognathine salamanders. This form of life history may be particularly suitable for salamanders in environments with abundant, well-oxygenated aquatic habitats, such as streams, springs, and caves, where food resources for newly hatched offspring are more abundant or more accessable in water than on land.

Along with the great diversity of reproductive modes found in amphibians, there also is considerable inter- and intraspecific variation in both egg size and clutch size, and some variation in the frequency of reproduction. In general, egg size appears to be dictated by reproductive mode in both anurans and urodeles. Eggs laid in oxygen-poor aquatic environments invaribly are small, regardless of the size of the adult female, whereas clutch sizes tend to be large and highly correlated with female body size. In well-oxygenated aquatic habitats, eggs are invariably larger, with clutch sizes correspondingly smaller. For eggs laid outside of water, oxygen limitations are less important, but problems of evaporative water loss tend to favor large eggs, regardless of the size of the female. Hence, tiny species of *Eleutherodactylus* with direct development produce enormous eggs relative to their body size, but cannot produce very many of them (in the most extreme cases, producing only one at a time). Larger ranids or bufonids with direct development can produce even larger eggs, but they are smaller relative to adult body size, and clutch sizes are larger.

Arboreal egg-layers exhibit a wide range of egg sizes and clutch sizes, and the significance of this variation has yet to be explored in detail. Foam-nesting rhacophorid treefrogs tend to have relatively small eggs and large clutches, presumably to facilitate rapid development in hot environments, where eggs are placed over ephemeral rain pools. Some hylid frogs that lay nonfoamy egg masses on leaves over water have relatively small eggs with little jelly protection, as in *Hyla ebraccata*. Others, such as frogs in the genus *Agalychnis,* have relatively large eggs with abundant jelly surrounding the clutch. Presumably the first mode of reproduction is advantageous in environments where rapid embryonic development is favored, whereas the latter may be advantageous where longer development time and larger hatchlings are favored.

In many amphibians, intraspecific variation in egg size or clutch size, or both, is related to variation in body size, with larger females usually producting larger clutches and often producing larger eggs. Indeed, selection for increased reproductive output probably is a major determinant of female body size and probably accounts for the fact that females of most amphibians are larger than males. Not all species show a positive relationship between body size and egg or clutch size, however. In some cases, this is because age of the female also affects these variables, regardless of body size. In some facultatively paedomorphic salamanders, alternative life history strategies are correlated with differences in egg size or clutch size. In some anurans that produce multiple egg clutches each season, second or third clutches often are smaller than first clutches, although this depends on the time intervals between clutches. At high altitudes, some females do not reproduce every year, and those that have longer intervals between clutches sometimes produce larger clutches. All of these patterns suggest that female amphibians often are energy limited, and allocate less energy to reproduction when food supplies are low or intervals between egg-laying events are short. When females are not energy limited, they may allocate the maximum possible amount of energy to reproduction, which can result in a statistical tradeoff between number of eggs and egg size that is not apparent when females lack the energy reserves to develop a full complement of eggs.

Some amphibians exhibit considerable variation in egg size even within clutches. The physiological basis for such variation, which presumably results from differential allocation of energy reserves to different eggs, has not been thoroughly investigated. Some investigators have suggested that this variation represents a "bet-hedging" strategy that is best suited for variable and unpredicatable environments in which small eggs with rapid development may be favored in some circumstances, and larger eggs with slower development in other circumstances. There have been relatively few rigorous tests of this hypothesis. Most studies have shown that egg size has little or no effect on time until hatching or time until metamorphosis, but a number of studies have shown a positive effect of egg size on size of larvae at hatching or at the first feeding stage. These studies indicate positive selection on egg size, but there is relatively little evidence of selection for variation in egg size. Many amphibians also exhibit geographic variation in egg size and clutch size, although again, the adaptive significance of such variation is poorly understood and deserves further experimental investigation.

Chapter 11 Parental Care

Wandering over the meadow, now sodden with a recent rain, I observed a small frog. . . . To my astonishment, I saw that its back was covered with little black bodies, set close together like paving-stones on a street. . . . I very quickly saw that these were tadpoles, so crowded in the small space that the tails and part of the bodies were hidden.
—Herbert H. Smith, "On oviposition and nursing in the Batrachian genus *Dendrobates*" (1887)

NINETEENTH-CENTURY naturalists who were familiar with the rather uniform breeding habits of North American and European frogs often were amazed by the variety of reproductive strategies encountered in the tropics. Some tropical frogs lay their eggs in water and abandon them, but others have remarkably complex forms of parental behavior. Although the occurrence of parental care in amphibians is no longer astonishing, it still holds considerable interest for behavioral ecologists. Parental care refers to any type of parental investment in offspring after the eggs are laid or the young are born, but does not include the initial energetic investment in producing gametes (Trivers 1972; Clutton-Brock 1991). I exclude from my discussion of parental care those species that have evolved viviparous reproduction; these modes of reproduction were discussed in chapter 10. For parental behavior to be considered true parental care, it is assumed that such behavior increases the survivorship of the young, although in practice this has been demonstrated experimentally only in a small subset of species that exhibit parental care. Parental care usually entails some cost to the caregiving parent, although again, only a few studies have thoroughly documented such costs.

Some form of parental care has been reported in most of the major amphibian families, having evolved independently many times. The eggs of amphibians lack protective shells or membranes and are exposed to a variety of dangers. Terrestrial eggs are susceptible to desiccation, whereas aquatic eggs suffer from floods, droughts, or lack of oxygen (see chapter 4). The eggs are subjected to attacks by pathogenic bacteria, fungi, and a host of predators, such as leeches, insects, spiders, snails, fishes, amphibians, and snakes (see chapter 14). Parental care presumably has evolved as a response to the dangers posed by these physical and biological threats to survival. Amphibian parental care has been reviewed a number of times (Salthe and Mecham 1974; Lamotte and Lescure 1977; McDiarmid 1978; Wells 1981a; Nussbaum 1985; M. Hayes 1991), with the most comprehensive reviews being those of M. Crump (1995b, 1996), Nussbaum (2003), and Lehtinen and Nussbaum (2003). Crump's papers include very complete tables summarizing reports of parental care in individual species and a thorough discussion of the evolution of parental behavior, but some interesting examples of parental care in amphibians have been described since those reviews were written. I will first describe the basic patterns of parental care in amphibians and then discuss experimental work on the benefits and costs of parental care and major trends in the evolution of parental care. Whenever possible, I will try to interpret the evolution of parental care in an explicitly phylogenetic context.

Patterns of Parental Care

The frequency of parental care varies among the major amphibian groups. McDiarmid (1978) estimated that parental care is present in about 10–15% of anuran species. Crump (1996) reported that parental care has been observed in about 6% of anuran species, representing 15–17 different families, depending on the family-level classification that is used. This figure undoubtedly underestimates its actual occurrence, because the reproductive biology of many species is unknown, especially in the tropics, where parental care is most common. Parental care has not been reported in the families Ascaphidae, Bombinatoridae, Brachycephalidae, Heleophrynidae, Pelobatidae, Pelodytidae, Pseudidae, or Rhinophrynidae. In several of the largest families of anurans, including the Bufonidae, Hylidae, Leptodactylidae, Myobatrachidae, and Ranidae, parental care either is uncommon, or is restricted to a few lineages within the family (some of these families are not monophyletic groups as presently constituted; see chapter 1). Parental care is more common in salamanders, occurring in at least 18% of all species. Parental care is particularly common in the family Plethodontidae, which includes more than 70% of living urodele species, and probably occurs in many species for which it has not been reported, simply because eggs of these species have never been observed. Parental care has not been reported in the family Rhyacotritonidae, and it is uncommon in hynobiids and ambystomatids (Nussbaum 1985, 2003). Crump (1995b, 1996) did not list any examples in the family Salamandridae, but more recent work on Asian newts of the genus *Pachytriton* in captivity indicates that females aggressively guard their eggs (Thiesmeier and Hornberg 1997, 1998). Egg attendance by females also has been reported in *Euproctus montanus* (Nussbaum 2003). The ancestral mode of reproduction in caecilians is oviparity, whereas most of the derived clades are viviparous (see chapter 10). Most oviparous caecilians are thought to exhibit parental care, but well-documented examples are rare (less than 10 species; M. Wake 1977a, 1992; Crump 1995b, 1996).

Parental Care in Anurans

Several classifications of anuran parental care have been proposed. McDiarmid (1978) recognized 12 categories, based on oviposition habitat (aquatic or terrestrial), site of parental investment (nest, burrow, or on the parent), nature of the larval stage (free-swimming or direct development), and sex of the caregiving parent. In a subsequent review, I combined his categories into four major types of parental care: attendance of eggs, attendance of larvae or young, transport of eggs, and transport of larvae (Wells 1981a). Because of more recent work, it is now necessary to add several additional categories, including attendance and transport of terrestrial juveniles and feeding of young (Crump 1995b, 1996; Lehtinen and Nussbaum 2003). In some anurans, either the male or female builds some sort of nest to receive the eggs, but they do not necessarily remain with the eggs after they are laid. These nests include mud basins constructed at the edges of streams, underground burrows, foam nests placed on the water or in vegetation, and nests made by wrapping leaves around the eggs. These modes of reproduction were discussed in chapter 10 and will not be included in the discussion of parental care unless parents remain with the eggs.

Attendance of Eggs

This is the most common form of parental behavior, and occurs in 13–15 anuran families, depending on which classification is used (tables 11.1–11.3). Attendance of aquatic eggs is relatively rare. In the large Neotropical tree frog *Hyla rosenbergi,* males construct mud nests in which eggs are laid. Males sometimes guard the nests after eggs are laid (Kluge 1981), although Höbel (2000) reported that males in a population in Costa Rica exhibited only facultative nest construction and did not guard their eggs. Other closely related species build similar nests (M. Martins 1993a, b). Parental attendance of nests has not been reported in most of these, but in *H. faber,* males guard their nests when densities of calling males are high (fig. 11.1). This suggests that the main benefit of parental care in this species is to protect the eggs from being damaged by intruding males (M. Martins,

Table 11.1 Examples of egg attendance by frogs

Species (source no.)	Attendant	Oviposition site	Calling site
Astylosternidae			
Trichobatrachus robustus (9)	Male	Rocks in stream	Rocks in stream
Bufonidae			
Nectophryne afra (12, 25, 56)	Male	Shallow pool	Shallow pool
N. batesi (54)	Male	Shallow pool	Shallow pool
Nectophrynoides malcolmi (28)	Male	Terrestrial nest	
Oreophrynella nigra (55)	Male or female[a]	Burrow or tunnel	Rock crevice
Centrolenidae			
Centrolene geckoideum (40, 66)	Male	Rock near waterfall	Rock near waterfall
C. notostictum (58)	Male	Leaf over stream	Leaf over stream
C. petrophilum (58)	Male	Rock in stream	Rock in stream
C. prosoblepon (47, 58)	Male[b]	Rock or leaf	Rock or leaf
Cochranella savagei (33)	Male	Leaf over stream	Leaf over stream
Hyalinobatrachium bergeri (59)	Male	Leaf over stream	Leaf over stream
H. colymbiphyllum (29, 57, 79)	Male	Leaf over stream	Leaf over stream
H. fleischmanni (35, 47, 57)	Male	Leaf over stream	Leaf over stream
H. orientalis (49)	Male	Leaf over stream	Leaf over stream
H. valerioi (29, 57)	Male	Leaf over stream	Leaf over stream
H. vireovittata (57)	Male	Leaf over stream	Leaf over stream
Hemisotidae			
Hemisus guineensis (54, 56)	Female	Burrow	Ground
H. guttatus (8, 63)	Female	Burrow	Ground
H. marmoratus (63, 68)	Female	Burrow	Ground
Hylidae			
Hyla faber (67)	Male	Mud nest	Mud nest or vicinity
H. rosenbergi (36)	Male	Mud nest	Mud nest or vicinity
Hyperoliidae			
Alexteroon obstetricans (18, 56)	Female	Leaf over water	Leaf over water
Hyperolius spinigularis (15)	Female	Leaf over water	Leaf over water
Leiopelmatidae			
Leiopelma archeyi (45)	Male	Under rocks or vegetation	Under rocks or vegetation
L. hamiltoni (45)	Male	Under rocks or vegetation	Under rocks or vegetation
L. hochstetteri (45)	Male	Small pools	Ground near pools
Leptodactylidae			
Cycloramphus boraceiensis (74)	Male	Rock crevice	Wet rocks
C. stejnegeri (31)	Female	Depression in soil	Unknown
Geobatrachus walkeri (30)	Female	Terrestrial nest	Unknown
Leptodactylus chaquensis (69)	Female	Aquatic foam nest	Shallow water
L. fallax (11, 32, 39, 77)	Female[c]	Terrestrial foam nest	Ground
L. fuscus (17, 52)	Female	Burrow built by male	Near burrow
L. insularum (53, 73)	Female	Aquatic foam nest	Shallow water
L. ocellatus (19, 22)	Female	Aquatic foam nest	Shallow water
L. podicipinus (69)	Female	Aquatic foam nest	Shallow water
L. validus (64)	Female	Aquatic foam nest	Shallow water

Notes: Species in the genus *Eleutherodactylus* are listed separately in Table 11.2. Dendrobatid frogs, which also carry tadpoles, are listed in Table 11.3. In cases where both males and females have been observed with egg clutches, the most frequent attendant is listed first.

[a] Both males and females of *Oreophrynella nigra* were found near egg clutches laid communally in underground tunnels. One female was found with a single clutch.

[b] Jacobson (1985) reported that *Centrolene proseblepon* females remained with eggs for up to 2 hours, but this may not be parental care.

[c] *Leptodactylus fallax* females reported to feed tadpoles.

[d] Several adults of *Cophixalus ornatus* of undetermined sex found under slabs of exfoliating rock with multiple egg clutches.

[e] One male *Arenophryne rotunda* was found sitting on an egg clutch; another clutch had no attendant.

[f] Females of *Assa darlingtoni* guard eggs, but males carry tadpoles.

[g] Males of *Chirxalus eiffingeri* attend eggs in bamboo stumps; females return to feed eggs.

Pombal, and Haddad 1998), as has been suggested for *H. rosenbergi* as well (Kluge 1981).

Females of several species of *Leptodactylus* remain with eggs in an aquatic foam nest or in a burrow near water (Lescure 1973, 1979; Vaz-Ferreira and Gehrau 1975; Lescure and Letellier 1983; Downie 1996; Prado, Uetanabaro, and Lopes 2000; I. Martins 2001; Ponssa 2001), and they often remain with the tadpoles after they hatch (see the following "Attendance of Tadpoles and Young"). In *L. fallax*, a species that places foam nests in cavities on the ground, both males and females remain near the nest and are aggressive toward human intruders and, presumably, potential predators (Gibson and Buley 2004). Attendance of foam nests by males has been reported in the Australian myobatrachid *Adelotus brevis* (J. Moore 1961) and the African bufonid *Nectophryne afra* (Scheel 1970). Males of the hairy frog of Africa, *Trichobatrachus robustus* (Astylosternidae), are reported to attend their eggs, which are laid in streams (Perret 1966).

Attendance of nonaquatic eggs is more common, and has been reported in bufonids, centrolenids, dendrobatids, hemisotids, hyperoliids, leiopelmatids, leptodactylids, mantellids, microhylids, myobatrachids, petropedetids, rhacophorids, rhinodermatids, and sooglossids (Crump 1995b, 1996; Lehtinen and Nussbaum 2003). The widespread occurrence and repeated evolution of egg attendance in different families suggests that the transition from unattended eggs to attended eggs is a relatively simple process, since it merely requires a parent to remain at the oviposition site after eggs are laid. Parental care is not essential for successful nonaquatic oviposition, however. Many frogs that lay eggs on land or on vegetation do not care for them, but simply abandon them at the oviposition site (Lamotte and Lescure 1977; see also chapter 10). There are, for example, many species of hylids that lay eggs on leaves overhanging bodies of water, but parental attendance of eggs has not been reported in any of these species (J. Hayes 1991). Many species of *Eleutherodactylus* that lay their eggs on the ground or in leaf litter also abandon them (Townsend 1996).

The details of parental care are not known for most of the species listed in tables 11.1–11.3; most accounts consist of brief observations of adult frogs found in association with eggs at oviposition sites. Nevertheless, detailed studies of a few species have revealed a considerable amount of variation in the nature and persistence of parental behavior. In some frogs, a parent sits on the egg mass, with the body pressed against the eggs. Species of frogs that exhibit this form of parental care include two species of *Leiopelma;* most, if not all of the microhylids from New Guinea (fig. 11.2 A, B); the African petropedetid *Phrynodon sandersoni;* many species of *Eleutherodactylus* (fig. 11.2 C); and some species of *Colostethus* and *Epipedobates* (Dendrobatidae; Lüddecke 1974; McDiarmid 1978; Amiet 1981, 1989; Simon 1983; Townsend, Stewart, and Pough 1984; B. Bell 1985; Weygoldt 1987; Johnston and Richards 1993; Crump 1995b; Diesel, Baurle, and Vogel 1995; Joglar, Burrowes, and Rios 1996; Burrowes 2000; Bickford 2001, 2004; Lehtinen and Nussbaum 2003). In some of these species, the parent remains with the eggs most of the time during development, but in others, parents attend eggs only at night and seek more protected retreat sites during the day (McDiarmid 1978; M. Hayes 1991; Bickford 2004). Attendance can be prolonged, especially in species with direct development (about three weeks in *Eleutherodactylus coqui;* up to three months in *Cophixalus parkeri*). Female African shovel-nosed frogs (*Hemisus*) have been observed in close contact with eggs when they were unearthed from underground burrows, but the details of their parental behavior underground are not known (Rödel et al. 1995; Rödel 1996; Kaminsky, Linsenmair, and Grafe 1999).

Other species are less attentive and do not always sit directly on the eggs. For example, males of the centrolenid frog *Hyalinobatrachium fleischmanni* and several closely related species do not attend their eggs continuously, but return periodically to sit on them for brief periods of time, apparently releasing water onto the eggs (M. Hayes 1991). In *H. fleischmanni,* such behavior occurs mostly after midnight and is so infrequent that Greer and Wells (1980) failed to observe it. M. Hayes (1991) reported that attendance of eggs was more frequent in dry weather than in wet weather, suggesting a degree of plasticity in parental behavior. Males of this species spend relatively little time attending eggs when they are not providing them with water, whereas males of some centrolenids attend their eggs for longer periods of time. For example, McDiarmid (1978) reported that males of *H. valerioi* attended eggs during the day and at night, although they usually did not sit on the egg masses (fig. 11.2 D). In contrast, males of *H. colymbiphyllum* attended eggs only at night. They also spent most of their time sitting next to, but not on, egg masses. In *Centrolene geckoideum,* which lays eggs attached to rocks near waterfalls, males have been observed sitting on or near egg masses, but the amount of time that males spend attending eggs has not been determined (Lynch, Ruiz, and Rueda 1983; T. Grant, Bolívar-G., and Castro 1998). Males of some hyperoliid frogs also remain near eggs laid on vegetation, but do not sit on the eggs (fig. 11.2 E).

Males of several African frogs in the genus *Petropedetes* are reported to attend eggs only at night, and they sit next to the eggs, not directly on them (Amiet 1981). Males of the Taiwanese rhacophorid frog *Chirixalus eiffingeri* remain at nest sites in bamboo stumps, sometimes in contact with eggs laid on the walls of the bamboo (fig. 11.2 F), but females return periodically to feed the tadpoles (see the following; Kam, Chuang, and Yen 1996). In *Colostethus stepheni,* a dendrobatid frog that does not transport its tadpoles, males remain within about 20 cm of the oviposition site after eggs are laid, but visit the site only occasionally after the first two to three days (Junca, Altig, and Gascon 1994; Junca 1996). In other species that do transport tadpoles, such as *C. beebei,* males visit egg clutches repeatedly to moisten them, but do not remain with them continuously (Bourne et al. 2001). Observations of two other dendrobatids in captivity, *Epipedobates pulchripectus* and *E. pictus,* revealed that males typically sat on their egg clutches at night, but deserted them for variable intervals during the day, either to rehydrate or to feed. Males of *E. pictus* were reported to become

Table 11.2 Examples of egg attendance in the genus *Eleutherodactylus*

Species (source no.)	Attendant	Oviposition sites	Calling sites
E. abbotti (26)	Male[a]	Leaf litter	Not reported
E. amadeus (17)	Male	Under rocks, logs	Ground or vegetation
E. amplinympha (23)	Male[a]	Rock crevice on cliff	Rocks
E. antillensis (33)	Male[b]	Leaf litter	Shrubs
E. augusti (3)	Male[a]	Under rock	Rocks, ground
E. auriculatoides (26)	Male[a]	Bromeliads	Not reported
E. bakeri (26)	Male	Bromeliads	Bromeliads?
E. cochranae (30)	Male	Bromeliads	Bromeliads
E. cooki (6, 25, 30, 31)	Male	Under rocks	Tops of rocks
E. coqui (11, 30)	Male	Dead leaves, petioles	Shrubs, trees
E. diastema (26)	Male[a]	Bromeliads, leaf axils	Bromeliads, leaf axils
E. glandulifer (26)	Male	Under rocks	Ground
E. guantanamera (19)	Male	Bromeliad axils	Bromeliads
E. hedricki (9)	Male	Tree holes	Tree holes, trunks
E. inoptatus (26)	Male	Under rocks, burrows	Not reported
E. intermedius (20)	Male[a]	Hole in soil	Hole in soil
E. montanus (26)	Male[a]	Under rocks	Not reported
E. portoricensis (13)	Male	Dead leaves, petioles	Shrubs, trees
E. tetajulia (24)	Male	Hole in tree fern	Hole in tree fern
E. unicolor (26)	Male[a]	Not reported	Not reported
E. ventrilineatus (26)	Male	Not reported	Not reported
E. wightmanae (26, 36)	Male	Leaf litter	Leaf litter
E. alticola (15	Either	Under rocks	Not reported
E. johnstonei (12, 27)	Either	Leaf litter	Shrubs, trees
E. affinis (26)	Female	Under rock	Not reported
E. albipes (35)	Female	Under rock	Not reported
E. angelicus (15)	Female	Terrestrial cavity	Not reported
E. anomalus (13)	Female[a]	Depression in sand	Ground or rocks
E. atkinsi (18)	Female[a]	Cavity in ground	Not reported
E. caryophyllaceus (5)	Female	Leaf surface	Shrubs
E. cundalli (11, 22)	Female	Leaf litter, caves	Shrubs, trees, caves
E. decoratus (7)	Female	Under rocks	Not reported
E. dimidiatus (16)	Female[a]	Leaf litter	Not reported
E. fitzingeri (13, 32)	Female	Leaf litter	Ground, shrubs, logs
E. glaucoreius (26)	Female	Soil cavities, banks	Not reported
E. lymani (28)	Female	Under rocks	Not reported
E. martinicensis (1, 10)	Female	Under rocks	Shrubs, walls
E. maussi (5)	Female	Leaf litter	Not reported
E. nicefori (26)	Female[a]	Under rocks	Not reported
E. noblei (34)	Female	Under leaves in tree buttress	Not reported
E. nubicola (1)	Female	Under rocks	Rocks, banks
E. pantoni (26)	Female	Soil cavities, banks	Not reported
E. pentasyringos (2)	Female	Under rocks	Not reported
E. percultus (26)	Female[a]	Bromeliad axil	Not reported

Notes: Species are arranged by the sex of the care-giving parent. Information based on data summarized in Wells (1981a), Crump (1995), and Townsend (1996) and later papers, with additional data supplied by Daniel Townsend.

[a] Indicates species for which only single observations of an attending parent are available, or the extent of parental care is uncertain.

[b] One male observed near egg clutch; other clutches found without attending parent.

Table 11.3 Parental care and aggressive behavior in dendrobatid frogs

Species (source no.)	Tadpole habitat	Sex caring for:		No. of tadpoles carried	Aggressive behavior	
		Eggs	Tadpoles		♂	♀

Notes: Many species use more than one type of tadpole deposition site; only the most commonly used sites are listed. For the genera *Allobates, Colostethus, Epipedobates, Mannophryne,* and *Phyllobates,* small numbers of tadpoles carried probably do not represent the entire complement. Aggressive behavior: (+) present, (–) absent, T = frogs are territorial in the field. Blank cells indicate that there is no information.

[a] Species in which aggressive behavior has been observed only in captivity.

[b] Males carry tadpoles; females feed tadpoles with unfertilized eggs.

[c] Males usually carry tadpoles, but occasional transport by females has been reported.

[d] Females feed tadpoles with unfertilized eggs.

[e] These species of *Mannophryne* were previously in the genus *Colostethus.*

progressively less attentive to their eggs and started advertising for additional mates before their first clutches hatched (Weygoldt 1987). Many other dendrobatids do not remain for long periods of time at the oviposition site, but return periodically to moisten the eggs and eventually to transport the tadpoles to water. Sometimes a parent can care for more than one clutch in different locations simultaneously (Wells 1978a; H. Zimmermann and Zimmermann 1981, 1988; Weygoldt 1987; K. Summers 1989). It is possible that some dendrobatids do not care for their eggs at all, but return to the oviposition site only to carry their tadpoles (Roithmair 1992).

Transport of Eggs

Frogs in four distantly related families have evolved the habit of carrying eggs on a parent's body. In each family a single clade exhibits a unique form of parental care. In the midwife toads, *Alytes* (Discoglossidae), pairs mate on land, and after the eggs are fertilized, the male wraps the strings of eggs around his hind legs. The eggs are carried for about

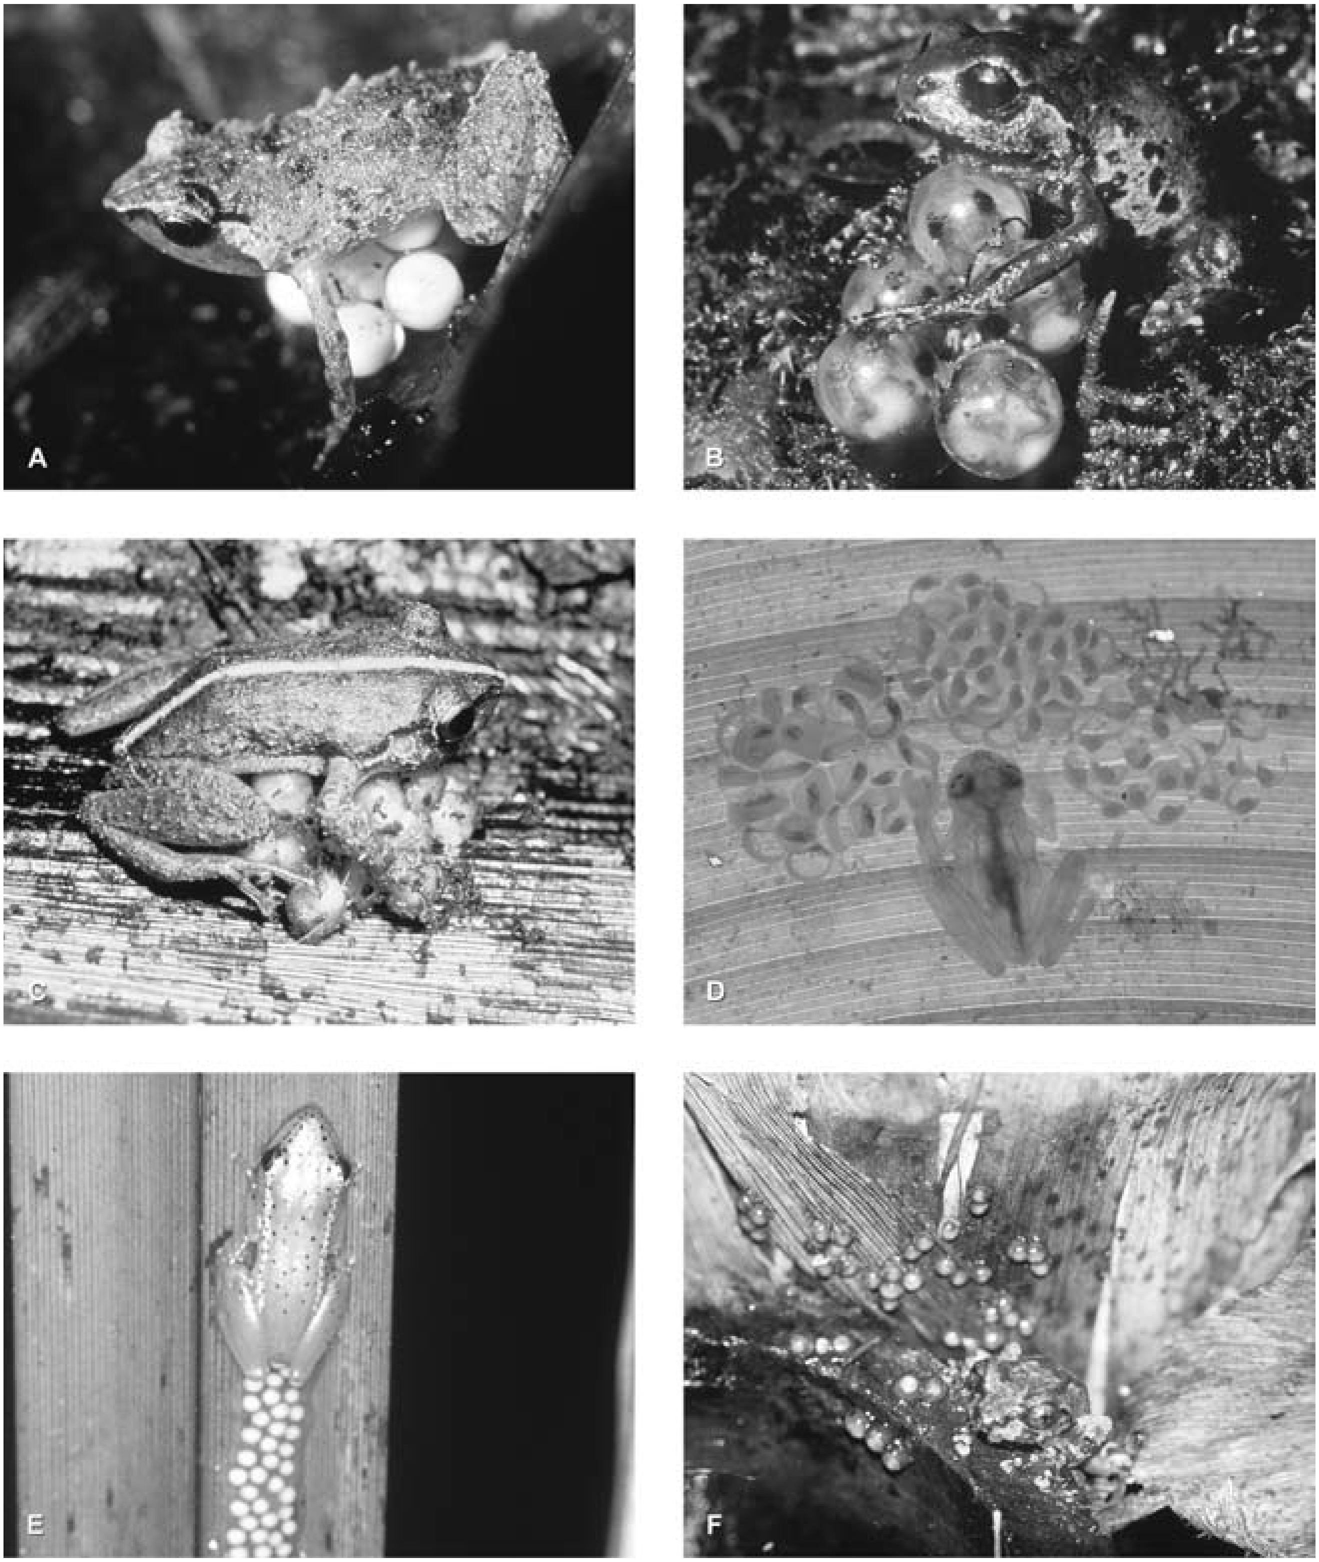

Fig. 11.2. Attendance of nonaquatic eggs by male anurans. (A) A male of a species of *Albericus* (Microhylidae) from New Guinea brooding a clutch of unpigmented eggs. (B) A small male of a species of *Oreophryne* (Microhylidae) from New Guinea brooding a clutch of very large eggs. (C) A male of *Eleutherodactylus coqui* (Leptodactylidae) from Puerto Rico brooding eggs. (D) A male of *Hyalinobatrachium valerioi* (Centrolenidae) from Costa Rica guarding three clutches of eggs laid on a leaf, photographed from below the leaf. (E) A male of *Hyperolius parkeri* (Hyperoliidae) from East Africa guarding a clutch of eggs on a leaf. (F) A male of *Chirixalus eiffingeri* (Rhacophoridae) guarding eggs at the edge of a hollow bamboo stump. The eggs usually are laid just above the water line, but some eggs may become submerged. Photos by David Bickford (A, B), Margaret M. Stewart (C), Walter Hödl (D, E), and Kentwood D. Wells (F).

a month until they hatch and tadpoles are released into ponds (Boulenger 1912; Lopez-Jurado, Caballero, and Dos-Santos Freitas 1979; Crespo 1982; König and Schlüter 1991; Márquez and Verrell 1991; Márquez 1992). Males are capable of carrying up to three clutches of eggs simultaneously, and some males carry more than 100 eggs at a time. Large males tend to have greater mating success and therefore carry more eggs than small males (Reading and Clarke 1988; Raxworthy 1990; Márquez 1993; Verrell and Brown 1993). The origin of this unique form of parental care, which is shared by all four species in the genus (*A. obstetricans, A. cisternasii, A. muletensis, A. dickhilleni*), is obscure. All living species that are closely related to *Alytes* lay eggs in water and lack parental care (see chapter 10). Discoglossid frogs are an ancient lineage, and the living species represent a small remnant of a much more diverse group (Sanchiz and Roček 1996) that might have included other species with parental care. The genus *Alytes* is estimated to be at least 15 million years old (Maxson and Szymura 1984), so this form of parental care could be at least that ancient.

In all other species that transport eggs, it is the female that carries the eggs. In the family Pipidae, one genus, *Pipa,* exhibits parental care; all others lay eggs in water (see chapter 10). After each egg is released by the female and fertilized by the male, the pair performs a complex acrobatic maneuver in the water that causes the egg to stick to the back of the female (see fig. 10.12 in chapter 10). Eventually the tissues on the female's back swell into a spongy matrix that engulfs the eggs. The eggs complete development in separate capsules within this tissue. In some species, including *P. parva, P. myersi,* and *P. carvalhoi,* the eggs hatch into tadpoles, which complete their development in the water. In others, including *P. pipa, P. arrabali,* and *P. snethlageae,* the eggs undergo direct development and hatch as miniature froglets (Rabb and Snedigar 1960; Rabb and Rabb 1960, 1963a; Weygoldt 1976a, b; Trueb and Cannatella 1986). Species with direct development are thought to represent the most derived condition (Duellman 1989a; see fig. 10.11 in chapter 10). As in midwife toads, it is hard to imagine the evolutionary steps leading to such an unusual form of parental care, but again, this behavior could have evolved millions of years ago. Fossil pipids in South America go back at least 95–100 million years, but the age of the genus *Pipa* is unknown (Báez 1996).

One of the strangest modes of egg transport was described in two species of Australian myobatrachids, *Rheobatrachus silus* and *R. vitellinus.* The female would ingest relatively late-stage embryos and then carry the eggs and larvae in her stomach; this behavior therefore grades into tadpole transport (Corben, Ingram, and Tyler 1974; K. McDonald and Tyler 1984; Leong, Tyler, and Shearman 1986). The female would give birth through her mouth (Tyler and Carter 1981). This peculiar behavior was possible because secretion of digestive enzymes is inhibited during gastric brooding, apparently in response to hormones secreted by the embryos (Tyler 1983; Tyler et al. 1983). These frogs were of great interest to digestive physiologists because of possible insights they might provide into mechanisms to shut down production of digestive enzymes, with possible applications to treating gastric ulcers (Tyler 1983). Unfortunately, it now appears that both species are extinct, part of a general decline in rainforest frogs in northern Australia (K. McDonald 1990; S. Richards, McDonald, and Alford 1993). Consequently, the opportunity to learn more about this unique form of parental care probably has been lost. The origins of this form of parental care are a mystery, and even the relationship of *Rheobatrachus* to other myobatrachids is uncertain (Ford and Cannatella 1993; Littlejohn et al. 1993).

Egg transport is characteristic of one group of Neotropical frogs, the Hemiphractinae. This group traditionally has been considered part of the family Hylidae (Sheil, Mendelson, and da Silva 2001), but both molecular studies (Ruvinsky and Maxson 1996; Faivovich et al. 2005) and tadpole morphology (Haas 2003) suggest that the group actually is rather distantly related to other hylids. Indeed, the group as a whole may represent as many as three separate clades that are not closely related to each other, in which case various forms of egg transport would have evolved independently (Frost et al. 2006). The embryos of these frogs are unique in developing large bell-shaped gills that provide enhanced surface area for gas exchange and sometimes completely envelop the developing embryos. In all species the female carries the eggs, but the site of egg transport and the structure of brood pouches varies considerably among different genera. In three largely terrestrial genera, *Hemiphractus, Cryptobatrachus,* and *Stefania,* large eggs are carried exposed on the back of the female, without an enclosed brood pouch (Duellman 1970; Trueb 1974; Duellman and Hoogmoed 1984; Jungfer and Boehme 1991; Crump 1995b). Del Pino (1980) thought that mucus glands on the back of the female produce secretions that glue the eggs in place, but mating and egg deposition has not been observed. Possibly the eggs are held onto the back of the female by mucus produced in the oviducts and extruded with the eggs, as has been reported for *Flectonotus goeldii* (Weygoldt and Carvalho e Silva 1991). The eggs of all of these genera undergo direct development and hatch into tiny froglets. In at least one species of *Stefania,* the hatchlings remain on the back of the female after hatching (fig. 11.3) and will even try to climb back on if they fall off (Gorzula, Morales, and Hernandez 1983; Jungfer and Boehme 1991), so egg transport grades into offspring transport in these species.

In the arboreal genus *Flectonotus,* eggs are carried in a dorsal brood pouch with an opening down the middle (Duellman and Gray 1983). In *F. goeldii* and *F. ohausi,* there is scarcely

Fig. 11.3. Female of *Stefania evansi* (Hemiphractinae) carrying froglets on her back. Members of this genus carry eggs exposed on the back of the female before hatching. Photo by Karl Heinz Jungfer.

any brood pouch. Eggs are attached to the dorsum of the female, with flaps of dorsal skin forming slight walls around them, but not meeting in the middle. There is little or no structural alteration of the skin to form a brood pouch (Del Pino 1980; Weygoldt and Carvalho e Silva 1991). The male places the eggs on the back of the female. He grasps each egg with his hind foot as it emerges from the female's cloaca. He then rotates the egg onto the female's back and beats the mucus secretions surrounding the eggs into froth. This eventually hardens to form a brood sac, which readily detaches from the female once the eggs hatch. In *F. fissilis,* the lateral skin flaps form a more complete brood pouch, with the edges glued together in the middle with mucus secretions. The most complete brood pouches are found in *F. pygmaeus* and *F. fitzgeraldi,* two closely related species. The brood pouch is completely enclosed (fig. 11.4 A). The pouch tissue swells during incubation and becomes moderately well vascularized, suggesting that there is some gas exchange between the mother and the embryos (del Pino 1980). Mating behavior has been observed in *F. pygmaeus*. The male opens the pouch with his feet and catches each egg as it is laid, pushing it into the pouch with his feet and body (Duellman and Maness 1980).

In all species of *Flectonotus,* eggs develop relatively rapidly (three to four weeks in captivity) and hatch as tadpoles in an advanced stage of development. These are deposited by the female in small bodies of water in bromeliads, the leaf axils of aroids and *Heliconia* plants, and holes in bamboo. The tadpoles do not have well-developed mouthparts (Wassersug and Duellman 1984). Initially, all species were thought to complete development without feeding by living off their abundant yolk reserves (Duellman and Gray 1983), but Weygoldt (1989b) reported that tadpoles of *F. goeldii* feed on detritus that falls into their bromeliads.

Fig. 11.4. Fully enclosed brood pouches of hemiphractine marsupial frogs. (A) Female *Flectonotus fitzgeraldi* from Trinidad with a clutch of four eggs. The male pushes the eggs into the pouch through the slit down the center of the back, which later closes over the eggs. (B) Female *Gastrotheca fissipes* from Brazil carrying a large clutch of eggs. The pouches of this genus have small posterior openings. Photos by Kentwood D. Wells (A) and Ivan Sazima (B).

The most complex brooding behavior is found in the genus *Gastrotheca,* a diverse group that includes both arboreal and terrestrial species (Duellman and Fritts 1972; Duellman 1974; Duellman and Hillis 1987). These frogs have completely enclosed brood pouches with a relatively small posterior opening (fig. 11.4 B). The male pushes the eggs into the pouch, as in *Flectonotus* (Duellman and Maness 1980). The tissue surrounding the eggs swells and becomes highly vascularized, probably providing for gas exchange between the mother and the embryos, but not exchange of nutrients (del Pino 1980). Incubation can be prolonged, up to 120 days in captivity in some species. More than half the species in the genus have direct development of eggs, and many of these live in lowland rainforest habitats. Other species in the genus have eggs that hatch into feeding tadpoles with well-developed mouthparts (Fitzgerald, Guillette, and Duvall 1979; Wassersug and Duellman 1984). Most species deposit their tadpoles in ponds, but some place them in smaller bodies of water, such as bromeliads (Duellman and Maness 1980). Tadpole-producing species of *Gastrotheca* are limited to high elevations in the Andes (Duellman and Hillis 1987; Duellman, Maxson, and Jesiolowski 1988).

The origins and evolution of egg transport in hemiphractines are difficult to reconstruct. There are no other hylids or leptodactylids that transport their eggs, and relatively few species that provide their eggs or larvae with any kind of parental care. Consequently, it is difficult to determine the intermediate steps leading from more typical aquatic or nonaquatic modes of reproduction to egg transport in this group. Molecular data suggest that this assemblage of frogs is very old, with the various genera diverging from one another as much as 50–100 million years ago (Duellman, Maxson, and Jesiolowski 1988; Frost et al. 2006). Hence, there has been ample time for the evolution of the distinct modes of egg transport seen in the different lineages, with little indication of transitions between them.

The morphology of the brood pouches suggests a transition from transport of eggs on the dorsum of the female as the ancestral condition, as seen in *Hemiphractus, Cryptobatrachus,* and *Stefania,* to the more complex, partially or completely enclosed brood pouches of *Flectonotus* and *Gastrotheca.* On the other hand, all of the species that lack a brood pouch have direct development, usually considered a derived reproductive mode. Duellman (1989a) used a phylogeny of hemiphractine frogs derived from molecular data and developmental characters to trace the evolution of reproductive modes in the group. He argued that direct development is the ancestral mode for the entire subfamily, with deposition of tadpoles, either feeding or nonfeeding, having evolved independently in several lineages. This analysis also suggested that evolution of a partially or completely enclosed brood pouch occurred only once. A basic assumption of this analysis is that the hemiphractines comprise a monophyletic clade, but this conclusion is subject to revision as more modern molecular techniques are used to explore the phylogenetic relationships of the group (Frost et al. 2006).

Attendance of Tadpoles

Most adult frogs are terrestrial, and only a few species attend aquatic tadpoles. Males of an African bufonid, *Nectophryne afra,* remain with tadpoles for up to two weeks after they hatch, and are reported to aerate the nest by kicking their legs while swimming in place (Scheel 1970). In the African bullfrog, *Pyxicephalus adspersus* (Ranidae), males remain with their tadpoles, which form dense schools after hatching (B. Balinsky and Balinsky 1954; W. Rose 1956; Poynton 1957). Some authors questioned whether this species actually protects the tadpoles (Wager 1956, 1965; Lambiris 1971). More recent observations by Kok, du Preez, and Channing (1989) and C. Cook, Ferguson, and Telford (2001) showed that males sometimes construct channels that allow their tadpoles to move from isolated shallow pools at the edges of ponds to deeper water, where they can complete their development. C. Cook, Ferguson, and Telford (2001) also confirmed the earlier observations of B. Balinsky and Balinsky (1954) that males attack potential tadpole predators and sometimes are killed in the process.

Females of African shovel-nosed frogs in the genus *Hemisus* remain with their tadpoles in an underground burrow (fig. 11.5 A, B). Eventually the female frees the tadpoles by digging her way out of the nest and constructing a slide or channel that allows the tadpoles to reach the water. The tadpoles follow the female closely (fig. 11.5 C) and may even ride on her back as she makes her way to deeper water, where the tadpoles complete development (Wager 1965; Rödel et al. 1995; Rödel 1996; Kaminsky, Linsenmair, and Grafe 1999).

Somewhat similar behavior has been observed in several Neotropical frogs in the genus *Leptodactylus,* but in these species, eggs are laid in foam nests floating in the water. In a Panamanian species, *Leptodactylus insularum,* females lead schools of tadpoles in shallow water and push their way through obstructing mud and vegetation into deeper pools (Wells and Bard 1988; Vaira 1997). They communicate with their tadpoles by means of a "pumping" display in which the rear part of the body was moved up and down in the water, creating a series of concentric waves that moved toward the tadpoles (fig. 11.6). Females also are aggressive toward simulated predators or other frogs (Vaira 1997; Ponssa 2001). Very similar behavior has been observed in a closely related species, *L. ocellatus.* Females attend schools of tadpoles and guard them against predators (Vaz-Ferreira and Gehrau 1975). This species also has been observed leading tadpoles with pumping movements similar to those of *L. insularum* (Jan Caldwell, personal communication). Females of an-

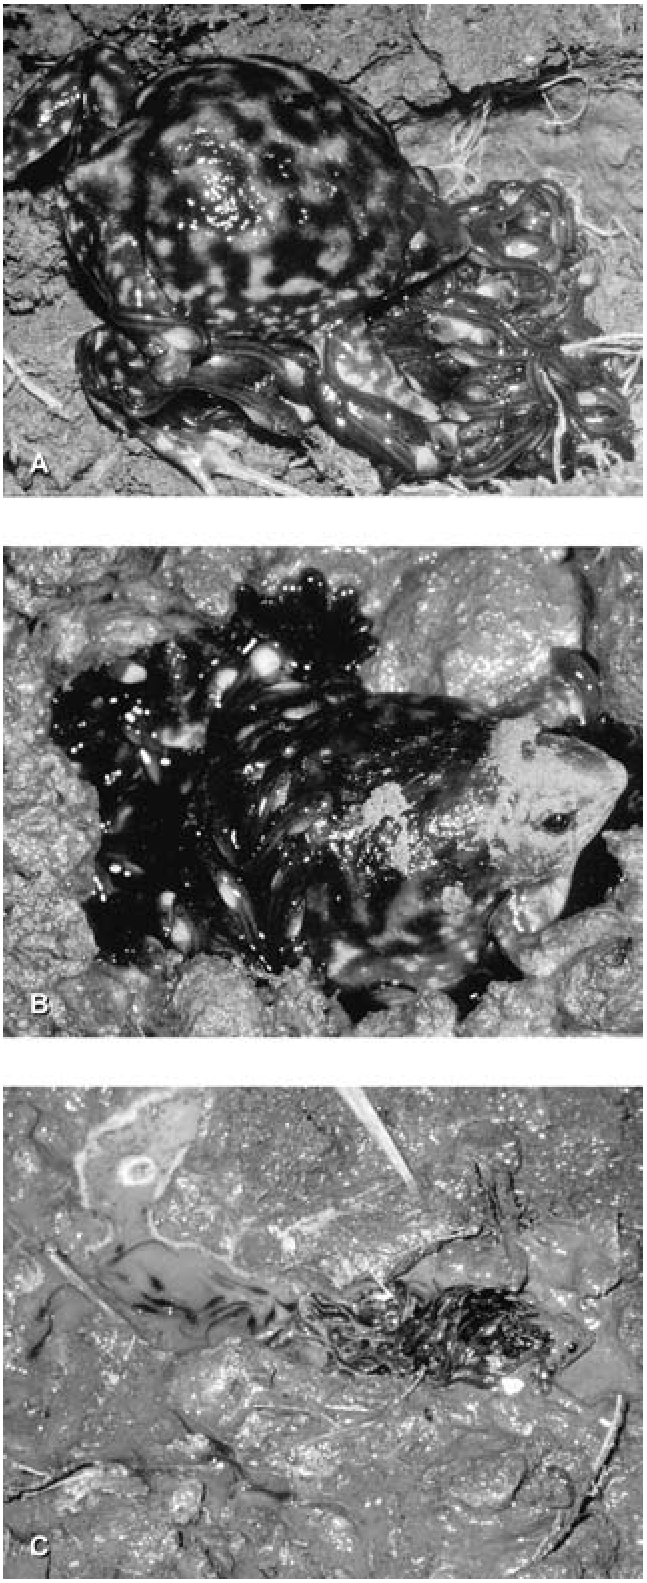

Fig. 11.5. Parental care in the West African frog *Hemisus marmoratus.* (A) Female attending a group of tadpoles in a subterranean nest, from which the top has been removed. (B) Tadpoles clustered around the female, with some tadpoles clinging to her back, as she digs out of the burrow. (C) School of tadpoles following the female in a shallow channel in the mud. Photos by Mark Oliver Rödel (A) and Stefan Kaminsky (B, C).

other species in the *L. ocellatus* group, *L. chaquensis,* also attend schools of tadpoles, but their behavior toward the tadpoles has not been observed in detail (Prado, Uetanabaro, and Lopes 2000).

Pumping movements by females attending schools of tadpoles have been reported in three species in the *L. melanonotus* group, which is thought to be closely related to the *L. ocellatus* group (Downie 1996; Prado, Uetanabaro, and Lopes 2000; Prado, Uetanabaro, and Haddad 2002; I. Martins 2001). In two of these species, *L. validus* and *L. leptodactyloides,* aggressive behavior by females has not been reported. Females of the third species, *L. podicipinus,* did attack simulated predators (sticks and hands). These frogs are all smaller than are members of the *L. ocellatus* group, so it is possible that aggressive attacks on predators are less common in this group. In some other species of *Leptodactylus,* a parent remains with nonfeeding tadpoles in an aquatic or terrestrial foam nest, but their behavior has not been studied in detail (G. Brooks 1968; Lescure 1973, 1979).

Parental attendance of tadpoles also has been reported in several species of anurans that have nonfeeding tadpoles that hatch from eggs laid in small bodies of water or in terrestrial nests (see chapter 10). For example, males of several microhylids from Madagascar remain with nonfeeding larvae in tree holes and leaf axils (Blommers-Schlösser 1975a). Males of the South American microhylid *Synapturanus salseri* are reported to remain with eggs and nonfeeding tadpoles in an underground nest (Pyburn 1975). In two species of *Leiopelma* in New Zealand, *L. hamiltoni and L. archeyi,* the larvae remain in the nest with the male through metamorphosis; in a third species, *L. hochstetteri,* larvae are aquatic and do not remain with a parent (B. Bell 1985; B. Bell and Wassersug 2003).

Transport of Tadpoles

In some anurans, attendance of tadpoles tends to grade into tadpole transport. The example of some tadpoles of *Hemisus marmoratus* riding on the back of the female to water has already been discussed. Heyer and Crombie (1979) found a female of the leptodactylid frog *Cyclorhamphus stejnegeri* under a log with 40 tadpoles on her back. Whether females transport tadpoles to water or simply attend them for some period of time is not known, but the morphology of the tadpoles suggests that they complete development out of water. In *Leiopelma archeyi* and *L. hamiltoni,* the tadpoles climb onto the back of the male, but the male evidently remains at the oviposition site until tadpoles metamorphose, rather than transporting them to another site (B. Bell 1985; B. Bell and Wassersug 2003). Tadpoles of *Sooglossus seychellensis* (Sooglossidae) attach themselves to the back of a parent, where they complete their development by drawing on their large yolk reserves. Originally males were thought to perform pa-

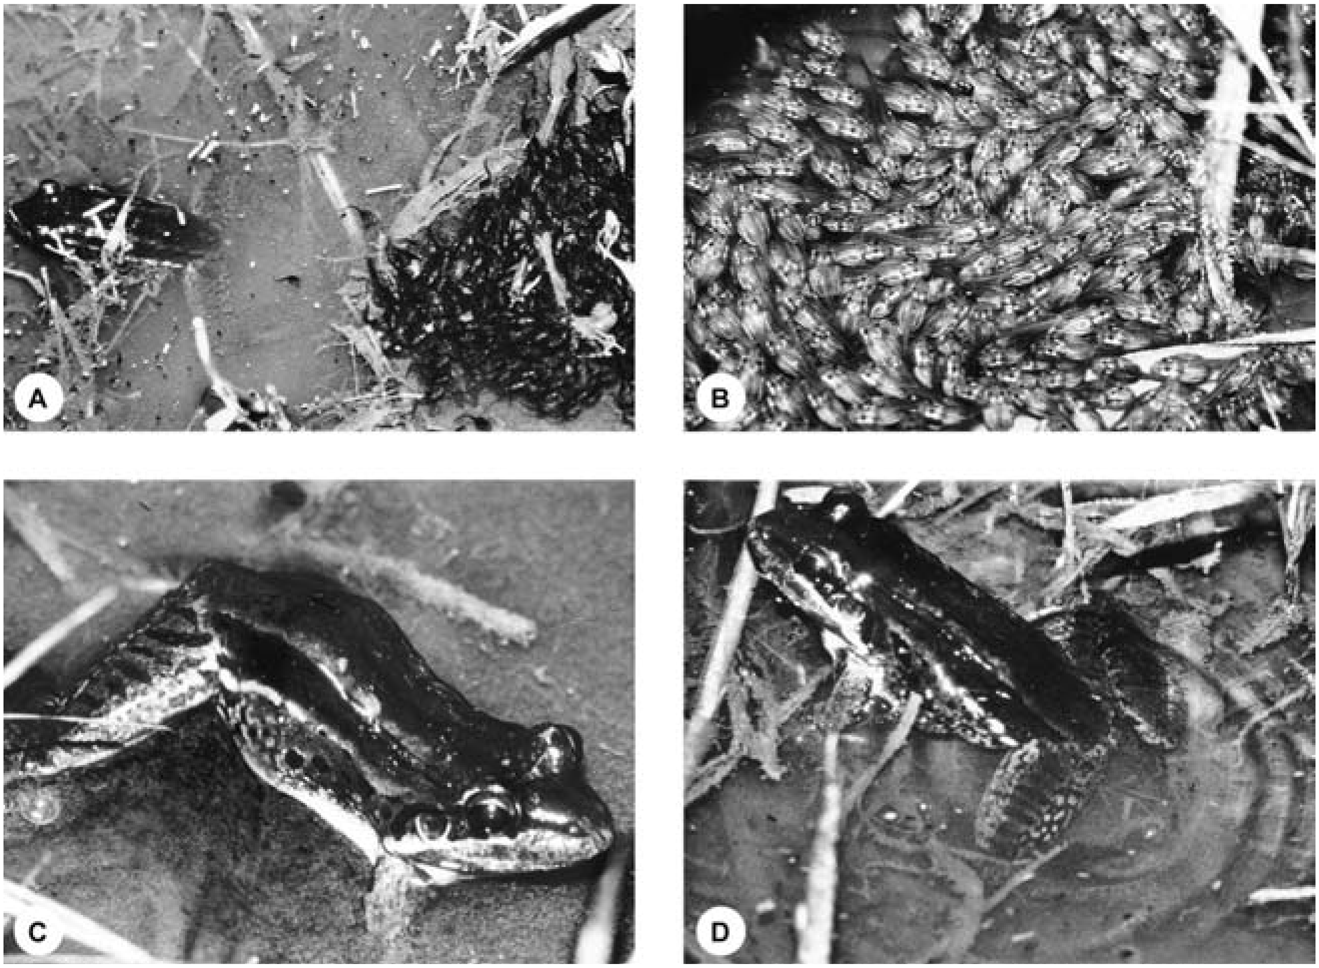

Fig. 11.6. Parental care in the Panamanian frog *Leptodactylus insularum.* (A) Female followed by a school of tadpoles. (B) Dense school of tadpoles. (C) Female giving pumping signal to tadpoles, with rear of the body elevated. (D) Female bringing the rear of her body down into the water, producing concentric waves on the water. Photos by Kentwood D. Wells.

rental duties, but more recent observations indicate that the female is the caregiving parent (Nussbaum 1984; Nussbaum, unpublished data cited in Crump 1995b). Tadpoles of the dendrobatid frog *Colostethus degranvillei* also are reported to complete development on the back of the female (Lescure 1984).

Most dendrobatid frogs carry their tadpoles on their backs from a terrestrial oviposition site to water (table 11.3). The only exceptions known at present are *Colostethus degranvillei* and two species with tadpoles that develop at the terrestrial oviposition site without being carried to water, *C. stepheni* and *C. chalcopis* (Junca, Altig, and Gascon 1994; Kaiser and Altig 1994; Kaiser, Coloma, and Gray 1994; Junca 1996). The reproductive biology of many species of *Colostethus,* a large and diverse genus, is unknown, and it is possible that other species that do not carry tadpoles will be discovered. The reproductive biology of the nocturnal species *Aromobates nocturnus,* which is thought to be the sister species to all other dendrobatids, also is unknown, but tadpoles have been found in streams (C. Myers, Paolillo O., and Daly 1991).

In *Colostethus, Mannophryne, Allobates, Epipedobates, Phyllobates,* and *Cryptophyllobates,* a parent carries up to 40 tadpoles at once (fig. 11.7 A). The tadpoles are placed in a variety of aquatic sites (fig. 11.7 B), including streams, streamside pools, swamps, temporary ponds, small pools on the forest floor, or water collected in stumps, logs, fallen bamboo, the petioles of fallen palm fronds, or seed pods (Jowers and Downie 2005). One species, *Mannophryne trinitatis,* even has been observed depositing tadpoles on wet leaf litter when suitable pools were not available (Downie, Livingstone, and Cormack 2001). Tadpoles of one species, *Colostethus bromelicola,* have been found in bromeliads up to five meters above the forest floor, and adults are never seen on the ground (Dixon and Rivero-Blanca 1985). It is not known whether the eggs are laid in bromeliads, or the

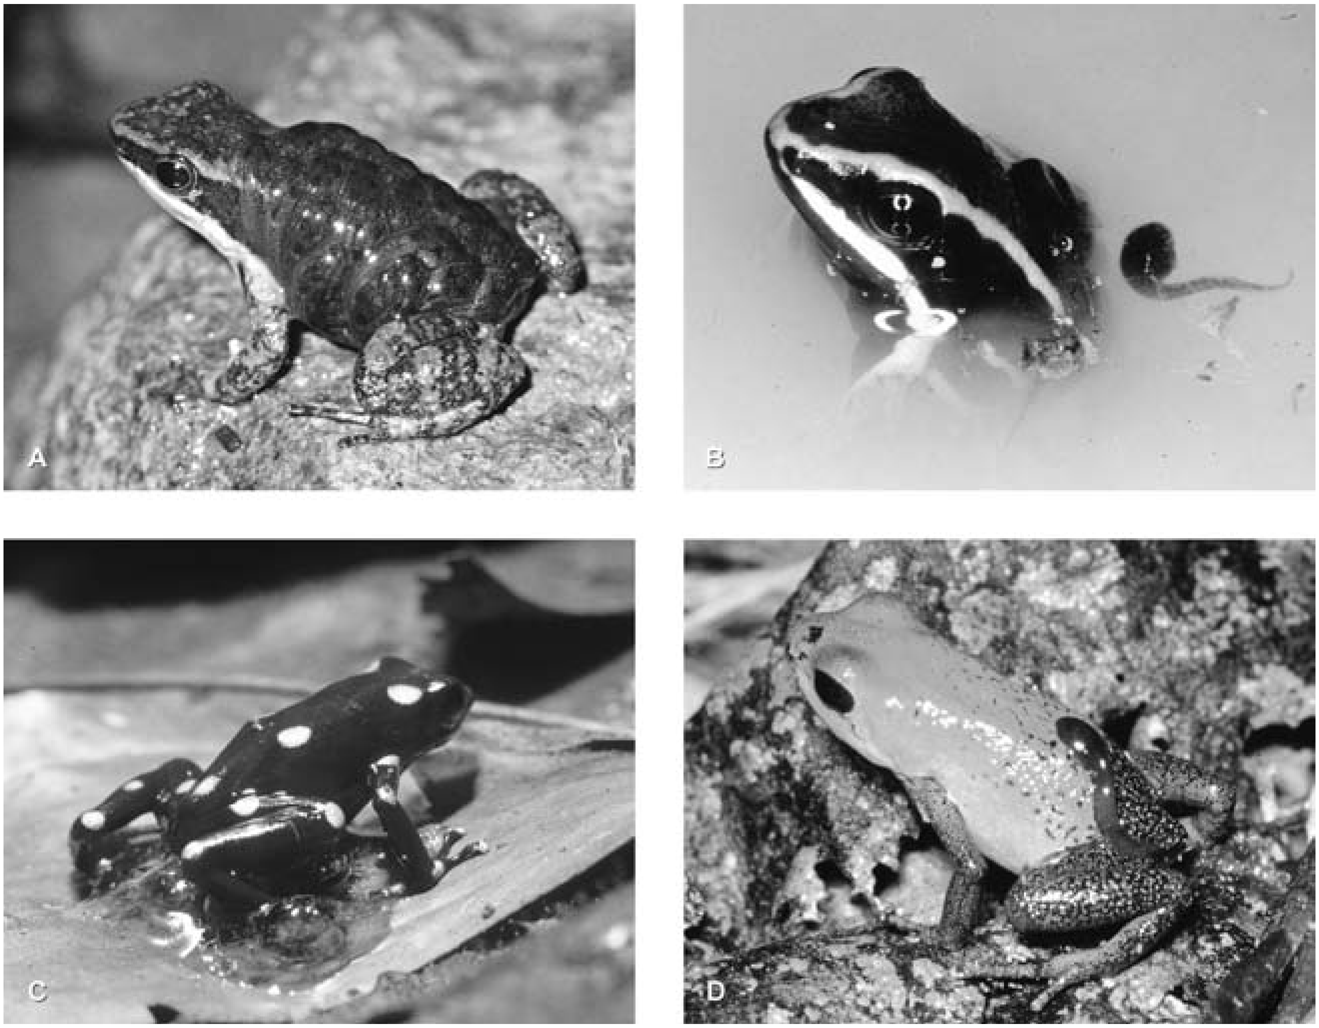

Fig. 11.7. Parental care in dendrobatid frogs. (A) Female *Colostethus panamensis* carrying a complete clutch of tadpoles. (B) Male *Allobates femoralis* depositing a tadpole in water. This species carries an entire clutch of tadpoles and releases them into small pools. (C) Male *Dendrobates auratus* sitting on eggs. The male returns to the eggs periodically to provide them with moisture, but does not brood them continuously. (D) Male *D. pumilo* carrying a single tadpole on his back. Photos by Kentwood D. Wells (A, C), Walter Hödl (B), and Edmund D. Brodie III (D).

tadpoles are transported to bromeliads from other oviposition sites. Another bromeliad-breeder, *C. beebei,* uses giant terrestrial bromeliads. Females lay eggs on leaves above the water, and males subsequently transport tadpoles to water-filled leaf axils (Bourne et al. 2001). Males also were reported to move tadpoles from pools that lacked sufficient food resources to other pools with accumulations of detritus and algae.

In these genera, tadpoles either are released simultaneously, or they drop off gradually over several days (Luling 1971; Lüddecke 1974, 1976; Lescure 1976; Silverstone 1976; Van Meeuwen 1977; Wells 1977a, 1980a, c, 1981a; C. Myers, Daly, and Malkin 1978; C. Myers and Daly 1979; Weygoldt 1980c, 1983, 1987; H. Zimmermann and E. Zimmermann 1981, 1985, 1988, 1990; H. Zimmermann 1983; Aichinger 1991; Coloma 1995; Fandiño, Lüddecke, and Amézquita 1997; Lötters, Jungfer, and Widmer 2000; Jowers and Downie 2005). In *Colostethus panamensis,* tadpoles grow while on the back of the female, drawing on their large yolk reserves. Individual females that were recaptured several times had fewer tadpoles on their backs each time, and there was a strong negative correlation between number of tadpoles carried and tadpole size (Wells 1980b). A similar negative correlation between number and size of tadpoles was reported for *Mannophryne trinitatis* (Cummins and Swan 1995), but in this case, it is the male that carries the tadpoles. These authors suggested that this correlation might be a result of smaller clutches having larger eggs, although they could not rule out the possibility of tadpoles growing while being transported. Subsequent work on the same species by Downie et al. (2005) showed that the tadpoles do grow while on the back of the male. After about eight days, all yolk reserves were exhausted and the larvae did not continue to grow.

In *Dendrobates,* tadpoles are shuttled from a terrestrial oviposition site (fig. 11.7 C) to water and are carried only briefly. Usually only one or two tadpoles are carried on each trip (fig. 11.7 D). Transporting parents often place individual tadpoles in separate bodies of water in tree holes, stumps, logs, bromeliads, or the leaf axils of plants (Senfft 1936; Dunn 1941; Eaton 1941; H. Zimmermann 1974, 1978; Silverstone 1976; Wells 1978a, 1981a; Graeff and Schülte 1980; Weygoldt 1980a, b, 1982, 1983, 1984a, 1987; H. Zimmermann and E. Zimmermann 1980a, b, 1981, 1984, 1988, 1990; Lescure and Bechter 1982; E. Zimmermann and H. Zimmermann 1982; Jungfer 1985; Summers 1989, 1990, 1992; 1999b; Van Wijngaarden and Bolanos 1992; Brust 1993; Summers and Amos 1997; Caldwell and Oliveira 1999; Summers and McKeon 2004). At least two species, *Dendrobates castaneoticus* and *D. quinquevittatus,* place their tadpoles in the water-filled woody fruit capsules of the Brazil nut tree and in pools formed in the petioles of fallen palm fronds (Caldwell and Myers 1990; Caldwell and Araújo 2004).

The transport of only a few tadpoles at a time is thought to be a derived form of parental care within the family (Weygoldt 1987; H. Zimmermann and E. Zimmermann, 1988, 1990; Summers and McKeon 2004). Placing tadpoles in separate bodies of water probably is advantageous because of the limited food supplies in the small bodies of water used by these frogs. Summers (1990) demonstrated experimentally that growth rates of *Dendrobates auratus* tadpoles decreased as tadpole density increased, while mortality increased. The larval period also was longer in more crowded sites. Larger bodies of water, such as water-filled tree holes, could support more tadpoles than small bodies of water. Many dendrobatid tadpoles compensate for limited food supplies in bromeliads and tree holes by eating other tadpoles, so placement of several tadpoles in the same small body of water makes them susceptible to cannibalism. This would favor the evolution of behavior to disperse tadpoles in different deposition sites (Summers 1990, 1999b; Summers and Amos 1997; Caldwell and Araújo 1998; Caldwell and de Oliveira 1999; Summers and Earn 1999; Summers and Symula 2001; Summers and McKeon 2004).

Two ranid frogs from Borneo, *Limnonectes palavaensis* and *L. finchi* (formerly considered subspecies of *L. microdisca*) have evolved a form of parental care with remarkable parallels to that of dendrobatid frogs. These are small forest-floor frogs about the size of the largest species of dendrobatids. Terrestrial egg clutches have been found in leaf litter, either attended by a male or unattended. Males have been seen carrying up to 52 tadpoles at once, and these are deposited in pools along the margins of streams, in the main body of slow-moving streams, or rain pools on the forest floor (Inger 1966; Inger , Voris, and Frogner 1986; Inger and Voris 1988). Other details of oviposition and parental care are unknown.

Other frogs have unusual ways of transporting their larvae. In South American *Rhinoderma* (Rhinodermatidae), the male picks up the eggs before they hatch and carries the hatched tadpoles in an enlarged vocal sac (see fig. 1.20 E in chapter 1), sometimes carrying more than one cohort of tadpoles at the same time (M. Crump 2002). In *R. darwinii,* the tadpoles remain in the vocal sac for up to 52 days before completing metamorphosis (Cei 1962; Busse 1970; Jorquera, Pugin, and Goicoechea 1972; Goicoechea, Garrido, and Jorquera 1986), whereas tadpoles of *R. rufum* emerge before metamorphosis and complete development in the water (Jorquera, Garrido, and Pugin 1982). Tadpoles of *R. darwinii* apparently receive nutrition through the membranes of the male's vocal sac, so tadpole transport grades into tadpole feeding. The internal structure of the sac indicates that secretory activity is present (Garrido, Pugin, and Jorquera 1975). The larvae are not capable of intestinal absorption until just before metamorphosis (Jorquera, Garrido, and Pugin 1982), suggesting that any nutrient passage would be through the skin. Goicoechea, Garrido, and Jorquera 1986) tested this hypothesis by injecting horseradish peroxidase and labeled amino acids into the circulatory system of the brooding male. These labeled tracers found their way into the tissues of the tadpoles, indicating that transfer of materials from the male's circulation to the larvae does occur. This type of nutrient transfer is analogous to processes found in some viviparous amphibians (see chapter 10), but involves a completely independent evolution of a different organ system.

In the Australian myobatrachid *Assa darlingtoni,* the female apparently remains with the eggs, but whether she provides active parental care is not known. When the eggs are ready to hatch, the male sits on them and the tadpoles wriggle into inguinal brood pouches through slits near the junction of the hind legs with the body (fig. 11.8). The tadpoles remain there up to 80 days before emerging as small froglets (Ingram, Anstis, and Corben 1975; Ehmann and Swan 1985). In both *Assa* and *Rhinoderma,* there is no obvious transitional stage from ancestral modes of reproduction to these highly specialized forms of parental care. The relationships of *Rhinoderma* to other anuran families are unclear (see chapter 1), and no other myobatrachid has a reproductive mode similar to that of *Assa.*

Attendance of Froglets

In some anurans with direct-developing eggs, a parent remains with the juveniles after they hatch. In *Cophixalus parkeri,* a microhylid frog from New Guinea, the young remain in the nest with a parent for 30–40 days after hatching (Simon

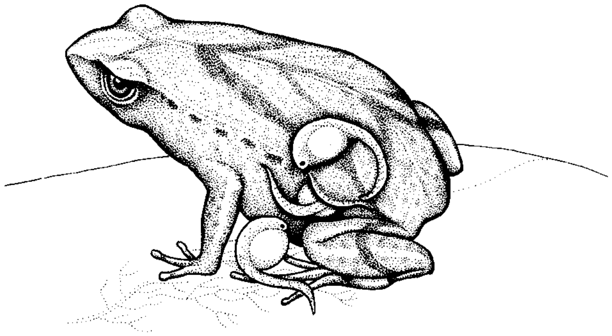

Fig. 11.8. Tadpoles entering the inguinal pouch of the male in the Australian myobatrachid frog *Assa darlingtoni.* Drawing by T. Wright from Roberts (1993).

1983). Similar behavior has been observed in many other genera of New Guinea microhylids, including *Xenobatrachus, Copiula, Hylophorbus, Callulops, Austrochaperina, Sphenophryne,* and *Liophryne,* although in most cases the duration of attendance apparently is shorter than in *C. parkeri* (Bickford 2001). In at least some species of *Sphenophryne, Liophryne,* and *Cophixalus,* males actually transport hatched young on their backs (see the following discussion). Juveniles of *Eleutherodactylus coqui* sometimes stay with a male in the nest for several days after they hatch (Townsend, Stewart, and Pough 1984), as do juveniles of a closely related species, *E. cooki* (Joglar, Burrowes, and Rios 1996). Another species in the same genus, *E. cundalli,* has made the transition from attending juveniles to transporting them; the tiny froglets are carried on the back of the female (Diesel, Baurle, and Vogel 1995; see the following.

Transport of Froglets

Transport of froglets is a form of parental care that was discovered only recently. It has been reported in several unrelated species of frogs with eggs that undergo direct development. In *Stefania evansi,* a hemiphractine frog, the eggs are carried on the back of the female, as described earlier, and the froglets remain on her back after hatching. They still have abundant yolk reserves (fig. 11.3) and presumably can remain on the female for some time and continue to grow (Gorzula, Morales, and Hernandez 1983; Jungfer and Boehme 1991). In *Eleutherodactylus cundalli* (Leptodactylidae), a Jamaican species, terrestrial eggs are laid on small terraces, crevices, and depressions in caves and attended by the female. They undergo direct development and hatch into small froglets that climb onto the back of the female. Between 30 and 72 froglets can be carried at once. As in *Stefania,* froglets still had yolk reserves when they initially climbed on the female, but eventually these were depleted as the froglets continued to grow. Most females carrying young were observed near the entrance to a cave, and one was seen outside, about 100 meters from the nearest cave entrance. Transport of the young in this species apparently serves to carry them out of caves to habitats with more abundant food supplies (Diesel, Baurle, and Vogel 1995). Similar behavior evidently occurs in *E. glaucoreius,* a species closely related to *E. cundalli* (Townsend 1996).

Froglet transport has been described in several genera of microhylid frogs from New Guinea (Bickford 2001, 2002). All of these species have direct development. Some species inhabit terrestrial or arboreal habitats similar to those used by Neotropical *Eleutherodactylus,* but others are largely subterranean. Males have been observed carrying groups of froglets in both terrestrial and arboreal species in several genera, including *Liophryne, Sphenophryne,* and *Cophixalus* (fig. 11.9). Froglets gradually jumped off of the parent's back into the leaf litter as they were carried for several days for distances of up to 55 meters from the oviposition site.

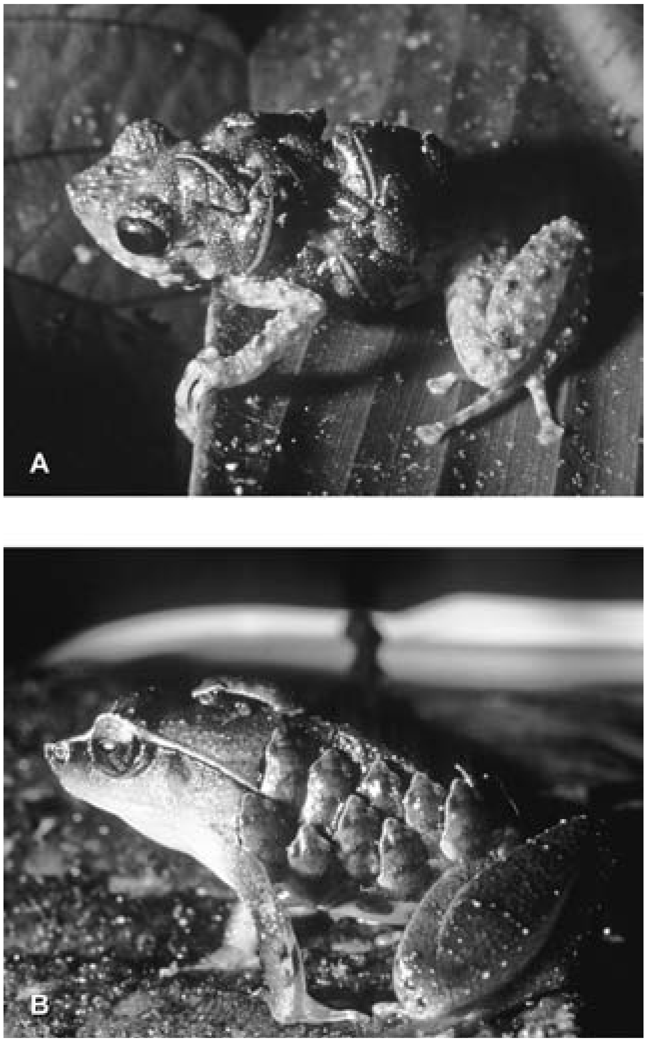

Fig. 11.9. Transport of froglets by microhylid frogs from New Guinea. (A) A male of an arboreal species of *Cophixalus* with young froglets on his back. (B) A male of the terrestrial frog *Liophryne schlaginhaufeni* carrying froglets. Photos by David Bickford.

The main function of froglet transport in these species appears to be dispersal of juveniles into suitable microhabitats. Bickford (2001) also conducted a phylogenetic study based on mitochondrial and nuclear gene sequences. He found that the current genus-level taxonomy of these frogs does not reflect true phylogenetic relationships. The species in which froglet transport has been described appear to be closely related, despite being placed in different genera. It seems likely that such behavior will be found in many other New Guinea microhylids, so the complete phylogenetic distribution of the behavior has yet to be determined.

Feeding of Tadpoles

Perhaps the most unusual form of parental care reported in frogs is the feeding of tadpoles with fertilized or unfertilized eggs. The behavior is always associated with the use of oviposition or tadpole deposition sites that have limited food resources. Several species of dendrobatid frogs feed their tadpoles. All of these species place their tadpoles in water-filled leaf axils of bromeliads and other plants. Tadpole feeding was first observed in *Dendrobates pumilio* in captivity (Graeff and Schülte 1980; Weygoldt 1980a, b) and subsequently confirmed in field observations and experiments (Brust 1993). The eggs are laid in leaf litter and attended by the male, which returns periodically to moisten them. It is the female that carries the tadpoles, apparently summoned to the oviposition site by the male's calls. The female places the tadpoles in the leaf axils of bromeliads or other water-collecting plants and returns every few days to feed them with unfertilized eggs (Graeff and Schülte 1980; Weygoldt 1980a, b; Brust 1993). The tadpoles are obligate egg-eaters and eventually die unless fed by the female. Similar behavior has been observed in *D. histrionicus, D. lehmanni, D. granuliferus,* and *D. speciosus* in captivity (H. Zimmermann and E. Zimmermann 1981, 1983, 1988, 1990; E. Zimmermann and H. Zimmermann 1982, 1985; E. Zimmermann 1983; Heselhaus 1984; Jungfer 1985; Weygoldt 1987), and in the field for *D. histrionicus* (H. Zimmermann 1989). Tadpoles of *D. granuliferus* have been found in the field in the leaf axils of plants, along with undeveloped eggs presumably deposited by females (Van Wijgaarden and Bolanos 1992). *Dendrobates arboreus* probably feeds its tadpoles as well (Summers et al. 1999). These species and *D. pumilio* all are members of the *D. histrionicus* species group, which is centered in northern South America and Central America. The occurrence of tadpole feeding in most or all of the members of this group suggests a single origin for this type of parental care in this clade. The tadpoles of the *D. histrionicus* group have mouthparts with reduced labial denticles, which is typical of obligate egg-eaters (see chapter 12).

Tadpole feeding also has been observed in several other dendrobatids found in Amazonian South America, including "*D. ventrimaculatus,*" *D. variablis, D. fantasticus, D. reticulatus, D. imitator,* and *D. vanzolinii.* These species are part of a confusing complex of similar-looking frogs often grouped together in the "*D. quinquevittatus* species group" (Silverstone 1975; C. Myers 1982; Caldwell and Myers 1990). Unfortunately, the name *D. quinquevittatus* has been used incorrectly in many accounts of parental care in captive animals (Meede 1980; Schülte 1981b; Lescure and Bechter 1982; H. Zimmermann and E. Zimmermann 1984, 1988, 1990; Weygoldt 1987; Crump 1995b). The species described by these authors actually is "*D. ventrimaculatus,*" which itself probably comprises a number of very similar species that have yet to be named (Caldwell and Myers 1990). How many of these have this unusual form of parental care is not known, but field studies of "*D. ventrimaculatus*" in Amazonian Ecuador indicated that frogs in that population do not feed their tadpoles (Summers and Amos 1997; Summers 1999b; Summers and Earn 1999; Summers et al. 1999). The name *D. quinquevittatus* is properly used for an entirely different species that does not deposit tadpoles in bromeliads or plant leaf axils, but in water-filled holes in stumps and logs, in leaf petioles of falling palm fronds, and in Brazil nut fruit capsules on the forest floor. The complex of tadpole-feeding species in Amazonia is more accurately described as the "*Dendrobates ventrimaculatus* complex" (Summers et al. 1999). Recently, two instances of females providing unfertilized eggs to tadpoles were reported for *Colostethus beebei* from Guyana (Bourne et al. 2001). This species is unusual among members of this genus in using terrestrial bromeliads as oviposition and tadpole deposition sites. *Colostethus beebei* exhibits several features of parental behavior that are convergent with the behavior of the Amazonian species of *Dendrobates.*

The details of parental care and tadpole development in most of these species have been observed in captivity, although there are field studies of *D. vanzolinii* from Brazil, "*D. ventrimaculatus*" from Ecuador, and *Colostethus beebei* from Guyana (Caldwell 1997; Summers and Amos 1997; Caldwell and de Oliveira 1999; Bourne et al. 2001). Parental care in Amazonian species of *Dendrobates* and in *C. beebei* differs in several respects from that of the *D. histrionicus* group. Eggs are laid on the leaves of bromeliads, *Heliconia,* or other plants, and in some cases, only a single egg is laid. Eggs are tended by the male, which transports the tadpoles to a water-filled leaf axil. Males call to and court females, either during tadpole transport or afterward, thereby inducing the female to lay additional eggs in or above pools where tadpoles reside. Hence, these species exhibit biparental care, in contrast to members of the *D. histrionicus* group, in which females transport tadpoles and lay trophic eggs without the male being present. In the population of "*D. ventrimaculatus*" studied by Summers and Amos (1997) in Ecuador, the basic reproductive biology is similar to that described previously, but there was no evidence of females laying trophic eggs. Instead, males performed all parental care, including carrying tadpoles from leaf axils where eggs are deposited to different leaf axils where the tadpoles develop. Many tadpoles simply hatched from egg clutches deposited on the sides of leaf axils and dropped into the pool below, or were deposited there by males. Although the frogs avoided depositing eggs above pools containing large tadpoles, tadpoles of different sizes often ended up in the same pool, and cannibalism of eggs and tadpoles was common (Summers 1999b).

Egg eating appears to be facultative in the Amazonian species, and the tadpoles have mouthparts typical of detritus-feeding species, not obligate egg-eaters (Kneller 1982; H. Zimmermann and E. Zimmermann 1984, 1988, 1990; Weygoldt 1987). *Colostethus beebei* also is a facultative egg-eater, with most of their nutrition coming from detritus, algae, or small insect larvae that accumulate in bromeliad pools (Bourne et al. 2001). Both Weygoldt (1987) and H. and E. Zimmermann (1988, 1990) suggested that this form of tadpole feeding is the ancestral condition leading to the more specialized behavior of frogs in the *D. histrionicus* group. An analysis of dendrobatid phylogeny based on mitochondrial DNA makes this scenario unlikely, however, because the Amazonian *Dendrobates* do not appear to be closely related to the *D. histrionicus* complex (fig. 11.10). The most likely hypothesis is that tadpole feeding has evolved independently in these two groups (Summers et al. 1999) and again in *C. beebei*. In the Amazonian clade, males transport tadpoles, a behavior that appears to be the ancestral condition for the entire genus *Dendrobates*. This necessitates cooperation between males and females if females are to locate tadpole deposition sites to feed the tadpoles. In the *D. histrionicus* group, however, transport of tadpoles by females and feeding of tadpoles appear to have evolved together, thereby releasing the male from further parental duties.

It has been known for more than half a century that tadpoles of some other frogs that live in bromeliads and similar small bodies of water eat frog eggs and sometimes have mouthparts adapted for egg eating (Noble 1929a; Dunn 1937; E. Taylor 1954; Lannoo, Townsend, and Wassersug 1987). Several of these species, quite unrelated to one another, have been shown to feed their tadpoles with eggs in a manner reminiscent of the behavior of dendrobatids de-

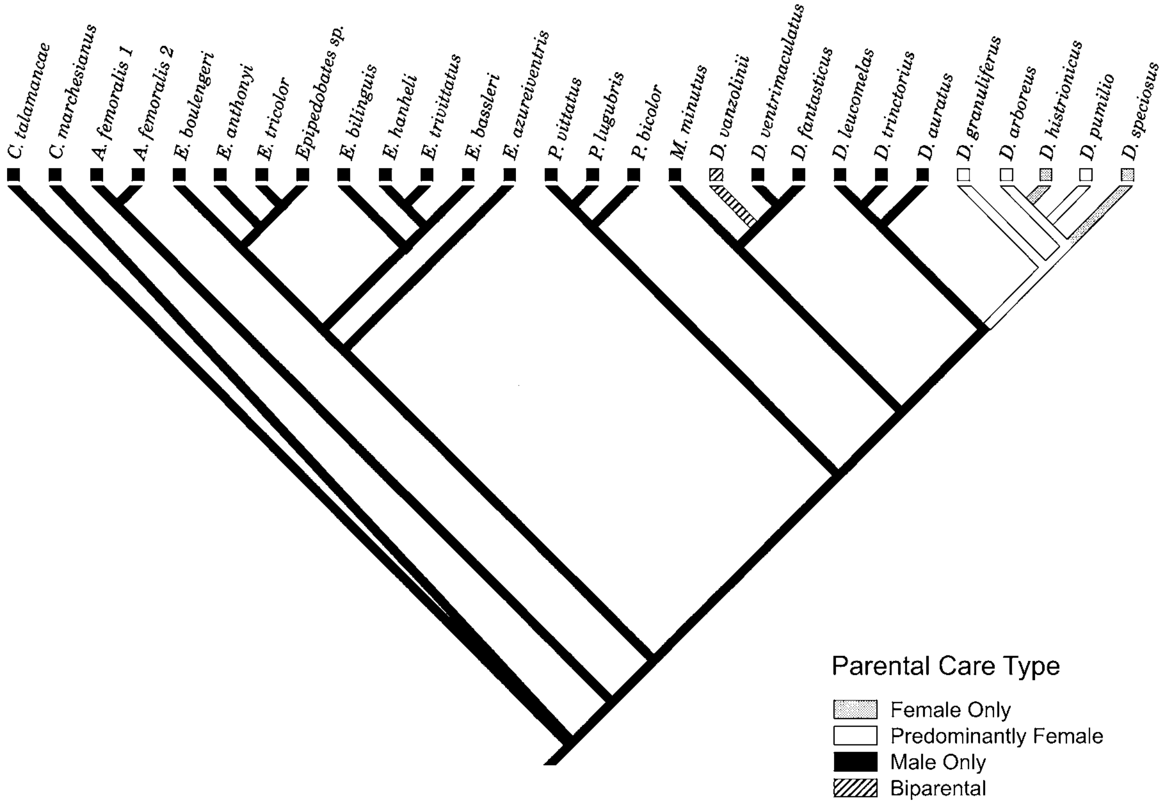

Fig. 11.10. Phylogeny of dendrobatid frogs, showing the evolution of male, female, and biparental care. The phylogeny is based on mitochondrial DNA sequences. This analysis indicates that biparental care in *Dendrobates vanzolinii* probably evolved from male parental care, which is ancestral for the whole family. A few species of *Colostethus* that are not included in this analysis have female parental care. Genera: *A = Allobates* (= *Epipedobates femoralis*); *C = Colostethus; D = Dendrobates; E = Epipedobates; M = Minyobates; P = Phyllobates.* From Clough and Summers (2000).

scribed previously. The best known of these tadpole-feeding frogs is *Osteopilus brunneus* from Jamaica. Dunn (1926a) reported finding eggs in the stomachs of tadpoles and described morphological adaptations of their mouthparts for egg eating. Lannoo, Townsend, and Wassersug (1987) conducted a much more detailed study of tadpole morphology and behavior (see chapter 12) and presented indirect evidence of females feeding their young, but they did not actually observe parental behavior. A study by Thompson (1996) confirmed that females do feed their tadpoles. The eggs of this species are very small, probably an adaptation to the extremely low oxygen levels in bromeliad tanks (see chapter 4). Clutch sizes are much larger than are those of dendrobatids, and some bromeliads have as many as 170 tadpoles in them. The eggs hatch within two days, but the tadpoles can take more than two months to reach metamorphosis. Females begin feeding their tadpoles immediately after they hatch and return, on average, every four days to deposit eggs. Early in the development period, females bring males to the bromeliads and deposit only fertilized eggs. Tadpoles eat some of these eggs, but others survive and join the developing brood. After some tadpoles have metamorphosed, the female usually switches to providing only unfertilized eggs for the remaining tadpoles. Presumably the tadpoles are now large enough to eat all of the eggs, so there would be no advantage to depositing fertilized eggs (some large tadpoles can have as many as 180 eggs in their stomachs; Lannoo, Townsend, and Wassersug 1987). As in some dendrobatids, the tadpoles are obligate egg-eaters and die if they are not fed.

Very similar behavior has been described in *Anotheca spinosa,* which has been studied mostly in captivity. E. Taylor (1954), D. Robinson (1961), and Duellman (1970) all reported finding frog eggs in the stomachs of tadpoles that were living in bromeliads and water-filled tree holes, but they did not observe any parental behavior. Jungfer (1996) placed a pair of adults in a terrarium and provided them with artificial containers designed to resemble water-filled tree holes. The frogs deposited large numbers (50–300) of small eggs on the walls of the containers, just above the water's surface. About a week after the first eggs were laid, the female returned to lay additional eggs. If the male was present, she attached fertilized eggs to the walls of the container, but if the male was not present, she laid unfertilized eggs directly in the water. The tadpoles typically swarmed around the female and began eating the eggs as soon as they were laid (fig. 11.11 A). The female returned every four to five days to lay additional eggs, averaging about 135 eggs per clutch. This continued for two to four months until the tadpoles reached metamorphosis. Larger tadpoles appeared to out-compete smaller tadpoles for nutritive eggs and transformed more quickly.

Yet another hylid with egg-eating tadpoles is a species from Brazil, *Osteocephalus oophagus*. This species lays eggs in a variety of small bodies of water, including bromeliads on tree branches or on the ground, the leaf axils of palms, the fallen palm bracts, and tree holes as much as 35 m above the ground. Females return to lay more eggs about every five days, very similar to the interval reported for the other two hylids. Females of this species deposit only fertilized eggs, some of which escape predation and hatch into tadpoles that join the developing brood; most are eaten by tadpoles already present (fig. 11.11 B). The tadpoles cannot complete development without being fed several times by the female (Jungfer and Schiesari 1995), and females do not deposit eggs at new sites while they have tadpoles developing in another site (Jungfer and Weygoldt 1999). Tadpoles of a recently described species from Ecuador, *O. deridens,* have been observed in the field with eggs in their digestive tracts, suggesting that this species has the same type of parental care (Jungfer et al. 2000).

A rhacophorid tree frog, *Chirixalus eiffingeri,* from Taiwan and Japan exhibits parental behavior very similar to that of these hylids, especially *Anotheca spinosa* (fig. 11.11 C, D). Eggs are laid just above the water's surface in a variety of sites, including hollows in the forks of trees, leaf axils, and cups formed when the hollow stems of bamboo are cut. Ueda (1986) reported egg attendance by males, which sometimes sat on the eggs to moisten them (fig. 11.2 F). He also reported that tadpoles of this species are obligate egg-eaters. Eggs that accidentally fell below the water line were eaten. In addition, females were observed laying unfertilized eggs directly in the water, and the tadpoles subsequently consumed these eggs. Kam, Chuang, and Yen (1996) reported that males remained with some egg clutches in bamboo cups in the field, but initially did not observe parental behavior by either males or females.

Through a series of laboratory and field experiments, Kam, Chuang, and Yen (1996), Kam et al. (1997, 1998, 2000, 2001, 2002), Kam and Yang (2002), Liang, Huang, and Kam (2002), and Huang, Huang, and Kam (2003) demonstrated that egg eating is necessary for the tadpoles to grow. They also showed that females rely on the location of bamboo stumps to relocate their offspring, and that there is complex tactile communication between tadpoles and females. When tadpoles were transferred from their original bamboo stumps to new ones that did not contain tadpoles, they were not fed by females and did not grow. When tadpole densities were high, growth was slower than when densities were low, but females evidently can increase their production of trophic eggs as the biomass of tadpoles in a pool increases. Kam, Chuang, and Yen (1996) estimated that each tadpole would consume about 87 eggs during a two-month development period. Since each clutch contains about 80 eggs, a female would have to lay several thousand eggs to successfully rear one clutch of tadpoles. This imposes a significant

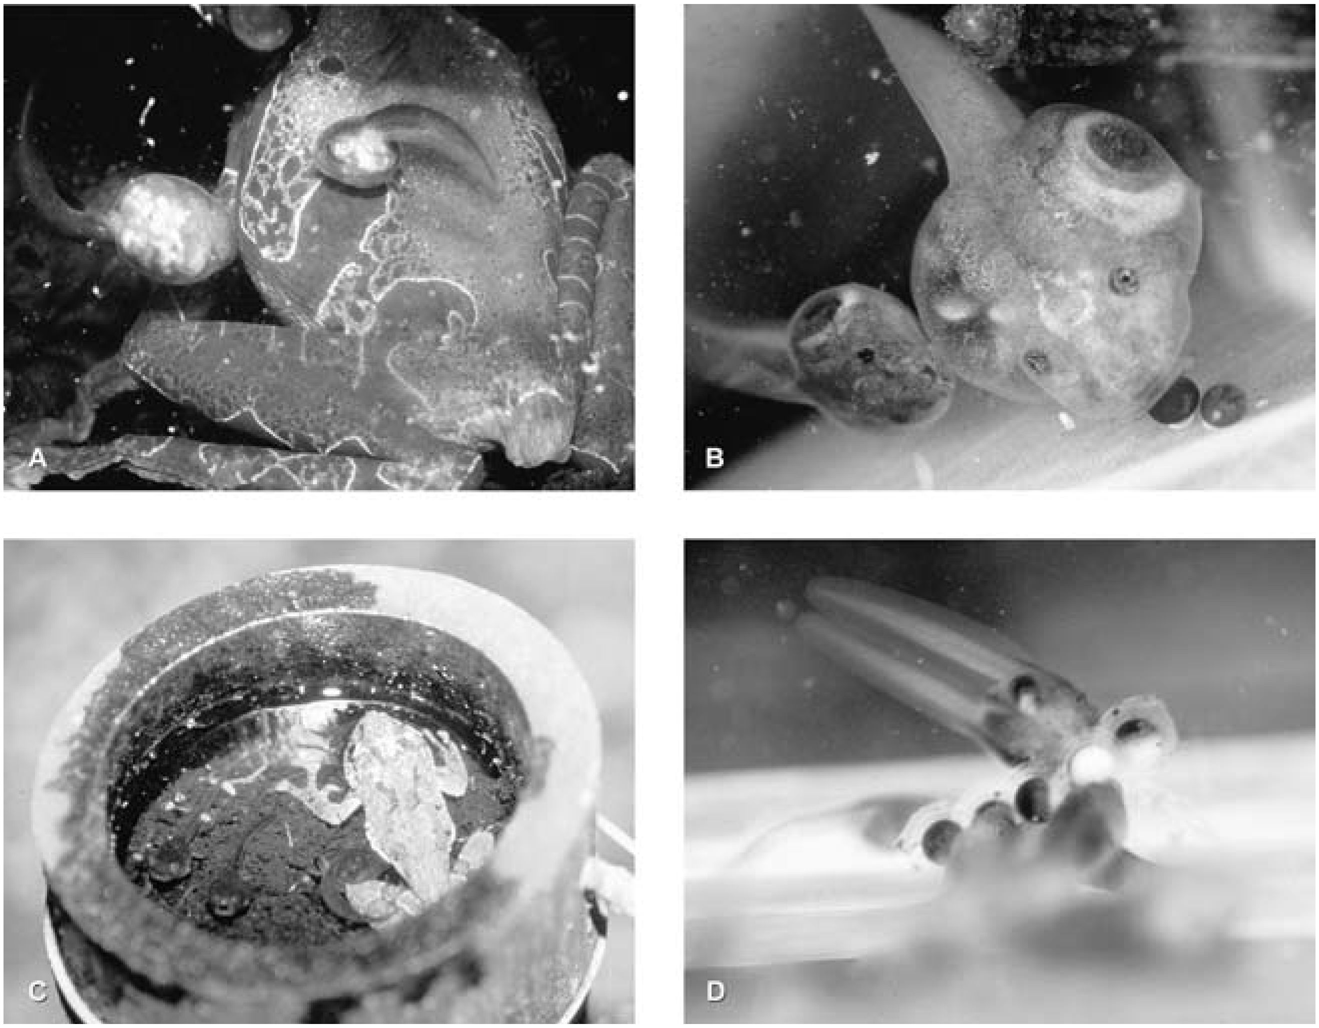

Fig. 11.11. Feeding of tadpoles by frogs that breed in small bodies of water. (A) Female of *Anotheca spinosa* (Hylidae), a bromeliad breeder, depositing unfertilized eggs in water. The stomachs of the tadpoles are full of eggs. (B) Tadpoles of *Osteocephalus oophagus* (Hylidae) feeding on newly deposited eggs. (C) Female of *Chirixalus eiffingeri* (Rhacophoridae) visiting a bamboo stump to deposit eggs to feed developing tadpoles. (D) Tadpoles of *C. eiffingeri* feeding on newly deposited eggs. energetic constraint on females, which do not normally produce a new clutch of fertilized eggs until they have finished rearing their current clutch of tadpoles (Kam et al. 2000). The necessity for females to provision their tadpoles also limits the growth of the tadpoles. Normally females feed their young about once every eight days. Experimental treatments in which tadpoles were fed on chicken egg yolk showed that tadpoles fed more frequently than this grew faster, while those fed only every two weeks grew more slowly (Liang, Huang, and Kam 2002). All tadpoles eventually reached metamorphosis, however, and tadpoles of this species are better able to tolerate periods without food than are herbivorous tadpoles in the same genus.

Perhaps the most surprising report of tadpole feeding is for *Leptodactylus fallax,* a frog found only on the islands of Dominica and Montserrat. As in other members of this genus, eggs are laid in foam nests, but these are placed away from water under rocks or logs, in tree stumps, or in underground burrows. Males defend oviposition sites and attract females to them. Pairs take up to 14 hours to construct the foam nest and lay eggs. The clutch size is relatively small (25–45 eggs), but individual eggs also are small and lack sufficient yolk reserves for tadpoles to complete development without feeding. Both males and females guard the nest, and the female periodically enters the nest to lay clutches of unfertilized eggs that are rapidly eaten by the tadpoles. Development is relatively slow, requiring up to two months to metamorphosis in captivity at temperatures similar to those in the field. Females provisioned eggs on average about every three days, with tadpoles in a single nest consuming an estimated 10,000–25,000 eggs (Gibson and Buley 2004). In a species from the Cerrado of Brazil, *L. labyrinthicus,* a substantial proportion of the eggs deposited in a foam nest do not develop and apparently are not fertilized, and these serve as food for developing tadpoles. There is no evidence, however, of females returning to the nest to provision the tadpoles (Shepard and Caldwell 2005).

I have described the behavior of tadpole-feeding frogs in some detail, because it represents a remarkable degree of convergence in parental behavior of frogs in several different families that use similar sites to rear tadpoles. Providing either fertilized or unfertilized eggs for tadpoles to eat seems like an expensive way for female frogs to rear their young, but this behavior should be viewed as only one alternative strategy for making use of sites that provide little or no food for the young. The other alternative is to provision the eggs with sufficient yolk reserves to allow the young to develop without feeding, also an expensive option. This strategy has evolved in a number of frogs that lay eggs in tree holes, leaf axils, and small pools (reproductive Mode 6; see chapter 10). The disadvantage of this strategy is that eggs must be large, so clutch sizes are small. If eggs or larvae are subject to high predation, then having small clutch sizes probably is not a viable option. On the other hand, if eggs are to be placed directly in small, oxygen-poor bodies of water, as they are in *Osteopilus brunneus* and *Osteocephalus oophagus,* then the eggs must be small because of gas exchange constraints (see chapter 4). Feeding the tadpoles probably is the only way the offspring can complete development.

In addition to convergence in overall parental behavior in these frogs, there also has been convergence in the system of communication between the tadpoles and their mothers. Studies of several species of *Dendrobates,* as well as *Anotheca spinosa* and *Chirixalus eiffingeri,* revealed that tadpoles respond to the arrival of the female by swimming vigorously and poking or chewing at the female's skin, especially on her back and cloacal region. Tadpoles of *Leptodactylus fallax* also showed increased activity and moved toward the female when she arrived at the foam nest (Gibson and Buley 2004). The activity of tadpoles appears to elicit egg deposition by the female, and therefore is functionally equivalent to the begging behavior of young birds in a nest (Weygoldt 1980a, Jungfer 1985, 1996; Ueda 1986; E. Zimmermann 1990). Tadpoles of *Osteocephalus oophagus* also swim and bump against the female as she lays eggs, but in this case, such stimulation is not necessary to elicit oviposition by females (Jungfer and Weygoldt 1999).

Frogs are not the only animals that have adapted to bromeliads by providing parental care to their young. In the same area of Jamaica where *Osteopilus brunneus* lives, a tiny crab (*Metopaulias depressus*) lives in the water-filled leaf axils of large ground bromeliads. This species produces large, yolky eggs and have a larval period of about two months, shorter than that of many marine crabs. The female remains with her larval brood in the bromeliads. She provides a number of important services, including cleaning leaf litter out of the leaf axils, depositing bits of broken snail shells that reduce the acidity of the water, and feeding the larvae with prey captured on the bromeliad leaves (Diesel 1989, 1992a, b). These crabs are generalist predators and might be expected to prey on the eggs or larvae of frogs. These two species seldom encounter one another, however, because the crabs prefer bromeliads of the genus *Aechmea,* which are avoided by *O. brunneus.* The frogs prefer bromeliads of the genus *Hohenbergia,* which are used less frequently by the crabs. In addition, the frogs use central leaf axil tanks almost exclusively, whereas the crabs prefer peripheral axils formed by older leaves (Diesel 1989; Thompson 1996).

Parental Care in Urodeles

Salthe and Mecham (1974), Nussbaum (1985, 2003), and Crump (1995b, 1996) have reviewed the parental behavior of urodeles. In many ways, the parental behavior of urodeles is less complex than that of anurans. Salamanders do not transport eggs or larvae, nor do they feed their young, so parental care consists entirely of attendance of eggs and larvae. Attendance of aquatic eggs by males has been reported in cryptobranchids in both North America (*Cryptobranchus*) and Asia (*Andrias;* Kerbert 1904; Stejneger 1907; B. Smith 1907; Tago 1929; S. Bishop 1941b; Nickerson and Mays 1973a; Kuwabara et al. 1989). Two stream-breeding hynobiid salamanders, *Hynobius kimurai* and *H. naevius,* are reported to have male parental care as well (Tago 1931; cited in Nussbaum 1985). Thorn (1962, 1967) reported that males of a pond-breeding species, *H. nebulosus,* also attend their eggs. This has not been observed in the field (Kunitomo 1910; Kusano 1980), and Nussbaum (1985, 2003) considered Thorn's interpretations questionable. There is considerable confusion about parental care in the European olm, *Proteus anguinus* (Proteidae). Reports based on observations in captivity have variously described egg attendance by males, females, or both (Vandel and Bouillon 1959; Briegleb 1962; Durand and Bouillon 1964; Durand and Vandel 1968; Durand 1986). Some of this confusion could be due to captive animals seeking shelter under a limited number of stones in aquaria and sometimes choosing sites with eggs. This species lives in deep, dark caves, and its behavior in nature has not been observed.

There are brief reports of females attending eggs in streams, usually attached to the undersides of rocks, in *Necturus* (S. Bishop 1926, 1941b; Ashton and Braswell 1979), *Desmognathus* (C. Pope 1924; Organ 1961c; Martof 1962a), *Eurycea* (Richmond 1945; Wood 1951, 1953a; Franz 1964; Baumann and Huels 1982; Bruce 1988a; Marshall 1996), *Gyrinophilus* (S. Bishop 1924; Bruce 1978a), *Pseudotriton*

(Goin 1947; Bruce 1978c), and *Dicamptodon* (Nussbaum 1969a; Nussbaum, Brodie, and Storm 1983; L. Jones, Bury, and Corn 1990; Steele, Brodie, and McCracken 2003a). Most of these reports are based on only a few observations of females with eggs, and the details of parental care in these genera remain largely unknown. Nevertheless, they do indicate that attendance of eggs by females is common in stream-breeding salamanders. Observations of stream-breeding Asian newts of the genus *Pachytriton* in captivity suggest that females aggressively guard their eggs, which are attached to the undersides of stones. Females also have been observed eating undeveloped eggs in their clutches and depositing secretions from the skin on their eggs, perhaps to inhibit fungal or bacterial growth (Thiesmeier and Hornberg 1992, 1997, 1998). The behavior of these newts has not been studied in the field, however.

Pond-breeding salamanders typically do not attend their eggs. Females of *Siren intermedia* have been discovered near clumps of aquatic eggs in mats of vegetation (Noble and Marshall 1932; Godley 1983), but these reports are anecdotal and do not provide any details of parental care. Other sirenids scatter their eggs individually and therefore probably do not have parental care (Nussbaum 1985). In *Amphiuma,* females lay eggs in burrows on the bottoms of shallow ponds (fig. 11.12 A). If a pond dries up, the female remains coiled around her eggs (J. Weber 1944; Baker 1945; Gunzburger 2001, 2003).

In several species of salamanders that lay eggs out of water, but have aquatic larvae, females remain with the eggs. In *Ambystoma opacum* (fig. 11.12 B), females lay eggs in the dry bed of a temporary pond and usually remain with the eggs until the pond fills (Noble and Brady 1933; Kaplan and Crump 1978; Petranka and Petranka 1981; Jackson, Scott, and Estes 1989; Petranka 1990; Figiel and Semlitsch 1995; Croshaw and Scott 2005). Petranka (1990) reported that about 25% of females in a population in North Carolina deserted their eggs within a month of oviposition. Eggs that were deserted suffered higher mortality than did those that were attended. Jackson, Scott, and Estes (1989), who studied a population in South Carolina, also found that eggs that were deserted early suffered higher mortality. Croshaw and Scott (2005) performed a series of laboratory and field experiments in which attending females were removed. Their results indicated that protection from predators and removal of eggs infected by fungi increased survivorship of eggs. In contrast to the behavior of *A. opacum,* there is no evidence of parental care in *A. cingulatum,* a species with similar breeding habits. Females of this species simply scatter their eggs in leaf litter at the bottom of dry ponds, where the eggs eventually are flooded by winter rains (J. Anderson and Williamson 1976).

In *Hemidactylium scutatum* (fig. 11.12 C), eggs are laid in sphagnum bogs above the water level, and larvae make

Fig. 11.12. Attendance of eggs and larvae by female salamanders. (A) Female *Amphiuma means* (Amphiumidae) with eggs after being excavated from a subterranean nest. (B) Female *Ambystoma opacum* (Ambystomatidae) with eggs. This species lays eggs in the fall on land in places likely to be flooded by snow or rain. (C) Female *Hemidactylium scutatum* (Plethodontidae) with eggs in a sphagnum moss nest. Maternal care occurs in most plethodontids that lay terrestrial eggs. their way into the water to complete development. Females usually attend their eggs, but sometimes they are abandoned (S. Bishop 1919; Blanchard 1934, 1936; Blanchard and Blanchard 1931; J. Wood 1953b; R. N. Harris and Gill 1980; Breitenbach 1982; R. N. Harris et al. 1995). In contrast to some other plethodontids, female *Hemidactylium* do not attempt to protect their eggs from attacks of predators, suggesting that parental care is poorly developed in this species (Carreño and Harris 1998). Variable egg attendance also has been reported in *Stereochilus marginatus,* a species with a somewhat similar mode of reproduction. Females attend some egg clutches, but they abandon others (A. Schwartz and Etheridge 1954; Rabb 1956; J. Wood and Rageot 1963).

An unusual phenomenon reported in *Ambystoma opacum, Hemidactylium scutatum,* and *Stereochilus marginatus* is communal nesting, with several females placing eggs in the same nest, which often is attended by only a single female. In the population of *A. opacum* studied by Petranka (1990), joint nesting was rare, with only 6.5% of more than 300 nests containing eggs of two or three females. In some cases, more than one female remained with the eggs, but in others only one female was present. Petranka's data suggested a slight decrease in survivorship for joint nests attended by only one female, but sample sizes were too small for rigorous statistical analysis. Very little is known about communal nesting in *Stereochilus,* because only a brief anecdotal report is available (J. Wood and Rageot 1963).

Communal nesting has been studied in more detail in *Hemidactylium.* On the basis of preliminary observations, R. N. Harris and Gill (1980) hypothesized that the presence of eggs from more than one female might be the result of successive females supplanting one another at the nest site. Each female would lay her own clutch of eggs and then remain with it, along with other eggs that were already present. They also suggested that later-arriving females might eat some of the eggs of other individuals, providing themselves with extra energy while attending their eggs. A more detailed five-year study refuted this hypothesis (R. N. Harris et al. 1995). There was no evidence that females supplanted one another, or that the last arriving female was the one most likely to attend the eggs. In fact, in more than half the cases, the first female remained with the eggs even as other clutches were laid nearby. There also was no evidence of aggression among females or egg eating. Communal nesting did not appear to be a form of brood parasitism, as seen in some birds, because females had approximately equal reproductive success when they attended their own eggs or contributed to a joint nest.

Another possibility is that in *Hemidactylium,* and in the other species that sometimes nest communally, joint nesting is a result of prime nest sites being in short supply. This did not appear to be the case for *Hemidactylium* in the Virginia populations studied by R. N. Harris et al. (1995), because the percentage of joint nesting was not related to population density (about a third of nests were communal, on average, regardless of population size). These investigators also manipulated densities in artificial habitats and found no effect on the proportion of joint nests; again, about a third of nests were communal in both low- and high-density treatments. They did find, however, that as many as seven females in the high density treatment sometimes laid eggs in the same nest, whereas all joint nests in the low-density treatment contained the eggs of only two females. Some females that laid eggs in either single nests or joint nests deserted their eggs before they hatched, and these suffered higher mortality than attended eggs. There was a greater tendency for single nests to be deserted than joint nests, suggesting that nesting with another female provides an advantage for females that desert their eggs. The eggs take about six weeks to develop, and this evidently imposes an energetic cost on brooding females; reduction in body mass was positively correlated with the number of days a female remained with her eggs. It has yet to be determined whether females desert their eggs because their energy reserves are depleted, or for other reasons (see further discussion of the "Costs of Parental Care," following).

Attendance of eggs by females is the rule in most other genera of plethodontid salamanders that lay eggs on land. These include species of *Desmognathus* that have aquatic larvae and lay eggs at the margins of streams and in seepage areas, such as *D. fuscus, D. ochrophaeus,* and *D. ocoee* (Tilley 1972; Forester 1977, 1978, 1979a, c, 1981, 1983, 1984; Forester, Harrison, and McCall 1983; R. L. Jones 1986; Juterbock 1986, 1987; Hom 1987). Females sometimes remain in the nest with hatched larvae for a few days before the larvae make their way to water. Parental care by females is common, perhaps nearly universal, in genera with direct development, including *Aneides, Chiropterotriton, Desmognathus, Ensatina, Hydromantes, Lineatriton, Parvimolge, Plethodon,* and *Pseudoeurycea* (Nussbaum 1985; Crump 1995b). In those species that have been studied in detail, females generally remain with the eggs throughout development; parental care can last two months or more in species that lay eggs in cool microhabitats (Fitzpatrick 1973b; Forester 1983; Bachmann 1984; R. L. Jones 1986; Juterbock 1986, 1987; Hom 1987; Ng and Wilbur 1995). The genus *Batrachoseps* is unusual among plethodontids in that maternal brood care apparently is absent in most species, but communal oviposition is relatively common (Maslin 1939; Jockusch and Mahoney 1997). Unattended clutches of other species are found occasionally, but it is difficult to determine whether this is a result of observers disturbing the nests. There are scattered reports of males of several species being found in or near nests, either alone with eggs or with a female (Storer 1925; Storm 1947; Vial

1968; Jockusch and Mahoney 1997), but there is not one unequivocal observation of a male providing parental care in any plethodontid salamander.

Parental Care in Caecilians

Nearly all aspects of the biology of caecilians are poorly understood because of their secretive and often subterranean habits, and their parental behavior is no exception. Although the morphology of the reproductive system has been studied in a number of species (reviewed by M. Wake 1977a, b, 1992), information on other aspects of reproduction is scarce. More than half the species for which the reproductive mode is known are viviparous, and their reproductive biology was discussed in chapter 10. Females probably attend eggs in many of the oviparous species (M. Wake 1977a), but most accounts of parental care consist of brief natural history notes. In the Sri Lankan species, *Ichthyophis glutinosus* (Ichthyophiidae), females coil around eggs, which eventually hatch into aquatic larvae (Sarasin and Sarasin 1887–1890; Breckenridge and Jayasinghe 1979). All other reports of females attending eggs are for members of the family Caeciliidae, all species with direct development (fig. 11.13). These include the African species *Idiocranium russeli* and *Afrocaecilia taitana* (Nussbaum, unpublished data cited in M. Crump 1995b), the South American species *Siphonops paulensis* (Goeldi 1899; Gans 1961), and species from three genera found only in the Seychelles islands, *Grandisonia, Hypogeophis,* and *Praslinia* (Brauer 1897; Nussbaum 1984).

Benefits of Parental Care

Although the supposed benefits of parental care have been the subject of much speculation, there is a dearth of quantitative information. I have already discussed transport and feeding of tadpoles in some detail, and the benefits of such behavior are obvious. I will limit my discussion here to the benefits of egg attendance, because most experimental studies have focused on this form of parental care. Parental attendance of eggs clearly enhances the survival of offspring (Highton and Savage 1961; M. Bachmann 1964; Vial 1968; Snyder 1971; Tilley 1972; Forester 1979a; R. N. Harris and Gill 1980; Simon 1983; Townsend, Stewart, and Pough 1984; Juterbock 1987; Jackson, Scott, and Estes 1989; Petranka 1990; M. Hayes 1991; R. N. Harris et al. 1995; Thompson 1996; Bickford 2001, 2004; Crespi and Lessig 2004). The precise way in which survival is improved is known for only a few species. In some amphibians, the presence of a parent has little or no effect on offspring survival (Woodruff 1977), and parental attendance is not true parental care. Although observational studies are an important first step in unraveling the adaptive significance of parental care, only controlled experiments are likely to yield definitive conclusions about proximate benefits. The most convincing are those performed in the field, where eggs are exposed to natural environmental conditions. Among the potential benefits that have been proposed for egg attendance by amphibians, the most reasonable are protection against conspecifics, protection against heterospecific predators, protection against desiccation, protection against fungus and other pathogens, and aeration and agitation of eggs.

Protection against Conspecifics

Predation of eggs by conspecifics apparently is widespread in aquatic and terrestrial salamanders (Salthe and Mecham

1974; Nussbaum 1985, 2003). Field observations of predatory behavior are limited to scattered reports of adult salamanders invading nests and eating eggs (S. Bishop 1941b; Tilley 1972; Kaplan and Sherman 1980), and there are even fewer observations of parents protecting eggs from predators. Often egg "guarding" is inferred from aggressive responses of females to fingers or other objects introduced into the nest. Brooding females of *Aneides aeneus* have been observed driving intruding males from nests (R. Gordon 1952). D. Snyder (1971) found that very few eggs of this species survived if the attending female was removed, and predation by conspecifics appeared to be a major source of mortality. Several workers have introduced conspecific adults into containers with brooding females, which invariably attack the intruders (Highton and Savage 1961; F. Rose 1966; Forester 1978, 1979a; Bachmann 1984). Forester (1983) found that brooding *Desmognathus ocoee* females became more aggressive as eggs developed and attributed this to the greater difficulty of replacing clutches lost late in the breeding season. However, Bachmann (1984) did not find a similar increase in aggressiveness in *Plethodon cinereus.*

Predation on eggs by conspecifics has been observed in leptodactylid, microhylid, and dendrobatid frogs. In *Eleutherodactylus coqui,* conspecific predation is a major source of embryo mortality, and parental males vigorously defend their clutches with aggressive vocalizations and by pushing and biting intruders (Townsend, Stewart, and Pough 1984; Stewart and Rand 1991). Conspecific predation also appears to account for most egg mortality in the closely related species, *E. cooki* (Burrowes 2000, Rogowitz et al. 2001). In the New Guinea microhylid *Cophixalus parkeri,* many eggs are lost to predators when the parent is removed, but actual defense of eggs has not been observed because of the frogs' secretive habits (Simon 1983). Egg predation by both males and females is common in dendrobatid frogs raised in captivity (Wells 1978a; Weygoldt 1980a, b; H. Zimmermann and E. Zimmermann 1981) and has been observed in the field for *Dendrobates auratus* (Summers 1989). Most dendrobatid frogs do not guard their eggs continuously, but in some species, the territorial behavior of males probably keeps intruders away from a resident's eggs (Wells 1980a; Roithmair 1992; Summers 1989, 1992). In *Dendrobates auratus,* males lead successive females to different oviposition sites (Wells 1978a). This probably makes attendance of eggs less efficient, but it prevents females from destroying or eating clutches laid by previous mates. Females, on the other hand, benefit from eating eggs, not only for their nutritional value, but also because this reduces the time that their mates will spend caring for other females' eggs (Summers 1990; see "Sex Roles in Parental Behavior," following).

Another form of protection against conspecifics has been reported in *Hyla rosenbergi.* Guarding males attack and usually repel other males intruding on their mud nests (Kluge 1981). This is important, because if the surface film of eggs is disturbed, they will sink to the bottom of the nest and die. Although it is not known whether males deliberately try to destroy other males' eggs, it is clear that paternal guarding is essential for egg survival when male densities are high. When male densities and the probability of intrusion were low, eggs were seldom guarded, indicating the facultative nature of parental care. Facultative parental care also was reported for a closely related species, *Hyla faber,* in Brazil. As in *H. rosenbergi,* males abandoned nests when densities of males at the site were low, but guarded their nests when densities were high (M. Martins, Pombal, and Haddad 1998).

Protection against Heterospecific Predators

It is often assumed that amphibian parents defend their eggs against heterospecific predators, but the evidence for this is mostly circumstantial. Eggs of the salamander *Desmognathus ocoee* quickly disappear when left unattended in the field (Tilley 1972), suggesting that predation is a major source of mortality. Forester (1978, l979a) introduced carabid beetles, ringnecked snakes (*Diadophis punctatus*), and three species of predatory salamanders (*Pseudotriton ruber, Gyrinophilus porphyriticus, Desmognathus monticola*) into laboratory chambers with brooding females of *D. ocoee.* The females successfully defended their clutches against the beetles, but generally could not defend against snakes or large salamanders. Similar results were obtained with *Plethodon cinereus;* most females fled when snakes were introduced into nest cavities, but one female did attack an intruding snake (Bachmann 1984). When eggs of *Ambystoma opacum* were enclosed in mesh predator-exclusion cages, without attending females, survival of eggs was higher than for unenclosed eggs (Croshaw and Scott 2005). Small millipedes (*Oxidus gracilis*) were identified as important predators of A. opacum eggs.

Adults of two large frog species, *Leptodactylus ocellatus* and *Pyxicephalus adspersus,* actually attack birds and other vertebrates feeding near their tadpoles (Balinsky and Balinsky 1954; W. Rose 1956; Poynton 1957; Vaz-Ferreira and Gerhau 1975; C. Cook, Ferguson, and Telford 2001), and other species of *Leptodactylus* have been induced to attack sticks and other model predators (Vaira 1997; Prado, Uetanabaro, and Lopes 2000; Prado, Uetanabaro, and Haddad 2002). The terrestrial eggs of *Eleutherodactylus coqui* are occasionally attacked by invertebrates, but this is a relatively minor source of mortality, and the incidence of invertebrate predation did not increase when parental males were removed (Townsend, Stewart, and Pough 1984). In contrast, predation by invertebrates appears to be a major source of mortality for *Cophixalus parkeri* eggs, and unattended eggs have almost no chance of surviving (Simon 1983). All of the terrestrial and fossorial microhylids (*Xenobatrachus, Copiula, Liophryne, Hylophorbus, Callulops,* and *Austrochape-*

rina) studied in New Guinea by Bickford (2001, 2004) exhibited defensive behavior against ants or other arthropod predators, but arboreal species did not. Many of the fossorial species were particularly aggressive in guarding their eggs, and often tried to block entrances to burrows. Some of these microhylids also attacked pencils inserted into nests as model predators. When attending parents (usually males) were removed from egg clutches of two common species, *Hylophorbus rufescens* and *Oreophryne* sp., all of the eggs died or disappeared. Most mortality in *Hylophorbus* was caused by ant predation, whereas unattended eggs of *Oreophryne,* an arboreal species, were more likely to die from desiccation (Bickford 2004).

Eggs of centrolenid frogs are laid in exposed positions on leaves overhanging water and are attacked by a variety of invertebrates, including small crabs, spiders, and insects (McDiarmid 1978; M. Hayes 1983), but apparently not by conspecifics (M. Hayes 1991). Males of several species guard their eggs (McDiarmid 1978; M. Clark 1981; Jacobson 1985; M. Hayes 1991), and removal of the male greatly decreases survivorship of eggs. McDiarmid (1978) attributed most of the mortality in unattended clutches to predation by invertebrates, but in *Hyalinobatrachium fleischmanni,* desiccation seems to be a more important source of mortality than predation (M. Hayes 1991).

Protection against Desiccation

There is little doubt that protection against desiccation is a major benefit of parental care in many terrestrial species, although it is not important in species that lay eggs in saturated microhabitats (Simon 1983). Most plethodontid females remain in contact with their eggs and usually coil around them during dry weather (Noble and Brady 1933; Organ 1960b; Brode 1961; Highton and Savage 1961; Vial 1968; McDiarmid and Worthington 1970; Tilley 1972; Forester 1979a). Some salamanders moisten their eggs by periodically voiding urine (Highton and Savage 1961; Brode 1961). D. Snyder (1971) found that survivorship of *Aneides aeneus* eggs was poor when the female was removed, even when the eggs were surrounded by predator exclusion cages; much of the mortality was due to desiccation. Similarly, Forester (1984) demonstrated that eggs of *Desmognathus ocoee* lost more water when left unattended than when brooded by the female. In *Plethodon cinereus,* eggs brooded by large females had greater mass and higher survivorship than did those brooded by small females. Furthermore, in dry years, maternal body size had a greater effect on hatchling size than did initial egg size, suggesting that brooding mothers protect eggs from desiccation (Crespi and Lessig 2004).

Many frogs sit directly on their eggs, sometimes covering them with their bodies and limbs (C. Myers 1969; Amiet 1981; Townsend, Stewart, and Pough 1984; B. Bell 1985; M. Hayes 1991; Diesel, Baurle, and Vogel 1995; Joglar, Burrowes, and Rios 1996; Quijano, Santos-Barrera, and Pacheco-Rodríguez 2002; Bickford 2004). This posture clearly is well suited to minimizing evaporative water loss, as well as transferring water from the highly permeable pelvic skin to the eggs. There is indirect evidence of the importance of parental care in preventing desiccation in *Leiopelma.* In two species that lay eggs in relatively dry sites, males sit on their eggs until they hatch; in a third species that lays eggs in semiaquatic sites, males remain near their eggs, but usually do not sit on them (B. Bell 1985). Dendrobatid frogs take up water from wet leaves or small puddles and then transfer it to terrestrial egg clutches (Senfft 1936; H. Zimmermann 1974, 1978; Wells 1978a; Weygoldt 1980a, b; H. Zimmermann and E. Zimmermann, 1980b, 1981, 1984). Whether they do so by releasing urine or by transferring water directly from the skin is not clear. Attending adults sometimes manipulate the eggs with their back legs, perhaps to enhance the uptake of water (fig. 11.7 C).

Similar manipulative behavior has been observed in the centrolenid frog *Hyalinobatrachium fleischmanni,* a species that lays eggs on the surfaces of leaves. M. Hayes (1991) placed water soluble dyes on egg clutches and showed experimentally that manipulation of the eggs caused the dye to diffuse more rapidly and more completely into the egg clutch, suggesting that the behavior would enhance water uptake. Experimental removal of brooding males showed that brooding reduced embryo mortality from desiccation. Hayes also artificially watered some clutches from which males had been removed. Survival of embryos was higher in these clutches than in unattended clutches that were not watered. Parental attendance was most important in the first few days after eggs were laid. Removal of males at that time resulted in higher mortality than removal of males later in development. As mentioned previously, males of this species and several other centrolenids do not attend their eggs continuously, but visit them for short periods of time, usually after midnight. Hayes found that extended bouts of brooding resulted in eggs becoming more susceptible to infection by fungi, and these clutches also were more likely to be invaded by predatory fly larvae (see Villa 1984). In other words, there was a tradeoff between increased likelihood of desiccation with too little brooding and increased mortality from fungi and fly larvae with too much brooding. Intermediate levels of brooding produced the highest survivorship.

Brooding by males is essential for maintaining the proper hydric regime for the eggs of *Eleutherodactylus coqui* (fig. 11.14). Brooding seems to be less important for *E. cooki,* which breeds in very humid caves (Burrowes 2000; Rogowitz et al. 2001). Males of *E. coqui* select oviposition sites, usually in curled dead leaves, rolled palm fronds, or other enclosed microhabitats that provide high-humidity environments for egg development (Townsend 1989a). They

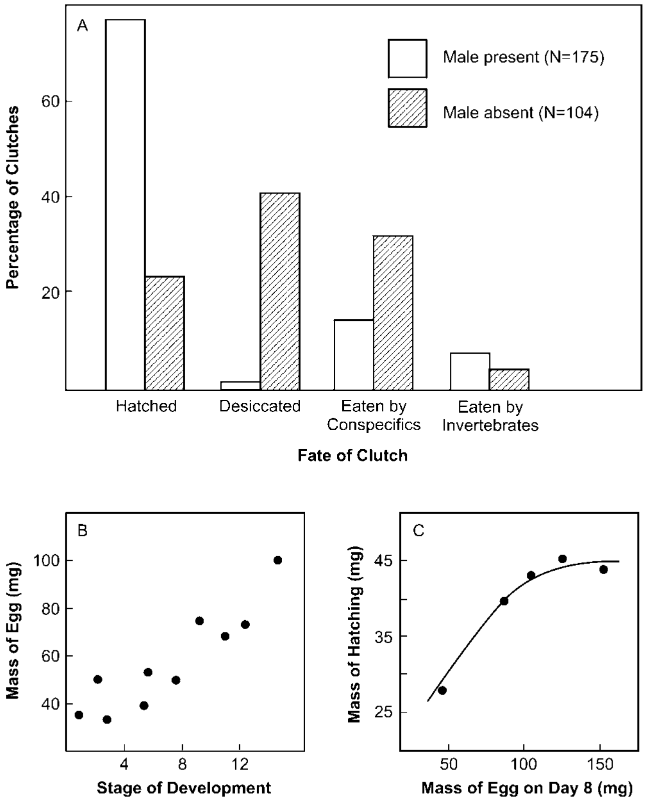

Fig. 11.14. Effect of male parental care on egg survival and development in the Puerto Rican treefrog *Eleutherodactylus coqui.* (A) Fate of control clutches with male present and experimental clutches with male absent. (B) Mass of the eggs as a function of stage of development in clutches attended by males. (C) Mass of hatchlings as a function of the mass of eggs at day 8. (A) Plotted from data in Townsend et al. (1984). (B, C) After Taigen, Pough, and Stewart (1984).

lead females to their nest sites (Townsend and Stewart 1986), and after the eggs are laid, the male remains with them until they hatch. When males were removed from eggs, 41% of the clutches died from desiccation, compared to 1% of attended clutches (fig. 11.14 A; Townsend, Stewart, and Pough 1984). Water is transferred by osmosis directly from the male's skin to the eggs. The water not only increases survivorship of eggs, but also the mass of hatchlings (fig. 11.14 B, C), thereby probably improving their chances of surviving outside the nest (Taigen, Pough, and Stewart 1984). Hydration of eggs also appears to be the most important benefit of parental care in an arboreal species of *Oreophryne* from New Guinea, but it appears to be of minor importance for terrestrial and fossorial species (Bickford 2001, 2004).

Protection against Fungus and Pathogens

Fungi often infect terrestrial amphibian eggs, and these infections are fatal if left unchecked (Villa 1979b; Simon 1983). Fungal infections often begin on eggs that have died from other causes and spread to living eggs (Forester 1979a). Tilley (1972) reported that living *Desmognathus ocoee* eggs could survive heavy fungal infections, but Forester (1979a) found that fungal infections frequently were fatal. Unattended eggs tend to develop fungal infections more rapidly than attended clutches (Storm 1947; Vial 1968; D. Snyder 1971; Salthe and Mecham 1974; Forester 1979a; Simon 1983), but there has been some controversy over the role of the parent in preventing fungal growth. Early literature suggested that adult amphibians might produce antifungal secretions in the skin (reviewed by Salthe and Mecham 1974), but several experimental studies have failed to support this hypothesis (Daniel and Simpson 1954; Vial and Preib 1966; Forester 1979a; Simon 1983). Thiesmeier and Hornberg (1997) speculated that females of the Asian newt *Pachytriton* release antifungal secretions from the skin, but experimental evidence is lacking. R. Austin (2000) found a substantial bacterial community on the skin of *Plethodon ventralis,* and at least some of these bacteria exhibited antifungal and antibacterial properties, suggesting that they might play a role in protecting eggs brooded by females. Periodic movement or abrasion of the eggs by the female also could inhibit fungal growth, but evidence for this is mixed (Tilley 1972; Forester 1979a). Females of *Desmognathus ocoee* selectively eat infected eggs, and this protects the rest of the clutch (Tilley 1972; Forester 1979a). Several species of microhylid frogs from New Guinea were observed to eat egg clutches infected with fungus, and in one species, *Sphenophryne cornuta,* an attending parent selectively ate only infected eggs (Bickford 2001).

Aeration and Agitation of Eggs

Several types of parental activities in aquatic amphibians have been interpreted as adaptations for aerating eggs. This is a reasonable hypothesis, since fanning eggs is an important component of parental care in many fishes (Blumer 1979; Perrone and Zaret 1979; Baylis 1981). This behavior helps to break up the boundary layer of still water surrounding the eggs, thereby facilitating diffusion of oxygen into the egg mass. Evidence for such behavior in amphibians is inconclusive. *Necturus* females keep eggs constantly agitated in aquaria by waving their gills, and *Cryptobranchus* males achieve the same effect through continuous movements of the body (Salthe and Mecham 1974). Such movements frequently occur when these species are exposed to low oxygen tensions as a means of enhancing the animal's own respiration (Guimond and Hutchison 1976); any advantage to the eggs could be incidental and has yet to be demonstrated. The apparently deliberate agitation of eggs by kicking in *Nectophryne afra* (Scheel 1970) is more reasonably interpreted as parental behavior, although the survival value of the behavior has not been investigated.

Agitation of eggs also occurs in terrestrial amphibians. Dendrobatids, centrolenids, and other frogs move their legs around in the eggs while wetting them (Wells 1978a; H. Zimmermann and E. Zimmermann 1981; M. Hayes 1991). This might ensure an even distribution of moisture, but it also could be important in preventing yolk stratification or adhesion of the embryo to the egg membranes (Salthe and Mecham 1974). Simon (1983) showed that survivorship of terrestrial frog eggs was enhanced by periodic agitation. Bickford (2001) observed many species of microhylids from New Guinea jostling eggs, but he did not present experimental data on the function of this behavior. Survivorship of eggs appears to be enhanced by jostling in *Desmognathus* (Forester 1979a), but not in *Hyalinobatrachium fleischmanni* (M. Hayes 1991) or *Ambystoma opacum* (Croshaw and Scott 2005).

Costs of Parental Care

In many species, attendance of eggs or larvae undoubtedly entails some cost to the parent, but measurement of such costs is extremely difficult. Theoretically, both benefits and costs should be measured in terms of lifetime fitness (Trivers 1972; Clutton-Brock 1991; Crump 1996), but in practice, one must be satisfied with estimates of proximate costs and benefits. Even this is difficult, because costs and benefits often cannot be measured in the same units. Benefits accrue as increased offspring survival, whereas costs include physical risk to the parent, energetic costs, and decreased opportunities for future reproduction.

Physical Risk to the Parent

There are a few anecdotal accounts of brooding amphibians being consumed by predators such as ants (Forester 1979c) or snakes (Forester 1978), but these observations mainly involve captive individuals. The best evidence for a direct risk to attending parents comes from observations of male African bullfrogs (*Pyxicephalus adspersus*) being injured or killed when defending schools of tadpoles against water birds (C. Cook, Ferguson, and Telford 2001). In two particularly grisly instances, herons pecked out the eyes of defending males and then ate their offspring. *Hyla rosenbergi* males are sometimes injured while defending their nests (Kluge 1981), but this probably is rare in other amphibians. In *Eleutherodactylus coqui,* intruding males are sometimes injured in fights, but parental males are not (Townsend, Stewart, and Pough 1984). To show that parental behavior is costly, one must demonstrate that risks to caregiving individuals exceed those incurred by individuals engaged in other activities. Indirect evidence that brooding females suffer increased mortality comes from Organ's (1961c) study of the demography of several species of *Desmognathus*. He found that sexually mature females had lower survivorship than males, and attributed this to greater exposure to predation in aquatic or semiaquatic nest sites.

Energetic Costs

The metabolic costs of egg attendance and other forms of parental care probably are trivial compared to other reproductive activities such as calling, searching for mates, and courtship behavior (see chapter 5). Nevertheless, brooding adults that are confined to nests have few opportunities to feed, and sometimes suffer reductions in body mass or stored energy reserves (Fitzpatrick 1973b; Krzysik 1980; Forester 1981). Brooding *Desmognathus* females frequently have empty or nearly empty stomachs (Tilley 1972) and use up significant amounts of fat. Fitzpatrick (1973b) estimated that about 16% of the annual energy budget of a *D. ochrophaeus* female was allocated to maintenance during brooding, but he did not attempt to estimate the cost of parental care relative to that of alternative uses of energy such as foraging, growth, or production of eggs.

A reduction in growth rates and body mass of brooding females also has been reported for *Plethodon cinereus* (Ng and Wilbur 1995). Brooding females of this species produced fewer eggs the following year than did those that abandoned their eggs or did not brood at all (Yurewicz and Wilbur 2004). It has been suggested that many temperate-zone plethodontids cannot produce eggs every year because they spend so much of the summer growing season brooding eggs without feeding (Sayler 1966; Hom 1988; Crump 1995b). Nevertheless, if the chances of eggs surviving without parental care are sufficiently poor, then females should remain with their eggs even if this entails high costs (Hom, Willits, and Clark 1990). For some salamanders, the energetic costs of parental care are relatively low. For example, Kaplan and Crump (1978) did not find any evidence that brooding entailed substantial energy costs in *Ambystoma opacum.* They attributed this to the brief period of parental care and the fact that most individuals do not feed during the fall anyway.

The New Guinea microhylid frog *Cophixalus parkeri* has an extraordinarily long brooding period, with some males remaining with eggs for nearly five months (Simon 1983). Brooding males consume much less food than nonbrooding adults, and often have empty stomachs. They sometimes resort to eating sphagnum moss from the nest area, a food that probably provides very little nutrition. Brooding adults also have reduced fat bodies compared to nonbrooding frogs (fig. 11.15 A). Hence, the prolonged period of parental care clearly imposes a heavy energetic cost. In *E. coqui,* neither brooding nor calling males do much feeding, but parental males were more likely to have empty stomachs (Townsend

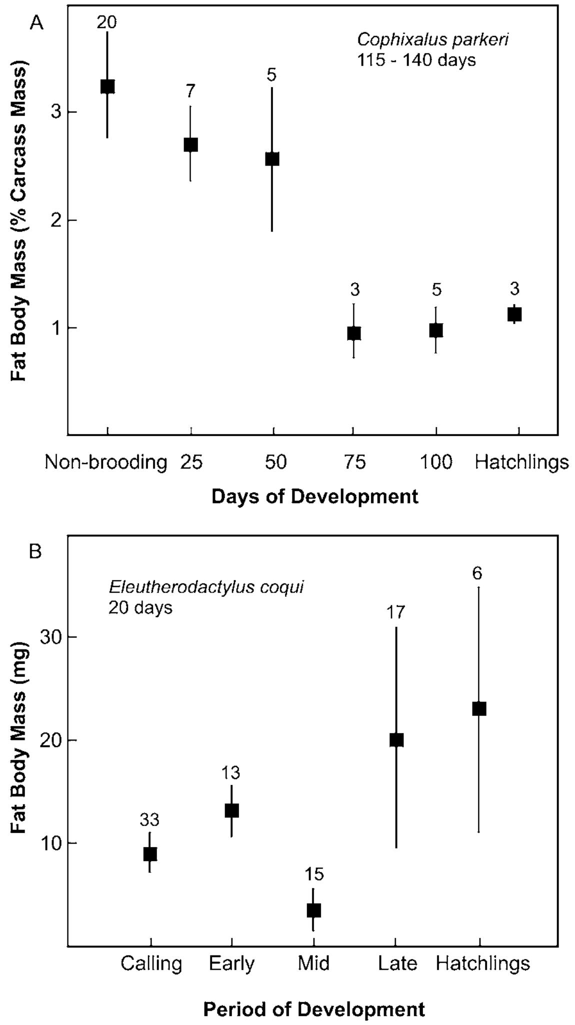

Fig. 11.15. The energetic cost of parental care in two terrestrial frogs. (A) Reduction in relative abdominal fat body mass in males of a microhylid frog from New Guinea, *Cophixalus parkeri,* as a function of stage of embryonic development. Fat reserves of males decrease throughout the long period of parental care in this species. (B) Change in absolute abdominal fat body mass in males of the Puerto Rican treefrog *Eleutherodactylus coqui* as a function of stage of embryonic development. Fat reserves of males decrease at the peak period of parental care, but increase late in embryonic development as some males leave the eggs periodically to feed. (A) After Simon (1983). (B) Plotted from data in Townsend (1986).

1986). Nevertheless, fat bodies were significantly reduced only in the middle of the brooding period (fig. 11.15 B), suggesting that the energetic cost of the relatively short (20 day) period of parental care is low compared to the cost for *Cophixalus.*

Almost nothing is known about the details of parental care by caecilians in the field, but Kupfer, Nabhitabhata, and Himstedt (2004) reported that body mass of females of *Ichthyophis kohtaoensis* in Thailand decreased during the breeding season and was lower for females brooding eggs at advanced stages of development. Body condition, adjusted for body length, also was lower for females brooding older eggs than for those brooding young eggs. Parental care is prolonged in this species, with clutches required up to three months to develop, but the constancy of female attendance has not been determined. Nevertheless, the changes in body mass and condition suggest that foraging opportunities for brooding females are limited, making parental care energetically costly. These observations are consistent with an earlier report that females in captivity showed a reduction in body mass during egg brooding, but in that case, captivity may alter natural foraging behavior (Kramer, Kupfer, and Himstedt 2001).

Shorter-term types of parental care, such as transporting larvae from oviposition sites to water, probably have relatively low energetic costs, because the time devoted to the activity is so short. The only attempt to investigate such costs is a study by Downie et al. (2005) on *Mannophryne trinitatis,* a dendrobatid frog in which males carry tadpoles for several days. They did not find any evidence that foraging of tadpole-carrying males was reduced relative to that of calling males, nor did the extra burden of tadpoles affect locomotor performance. They were not able to measure actual metabolic costs of carrying tadpoles, however.

Reproductive Costs

Prolonged parental duties also could limit opportunities for future reproduction. For females, this is largely an energetic cost, since an inability to feed while brooding eggs would reduce a female's capacity to produce more eggs. Alternatively, parental care might limit reproductive opportunities because environmental conditions are not suitable for reproduction all year. For example, some plethodontids might be limited to annual or biennial reproduction because of the costs of parental care, although another possibility is that ecological factors restrict opportunities for more frequent reproduction, thereby making extended parental care possible. Many salamanders that lack parental care also have annual or biennial reproductive cycles (Salthe and Mecham 1974).

Data on frequency of reproduction in tropical frogs are so scarce that it is impossible to say whether parental care limits reproduction by females. In the dendrobatid frog *Colostethus panamensis,* a species with female parental care, females apparently reproduce no more than twice a year (Wells 1980a), a surprisingly low figure for a species with favorable breeding conditions for nine or ten months a year. Females of some other dendrobatids with male parental care, such as *Dendrobates auratus,* produce clutches every 10 to 14 days (Senfft 1936), but this also is true for species such as *D. pumilio,* in which females assume some parental duties and even feed their tadpoles (Weygoldt 1980a, b).

For males, the chief cost of parental care would be an inability to advertise for additional mates while attending eggs. This seems to be true for *Hyla rosenbergi* (Kluge 1981). In *Eleutherodactylus coqui,* most males remain with their eggs throughout development and do not advertise for additional females; a few leave their eggs late in development and occasionally succeed in attracting additional mates (Drewry 1970; Townsend, Stewart, and Pough 1984). Nevertheless, a reduced opportunity to obtain mates does appear to be a significant cost of parental care in that species (Townsend 1986, 1989b). On the other hand, if males can care for eggs and attract additional mates at the same time, then the cost of parental care is greatly reduced. Attendance of multiple egg clutches by males has been reported in cryptobranchid salamanders (B. Smith 1907; S. Bishop 1947; Nickerson and Mays 1973a; Kuwabara et al. 1989), several species of *Eleutherodactylus* (Drewry 1970; Joglar, Burrowes, and Rios 1996; Rogowitz et al. 2001), some centrolenid frogs (McDiarmid 1978; M. Hayes 1991), some microhylid frogs in the genus *Cophixalus* (Hoskin 2004), and other anurans (Wells 1981a). Male midwife toads (*Alytes*) frequently carry eggs from several different females (Reading and Clarke 1988; Raxworthy 1990; Márquez 1993; Verrell and Brown 1993). Furthermore, the relatively short breeding period of some midwife toad populations reduces the cost of parental care, because females are available for only a short period of time (Márquez 1992).

Sex Roles in Parental Care

The publication of Trivers' (1972) important paper on parental investment led to increased interest in male and female roles in all aspects of reproductive behavior, including parental care. Once viewed as an example of cooperation between the sexes, parental behavior is now evaluated in terms of potential evolutionary conflicts in the reproductive interests of males and females (Trivers 1972; E. O. Wilson 1975; Maynard Smith 1977, 1978; Grafen and Sibly 1978) or parents and offspring (Trivers 1974). Amphibians and fishes are particularly useful groups for testing theoretical ideas about parental care, because these groups include species with no parental care, parental care by males alone, parental care by females alone, and biparental care. There now is a considerable theoretical and empirical literature on the origins of maternal and paternal care in these groups (G. Williams 1966, 1975; Trivers 1972; Dawkins 1976; Dawkins and Carlisle 1976; Maynard Smith 1977, 1978; Grafen and Sibley 1978; McDiarmid 1978; Ridley 1978; Blumer 1979; Perrone and Zaret 1979; Barlow 1981; Gross and Shine 1981; Baylis 1981; Wells 1981a; Gross and Sargent 1985; Nussbaum 1985, 2003; Clutton-Brock 1991; Crump 1995b, 1996; Beck 1998; Lehtinen and Nussbaum 2003).

Mate Desertion and Parental Care

Theoretical models often are designed to predict which parent will desert offspring first. Such behavior would force the remaining parent either to desert the offspring or to care for them alone (Trivers 1972; Dawkins 1976; Dawkins and Carlisle 1976; Maynard Smith 1977, 1978; Grafen and Sibly 1978; Ridley 1978; Gross and Sargent 1985; Clutton-Brock 1991). These models assume that strategies adopted by individuals of one sex depend on activities of both same sex and opposite sex individuals in the population. Although such models show how a set of specified alternative strategies could be maintained in a population, they tell us little about how such strategies originated because this depends largely on initial conditions (Maynard Smith 1977). Since both maternal and paternal care in amphibians almost certainly evolved from a condition of no parental care, it is unlikely that desertion by one parent requires the other to care for eggs. Therefore, it is more appropriate to ask why individuals of either sex remain with the eggs instead of deserting them.

Mode of Fertilization and Parental Care

Parental care by males alone is more common among animals with external fertilization than among those with internal fertilization (Trivers 1972; Wells 1977b, 1981a; Ridley 1978; Gross and Shine 1981; Clutton-Brock 1991). Among vertebrates, care by the male alone is uncommon in mammals, birds, reptiles and salamanders with internal fertilization, but is relatively widespread in teleost fishes, frogs, and the few salamanders with external fertilization. Two general explanations of this relationship have been proposed. First, with external fertilization, males must be present when eggs are laid and therefore are available to assume parental duties (G. Williams 1966, 1975; Trivers 1972; Wells 1977b, 1981a; Maynard Smith 1978; Crump 1995b, 1996). In species with internal fertilization, male parental care often is not an option, because mating occurs long before eggs are laid. In many temperate-zone plethodontid salamanders, for example, mating can occur in both the fall and spring, but oviposition occurs in the summer (Houck 1977a); parental care by females is nearly universal. External fertilization also increases the probability that all eggs in a clutch are a male's own, thus reducing the probability that a male will care for another's eggs (G. Williams 1966, 1975; Trivers 1972; Maynard Smith 1978; Ridley 1978; Blumer 1979). The importance of the certainty of paternity hypothesis in the evolution of paternal care has been questioned on theoretical grounds (Maynard Smith 1978; Werren, Gross, and Shine 1980; Gross and Shine 1981). It cannot explain the widespread occurrence of either male or female parental care in species with external fertilization (Wells 1981a; Crump 1995b, 1996). In addition, there are cases of multiple paternity of egg clutches in both anurans and urodeles with external fertilization (see chapters 8 and 9), so males cannot always be certain of their paternity.

Beck (1998) used phylogenetically based comparative methods to examine the relationship between mode of fertilization and sex of the caregiving parent in anurans. He concluded that mode of fertilization did not explain the occurrence of male or female parental care in this group. There are several problems with his analysis, however. First, he limited his analysis to anurans, nearly all of which have external fertilization. When salamanders are included in the analysis, it is clear that most salamanders have female parental care, with the only exceptions being species with external fertilization. In anurans, on the other hand, paternal care is at least as common as is maternal care, suggesting that external fertilization facilitates the evolution of paternal care. Second, the sample of anuran species with internal fertilization is very small and biased by reproductive mode. Of the genera known to have internal fertilization, two (*Ascaphus* and *Mertensophryne*) do not have any parental care and are therefore irrelevant to the analysis. Five other African bufonids have viviparous reproduction, as does *Eleutherodactylus jasperi.* In these species, parental care consists of embryos being retained in the reproductive tract of the mother, so male parental care is not possible, and they should be omitted from the analysis (Crump 1996). The sole remaining species is *Eleutherodactylus coqui.* All of the closest relatives of this species within the genus *Eleutherodactylus* have male parental care, regardless of mode of fertilization (Townsend 1996).

There is evidence for amphibians that the proximity of the male during oviposition is more important than mode of fertilization in determining the pattern of parental care, especially if the male chooses the oviposition site. In *Eleutherodactylus coqui,* males perform all parental care, but fertilization is internal (Townsend et al. 1981; Townsend, Stewart, and Pough 1984). Nevertheless, mating occurs immediately before oviposition at a site chosen by the male, so the male is available to assume parental duties. A Central American species, *E. angelicus,* also might have internal fertilization, although the evidence is circumstantial, and nothing is known about the timing of mating and oviposition. Females attend eggs in this species (M. Hayes 1985).

Among salamanders, the best-documented cases of male parental care are in cryptobranchids, which have external fertilization (S. Bishop 1941b; Nussbaum 1985, 2003). Oviposition takes place at a nest site previously chosen by the male, and the males then simply stay with the eggs. Sirens are assumed to have external fertilization (see chapter 10), yet in one species, females are reported to attend their eggs. In this species, however, eggs are laid in tangles of vegetation probably chosen by the female. Unfortunately, mating has never been observed in sirens, either in the field or in captivity. Male parental care might occur in the European olm (*Proteus anguinus*), although the details of parental care are unclear (see the previous discussion). Even though this species has internal fertilization, mating apparently takes place immediately before oviposition, so the male is available for parental duties. For most salamanders, the evolution of fertilization by means of spermatophores probably set the stage for the evolution of female parental care, not because fertilization is internal, but because courtship and oviposition generally are separated in both space and time, and oviposition sites are chosen by females alone. This enables females of many species to make use of cryptic, protected oviposition sites that probably are not suitable for courtship (Nussbaum 1985).

Territoriality and Parental Care

If a male defends an oviposition site that enhances his attractiveness to females, he might remain in his territory and continue to attract females while giving his eggs some protection. In the initial evolution of parental care, the reproductive cost to the male, in the form of decreased opportunities for future matings, would be relatively low (Trivers 1972; G. Williams 1975; Wells 1977b, 1981a; Woodruff 1977; McDiarmid 1978). This argument has been applied to the evolution of male parental care in fishes (G. Williams 1975; Ridley 1978; Blumer 1979; Perrone and Zaret 1979; Barlow 1981; Baylis 1981; Gross and Sargent 1985; Clutton-Brock 1991). There is little doubt that it applies to amphibians as well, but several additional factors must be considered (Wells 1981a). First, one cannot assume that a male remaining at an oviposition site protects the eggs. In *Rana clamitans* and *R. catesbeiana,* males remain in their territories and continue to call after fertilizing eggs (Wells 1977c; R. D. Howard 1978a), but there is no evidence that this is advantageous to the eggs. The same is true for Australian frogs of the genus *Pseudophryne,* which lay eggs in burrows (Woodruff 1977). Second, a correlation between male parental care and territoriality is expected only if males defend oviposition sites. Many species of frogs defend calling sites separated from oviposition sites (chapter 8). Finally, some forms of parental care make territory defense difficult, so the advantages of parental care have to be balanced against the disadvantages of losing the territory.

In an earlier review, I suggested that frogs in the genus *Eleutherodactylus* would be useful for comparative studies of parental strategies, because the genus contains species with maternal care, paternal care, or no parental care at all (Wells 1981a). Since that paper was published, additional examples of parental care in this group have been reported, although most such reports are anecdotal, and many are based on unpublished information (Townsend 1996). Although the data are still very incomplete, several trends are evident. In general, parental care by females appears to be strongly associated with oviposition in nests on the ground, including spaces under rocks, holes in sand or soil, subterranean burrows constructed by the female, or in leaf litter. These sites also are the ones most commonly used by species that apparently lack parental care.

Some species with male parental care also nest on the ground or in leaf litter, but many others use elevated sites in such as tree holes, bromeliads, curled dead leaves hanging in vegetation, the axils of palm trees, and the sides of rocks in caves (table 11.2). The evolution of arboreal habits potentially exposes frogs and their eggs to drier conditions than those experienced by ground-dwelling frogs. This requires the use of specialized oviposition sites in sheltered locations that provide high-humidity environments for egg development (Townsend 1989a), just the types of sites that are likely to be in short supply and defensible as territories by males. Indeed, aggressive defense of oviposition sites has been reported in several species of *Eleutherodactylus.* Townsend (1996) also reported that males have been observed calling from oviposition sites in seven species, and accumulation of multiple egg clutches at a defended site is relatively common. In some species, such as *E. coqui,* males usually do not call directly from the oviposition site, but instead lead the female there from an elevated calling site (Townsend and Stewart 1986). Once a male has acquired an egg clutch, however, he sometimes calls from the nest during late stages of embryonic development.

Townsend (1996) also identified geographical correlates of parental care in *Eleutherodactylus.* Parental care by males appears to be quite uncommon among species from the mainland of South and Central America. Townsend could find only two examples of possible male parental care out of 28 species for which some information was available. One was for an *E. augusti* male found under a rock with a clutch of eggs (Jameson 1950); the other was for an *E. diastema* male found in the leaf axial of a bromeliad with an egg clutch (Dunn 1937). The former is known to call from the oviposition site, and the latter exhibits a high degree of site fidelity and very likely is territorial (Wells, unpublished observations; Wilczynski and Brenowitz 1988). All other mainland species for which egg clutches are known (a very small proportion of the total) either have no parental care or female parental care. In contrast, parental care by males is much more common in the West Indies, especially in Hispaniola, Puerto Rico, and the Lesser Antilles. This pattern reflects a fundamental difference in the ecology of *Eleutherodactylus* in these areas. Many mainland species are terrestrial, forest-litter inhabitants, with arboreal habitats being dominated by hylids and centrolenids. Many West Indian species are terrestrial as well, but others have moved into arboreal microhabitats, especially on islands where hylids are uncommon or absent. Many of these make use of elevated oviposition sites and have male parental care.

Phylogenetic history appears to be important as well, in part because phylogeny and ecology are correlated to some degree. For example, all of the *Eleutherodactylus* of Puerto Rico and the Lesser Antilles are thought to be closely related, and indeed, appear to form a monophyletic group that is largely arboreal, but with some terrestrial, cave, and rock-dwelling species (Hedges 1989, 1996; Joglar 1989, 1998). The common occurrence of male parental care in these frogs could represent a single origin from a common ancestor. A distinct clade, the subgenus *Euhyas,* is endemic to the western Caribbean (Cuba, Jamaica, and Hispaniola) and is primarily terrestrial. Every example of female parental care among West Indian species cited by Townsend (1996) comes from this lineage. This includes all Jamaican species for which parental care is known, except for *E. alticola,* which is reported to have either male or female parental care. There are Cuban and Hispaniolan species in this subgenus with male parental care as well (Townsend 1996), and all of these probably evolved arboreal habits secondarily (Hedges 1989).

Other anuran species show a similar association between male territoriality, defense of specialized oviposition sites, and male parental care (table 11.1). In species in which females attend their eggs, oviposition usually occurs in burrows constructed by the female, foam nests formed by pairs in amplexus, and natural cavities on the ground under logs, rocks, or leaf litter. In species with male parental care, males usually call from tree holes, burrows, rock cavities, nests constructed by the male, leaves overhanging streams, or other types of oviposition sites likely to be in short supply or variable in quality and defensible as territories. Active territorial defense of these sites has been reported in several species, and in some, males have been observed attending more than one clutch, or are known to continue to call while attending eggs. Many dendrobatid frogs exhibit a slightly different strategy. Males often are territorial, but instead of defending a single oviposition site, they defend an area containing several suitable sites and then court females and lead them to oviposition sites (Wells 1978a; Summers 1989, 1992; Roithmair 1992).

As in the genus *Eleutherodactylus,* the phylogenetic history of other anurans appears to affect the role of the two sexes in parental care, although this also reflects the phylogenetic distribution of territorial defense of oviposition sites by males. In centrolenids, for example, only male parental care has been well documented (table 11.1). The only report of females remaining with eggs is Jacobson's (1985) account of *Centrolene prosoblepon* females remaining near their eggs for several hours after completing oviposition. It is not clear whether this is an example of parental care, or simply the result of exhausted females resting after laying eggs. Parental care apparently is rare in hyperoliids, some of which lay eggs on leaves over water in a manner similar to that of centrolenids. Only female parental care has been observed in this family. Male parental care appears to be much more common than female parental care in microhylid frogs, the main exceptions being burrowing or ground-nesting species. Male parental care clearly is the dominant pattern in several microhylid genera from Madagascar (*Anodonthyla, Cophyla, Platypelis,* and *Plethodontohyla*), all in the subfamily Cophylinae. The same is true for microhylids from New Guinea and Australia (Bickford 2001, 2004). Female parental care predominates in leptodactylid genera other than *Eleutherodactylus,* perhaps reflecting a correlation with oviposition in foam nests or nest sites selected by the female.

Sex Roles in Egg and Tadpole Transport

Why is egg transport almost exclusively a female activity in frogs? McDiarmid (1978) suggested that females are more likely to be able to carry a complete clutch because they often are larger than males. This explanation seems unlikely, because it should apply equally well to tadpole transport. Yet there are many species of dendrobatid frogs in which males have no difficulty transporting entire clutches of tadpoles. I believe several other factors are more important. First, there would be severe problems in transferring eggs from the female to the body of the male if fertilization is external. In pipids and egg brooding hylids, the actions involved in placing the eggs on the female's back or in a brood pouch are modifications of normal amplexus, in which the male is on top of the female. Although specific movements vary considerably among species, all allow the eggs to pass the male's cloaca and be fertilized before being positioned on the female (Rabb and Rabb 1960, 1963a; Weygoldt 1976a; Duellman and Maness 1980). Rather complicated gymnastics would be required for eggs to end up on the back of the male. In *Alytes,* the only genus with male transport of eggs, the eggs are laid in strings, thus facilitating their attachment to the male's legs. Another factor that would mediate against the evolution of egg transport by males is territoriality; a frog carrying eggs probably cannot defend a territory because of potential injury to the eggs. Furthermore, if a male could carry only one clutch at a time, then a prolonged period of parental care would prevent a male from obtaining additional mates (Wells 1981a). Again, *Alytes* is an exception; males can carry several clutches simultaneously, and there is no evidence that males are territorial (Márquez 1992; Verrell and Brown 1993).

Carrying tadpoles on the back probably interferes with aggressive defense of territories, and this could influence the sex of the care-giving parent in dendrobatid frogs. When male-male competition for mating territories is intense, then one might expect selection to work against males carrying tadpoles. On the other hand, when competition for territories is less intense, or when males are not territorial, then either sex might carry tadpoles. These predictions are most relevant to species that carry tadpoles for several days before releasing them, as in some species of *Colostethus* and *Mannophryne* (table 11.3). Tadpole transport by males is the predominant form of parental care in these genera and is assumed to be the ancestral condition for all dendrobatids with parental care (Summers et al. 1999). In *Colostethus panamensis, C. pratti,* and *C. talamancae,* however, females carry tadpoles and males defend long-term territories (Wells 1980a, b, 1981a, unpublished observations). In *Mannophryne trinitatis, M. collaris,* and *Colostethus palmatus,* females defend territories and males carry tadpoles. Males are aggressive toward other calling males, but apparently do not defend fixed territories (Test 1954; Sexton 1960; Duellman 1966; Lüddecke 1974, 1976; Durant and Dole 1975; Van Meeuwen 1977; Wells 1980c, 1981a). In some other species, such as *C. flotator,* males are aggressive toward one another and apparently are territorial (Wells 1981a; unpublished observations). Males also carry tadpoles, but these are transported to pools and released very quickly (Wells, unpublished observations). Whether a male subsequently returns to the same territory is not known. Patterns of male and female parental care in *Colostethus* and *Mannophryne* probably also reflect phylogenetic history, but a complete phylogeny of these genera is not yet available.

Males carry tadpoles in most species of *Dendrobates, Allobates, Epipedobates, Phyllobates,* and *Cryptophyllobates,* apparently reflecting the ancestral condition for the family (Summers et al. 1999; Lötters, Jungfer, and Widmer 2000; Lehtinen and Nussbaum 2003). In most species, tadpole transport requires only a few minutes to a few hours. Even when males are territorial, as in *Dendrobates auratus, D. leucomelas,* and *Allobates femoralis,* they must stop defending their territories only for short periods of time to carry tadpoles to water, and then are free to return and resume calling and territorial behavior (Summers 1989, 1992; Roithmair 1992). Parental care by females has evolved in two different lineages within the genus *Dendrobates.* In members of the *Dendrobates histrionicus* complex, including *Dendrobates pumilio, D. granuliferus, D. histrionicus, D. lehmanni, D. arboreus,* and *D. speciosus,* males are very aggressive in defending territories, and tadpoles are carried by females and later fed with trophic eggs (table 11.3). In *D. pumilio, D. granuliferus,* and probably *D. arboreus,* males attend the eggs before females take over all other parental duties, but they do not remain continuously with the eggs and are free to defend territories and advertise for additional mates. In the more derived species, such as *D. histrionicus* and *D. speciosus,* however, females perform all parental care (fig. 11.14), and males can return immediately to territorial defense and calling to attract mates.

In members of the "*Dendrobates ventrimaculatus* complex" in Amazonian South America, biparental care predominates. In contrast to the members of the *D. histrionicus* complex, males not only attend the eggs, but also carry the tadpoles. As described earlier in the chapter, males of most species then call the females and lead them to the tadpole deposition sites, where the females feed the tadpoles. In at least one species, *D. vanzolinii,* males and females form long-term monogamous pair bonds while caring for their young (Caldwell 1997; Caldwell and Oliveira 1999). The ancestral condition for this clade appears to be parental care performed entirely by the male. This is seen in a population of "*D. ventrimaculatus*" from Ecuador, which exhibits egg attendance and tadpole transport by males, but not feeding of tadpoles by females (Summers et al. 1999). Additional behavioral data on other populations of Amazonian frogs and further resolution of the taxonomy and phylogeny of the group are needed before the evolution of male and female parental care can be completely understood.

Summers and Earn (1999) suggested that differences in parental strategies within the genus *Dendrobates* are related in part to the size of pools used for tadpole deposition and the amount of food available in these pools. Species that have only male parental care often deposit tadpoles in relatively large pools in tree holes, stumps, fallen logs, or seed husks on the ground, where organic detritus tends to accumulate. While tadpoles in these pools often are cannibalistic, they often can survive without feeding on other tadpoles and without being fed by the female. Males sometimes deposit more than one tadpole in the same pool, although more commonly they disperse them among different pools. Summers and Earn (1999) suggested that placement of small tadpoles in pools that already contain larger offspring of the same male could be a form of facultative tadpole feeding.

Most of the species that have biparental or female parental care with tadpole feeding use very small pools in bromeliads or *Heliconia* leaf axils, or in the case of *D. vanzolinii,* tiny pools in tree saplings and vines (Caldwell and de Oliveira 1999). Such pools are more abundant in the rainforest than are larger pools, but they also lack sufficient food for tadpole development. Hence, the use of these small pools favored the evolution of parental feeding of tadpoles and led to the evolution of either female or biparental care (Caldwell and de Oliveira 1999; Summers and Earn 1999). Biparental care is most likely to evolve when males and females remain in habitats near their tadpole deposition sites, which would enable males to lead females to these sites. Parental care by the female alone is most likely to evolve when tadpole deposition sites are a considerable distance from the normal home ranges of males and females. In *Dendrobates pumilio* and related species, for example, the adults are primarily terrestrial, but tadpole deposition sites often are in bromeliads high in the canopy.

Parental Care and Sex Role Reversal

G. Williams (1966), Trivers (1972), Knowlton (1982) and others have hypothesized that high male parental investment leads to reversal of the usual sex roles in reproductive behavior, with females competing among themselves for access to males. This type of mating system is found in some pipefishes (Vincent et al. 1992), and in insects that exhibit high levels of male parental investment, such as giant waterbugs (Heteroptera: Belostomatidae; R. L. Smith 1979; Kruse 1990) and katydids (Orthoptera: Tettigoniidae; Gwynne 1985; Gwynne and Simmons 1990; L. Simmons 1992). Dendrobatid frogs have been cited repeatedly as possible examples of sex role reversal because males often provide parental care, and females of some species are more aggressive or more colorful than males (Trivers 1972; E. O. Wilson 1975; Ridley 1978; Kluge 1981). One must be cautious in interpreting these patterns, however, because an extensive male role in parental care is not necessarily equivalent to high male parental investment. In species where males can simultaneously care for eggs and attract additional mates, the cost of parental investment is relatively low. For sex role reversal to occur, male parental care must be so expensive that it inhibits males from obtaining additional mates, thereby decreasing the availability of males in the population and limiting female reproductive success (Trivers 1972; Knowlton 1982; Gwynne 1991; Vincent et al. 1992)

The following types of data are needed to demonstrate a relationship between male parental investment and sex role reversal in frogs: (1) receptive females should outnumber receptive males; (2) the shortage of males must be related to male parental investment and not simply to an unequal population sex ratio; (3) it should be relatively common for more than one female to approach a male simultaneously; (4) female-female aggressive encounters should be related to competition for mates and not solely to competition for ecological resources such as feeding sites or shelters; (5) females should take the more active role in courtship; and (6) males should discriminate between females when given a choice of mates (Wells 1981a). Such behavior is most likely when females produce many small clutches of eggs at short intervals and the time required to care for each clutch is longer than the interclutch interval. Female egg production might outstrip the ability of males to care for them, and a shortage of males would result. One must keep in mind that both males and females can be subject to sexual selection, and it is possible for individuals of both sexes to compete against same-sex individuals for access to mates (Andersson 1994).

The possibility of sex-role reversal has been investigated in some detail in *Dendrobates auratus,* a species originally cited by Trivers (1972) as an example of this phenomenon. Observations of this species in captivity and in the field revealed that more than one female sometimes approaches a calling male. Females sometimes fight with one another over males, females assume an active role in courtship, and they sometimes destroy the eggs of other females (Senfft 1936; H. Zimmermann 1974, 1978; Wells 1978a). All of these observations are consistent with the sex-role reversal hypothesis. Somewhat similar behavior has been observed in several other species with male parental care, including *Dendrobates azureus, D. leucomelas, D. tinctorius, Allobates femoralis, Phyllobates terribilis,* and *P. vittatus* (Polder 1974b; H. Zimmermann and E. Zimmermann 1980a, 1981, 1985; H. Zimmermann 1982; Weygoldt 1983).

In a detailed field study of *D. auratus* in Panama, Summers (1989) found that the availability of receptive males did not limit the mating success of females. There always were numerous males defending territories and calling to attract females. Females were observed to fight with one another and interfere with courtship attempts, as had been observed in the laboratory, but males also competed for access to females. Females took the more active role in courtship. Summers concluded that aggression among females and courtship of males by females reflected competition for particular males that controlled high-quality tadpole deposition sites. Furthermore, it was advantageous for females to try to prevent males from mating with other females, because they suffered a fitness cost if males mated polygynously. When males cared for the eggs of more than one female simultaneously, they often deposited several tadpoles in the same pools. Because the tadpoles are cannibalistic, this could potentially reduce the fitness of a particular female (Summers 1990). Hence, there appears to be a conflict of interest between males, which maximize their reproductive success by mating with as many females as possible, and females, which maximize their reproductive success by monopolizing the services of particular males. The same interpretation probably applies to the very similar behavior of *D. leucomelas,* but this species has not been studied in as much detail (Summers 1992).

Females also have been observed to compete with one another for access to males in *Alytes obstetricans,* another species with male parental care (Verrell and Brown 1993). In a laboratory colony, females tried to interfere with mating by pushing males that were already in amplexus with other females. Females could not completely control access to particular males, at least in the confines of a laboratory, because one male mated with two females that had competed with one another. Males showed little evidence of aggression or competition for mates other than calling to attract females. Females could not be competing for males with high-quality territories in midwife toads, because males are not territorial, but they might compete for access to males perceived to be superior caregivers for their eggs.

Ecology and the Evolution of Parental Care

Several authors have proposed complex evolutionary schemes relating ecological variables to the evolution of parental care in amphibians, particularly terrestrial species (Salthe 1969; Salthe and Duellman 1973; Salthe and Mecham 1974; Lamotte and Lescure l977; McDiarmid 1978; Nussbaum 1985, 2003; Crump 1995b; Lehtinen and Nussbaum 2003). Some have suggested that parental care in amphibians evolved as part of a more widespread tendency toward terrestrial modes of reproduction. According to this view, rigors of the aquatic environment, especially predation, favored placement of eggs away from water. This in turn introduced new dangers, such as the problem of desiccation. Consequently, terrestrial reproduction set the stage for increased parental attendance of eggs and eventually the evolution of more elaborate forms of parental care (Salthe and Duellman 1973; Salthe and Mecham 1974; McDiarmid 1978; Duellman and Trueb 1986; Crump 1995b). Some authors have assumed that parental care in anurans and urodeles evolved in response to similar selective pressures, and Salthe and Mecham (1974) called particular attention to the apparent parallelism between terrestrial plethodontids and frogs with direct development, such as *Eleutherodactylus.*

I believe the available evidence indicates that parental care in terrestrial salamanders and terrestrial frogs had quite different origins and evolved in response to different selective pressures, a conclusion also drawn by Nussbaum (1985, 2003) and Crump (1995b, 1996). Salamanders and frogs differ in several respects. First, terrestrial reproduction without parental care is relatively common in frogs (Lamotte and Lescure 1977; Lehtinen and Nussbaum 2003), but is rare in salamanders (Nussbaum 1985, 2003). Second, parental attendance of eggs is rare in aquatic frogs, but is relatively common in aquatic salamanders (Nussbaum 1985, 2003; Crump 1995b, 1996). Finally, both terrestrial reproduction and parental care are virtually nonexistent in temperate zone frogs, but are characteristic of most temperate zone salamanders. These patterns provide some insights into the evolution of parental care.

The Evolution of Parental Care in Urodeles

Nussbaum (1985, 2003) argued that the relative scarcity of food in many running-water environments has favored large egg size in salamanders because larvae hatching from large eggs will be better able to capture the relatively large but scarce prey items found in streams (see also chapter 10). In contrast, salamanders that breed in ponds produce relatively small eggs, perhaps because small larvae can utilize abundant small zooplankton present in such habitats, and because of constraints on gas exchange in low-oxygen environments (see chapter 4). One cost of large egg size in stream-breeding salamanders is a longer embryonic period, especially in cold water (see chapter 10), and this in turn exposes the embryos to a greater risk of predation. Hence, selection has favored placement of eggs in hidden nest sites and maternal attendance to reduce embryo mortality in stream-breeding salamanders. Pond breeders generally have evolved other strategies for protecting their eggs from predators, including encasing the eggs in thick coats of jelly, scattering eggs individually on the bottoms of ponds, or hiding eggs individually in vegetation (see chapter 10 for more details).

As mentioned earlier, conspecific predation on eggs appears to be widespread among salamanders, particularly those using aquatic or semiaquatic nest sites. Such predation results in part from competition among females for suitable nest sites. Salamanders breeding in streams usually place their eggs in specially selected sites that have the proper orientation to the current and are hidden from potential predators. Such sites probably are in short supply in many habitats, and those available probably vary in quality. Consequently, intraspecific competition for nest sites would be expected. By preying on eggs already present in a nest site, an intruding female might cause the resident female to abandon the site, thereby making it available to the intruder. Such predation would favor parental protection of nest sites, even in the absence of strong predation pressure from other species.

Once parental care had evolved in aquatic salamanders, they were preadapted for reproduction in terrestrial microhabitats. Presumably, the principal benefits of parental care gradually shifted from protection against predators to protection against desiccation in fully terrestrial nest sites, as in many species of *Plethodon.* Parental attendance of eggs probably accounts for the success of plethodontids in colonizing a variety of microhabitats in the temperate zone. Subsequently one lineage invaded the humid tropics and has since undergone extensive radiation (D. Wake 1987; see also chapter 1).

This scheme yields several testable predictions. First, facultative parental care should be relatively common in aquatic salamanders. Specifically, when nest sites are not in short supply, or when population densities are low, females might not guard their eggs. This would not be predicted if eggs were guarded mainly against heterospecific predators. Unfortunately, there are few reliable data on intraspecific variation in parental care. J. Wood (1953a) found large clutches of *Eurycea bislineata* eggs, apparently laid by several females, in masses of dead leaves; most were not attended. In other areas, where females lay eggs under rocks or similar defensible sites, parental attendance is more prevalent (S. Bishop 1941b; Baumann and Huels 1982). The evidence for parental attendance in *Pseudotriton* also is mixed, suggesting facultative variation among populations (Salthe and Mecham 1974; Bruce 1972a, 1975, 1978c). A second prediction is that parental care might become facultative or be lost altogether in terrestrial species that place their eggs in saturated microhabitats where predation is not very severe. For example, the frequent abandonment of eggs by females of *Hemidactylium* and *Stereochilus,* both of which lay eggs in very wet sites, is consistent with this prediction.

One also might expect secondary loss of parental care in some tropical salamanders that lay their eggs in moss mats and similar microhabitats. Unfortunately, the eggs of most tropical plethodontids have not been found, so it is impossible to generalize about the frequency of parental care.

The Evolution of Parental Care in Anurans

The possible origins of terrestrial reproduction and direct development in frogs were discussed in chapter 10. Although parental care in anurans often is associated with terrestrial reproduction, this is not universally true. What does seem to be generally true is that parental attendance of eggs usually is associated with the use of small, discrete oviposition sites, whether these are on land or in the water. Such sites include small pools, basins constructed by the sides of streams, spaces under rocks, rock crevices, burrows, sheltered sites in leaf litter, and oviposition sites on leaves, in leaf axils of bromeliads and other plants, in hollow bamboo stems, and in tree holes. Not only are these sites generally hidden from predators, but they also are readily defended against intruders, and when on land, often provide the high humidity conditions necessary for embryonic development. Anurans that place their eggs in highly exposed sites, or that group their eggs with those of other individuals, seldom exhibit any form of parental care.

What makes the analysis of the evolution of parental care in anurans very difficult is the frequent independent evolution of parental care in many different lineages of frogs, probably in response to a variety of selective pressures. This contrasts with the situation in salamanders, where the vast majority of species with parental care are in the family Plethodontidae, a group with a much less diverse array of reproductive modes. McDiarmid (1978), Duellman and Trueb (1986), and Crump (1995b, 1996) all provided hypothetical scenarios for the evolution of parental care in anurans, progressing through a series of steps toward increasingly terrestrial reproduction. They envisioned the process beginning with frogs placing their eggs near water, but retaining aquatic larvae and either not providing parental care (as in phyllomedusine hylids) or providing some parental care (as in centrolenids). Other species lay eggs in terrestrial sites that are close enough to water to allow tadpoles to move to water or be transported to water by a parent. The final step is considered to be the evolution of terrestrial oviposition, with eggs giving rise to nonfeeding tadpoles or direct development, or in some cases, transport of eggs by the parent.

This type of scenario can be a useful heuristic tool, but I believe it is somewhat misleading when one considers particular lineages of frogs. In most cases, there is little evidence that either reproductive modes or parental care actually evolved through the proposed intermediate steps. This is particularly true of complex forms of egg and larval transport; in most lineages, the closest relatives of species with these complex forms of parental care do not have similar reproductive modes, and intermediate steps leading to the evolution of parental care cannot be identified. Probably a more productive approach in the future will be to examine in detail certain lineages that exhibit variation in reproductive modes and parental care and attempt to reconstruct the evolution of parental care in a more explicitly phylogenetic context, as has been done for dendrobatid frogs (Summers et al. 1999) and some other clades (Lehtinen and Nussbaum 2003).

Summary and Conclusions

Amphibians display a remarkably complex array of parental strategies. Although many species lay their eggs in water or on land and abandon them, others exhibit various forms of parental care, including attendance of eggs or larvae at the nest site or transport of eggs, larvae, or juveniles on the body of a parent. The frequency of parental care in caecilians is unknown because their reproductive biology is poorly understood. Parental attendance of eggs, usually by the female, appears to be the rule among urodeles, particularly those in the family Plethodontidae. Parental care probably occurs in only 10–15% of all anuran species, but frogs exhibit the greatest diversity of parental behavior. Several experimental studies have shown that parental care enhances the survivorship of eggs and larvae. Putative benefits include protection from predators, protection from desiccation, protection from fungus and other pathogens, aeration of eggs, and in a few species, provision of food to the larvae. In most species, parental care probably provides more than one type of benefit. Potential costs of parental attendance include physical risk to the parent, energetic costs, and decreased opportunities for future reproduction, particularly in species with male parental care.

The evolution of sex roles in parental care is a topic of considerable interest to behavioral ecologists, and the amphibians can serve as a model system for testing hypotheses about parental investment. Mode of fertilization tends to be associated with the form of parental care, with male parental care being more common in species with external fertilization. This association appears to be derived from the temporal coincidence of mating and oviposition and the role of the male in choosing the nest site, rather than the mode of fertilization per se. Territorial defense of oviposition sites by males probably preceded the evolution of male parental care in some species, because males can continue to attract females while attending previous egg clutches. In species that transport eggs or tadpoles, however, territorial behavior by males could select against parental care if eggs or tadpoles are likely to be injured, or if prolonged parental care reduces a male's chances of retaining his territory. Some dendrobatids exhibit apparent sex role reversal associated with high levels of male parental investment; females are more aggressive in competing with one another than males and take a more active role in courtship. Nevertheless, such competition among females probably has more to do with competition for the best-quality males or oviposition sites than with a shortage of males. brought about by high male parental investment. Possible sex role reversal also occurs in midwife toads, a species in which males provide parental care, but do not defend territories or offer resources to females.

Parental care probably evolved independently many times in anurans, usually in response to the rigors of terrestrial reproduction, whereas parental care in plethodontid salamanders probably originated in an aquatic environment and subsequently contributed to the success of this family in colonizing terrestrial habitats. Among aquatic salamanders, maternal care occurs almost exclusively in stream-breeding species, which usually have relatively large eggs and long embryonic periods. The long embryonic period entails increased risks of predation, and selection has favored parental attendance to increase embryonic survival.

A greater understanding of the evolution of parental care in amphibians will require more detailed phylogenetic information on the relationships of species in particular clades, as well as more comparative information on the occurrence of parental care, particularly in tropical frogs, and the role of the sexes in such behavior. There also is a need for additional quantitative and experimental studies of the costs and benefits of parental care. In particular, the sources of embryonic and larval mortality and the importance of parental care in reducing such mortality need to be carefully investigated. This information, coupled with data on the energetic and reproductive costs of parental care, will provide new insights into relationships between reproductive modes, parental behavior, and mating systems in amphibians.

Chapter 12 The Ecology and Behavior of Amphibian Larvae

So still the Tadpole cleaves the watery vale
With balanced fins, and undulating tail;
New lungs and limbs proclaim his second birth,
Breathe the dry air, and bound upon the earth.
—Erasmus Darwin, *The Temple of Nature* (1803)

The remarkable transformations that amphibians undergo during metamorphosis have fascinated biologists since the time of Aristotle. Indeed, the name *amphibian* comes from Greek roots meaning "double life," and this unique feature of their biology has long been a distinguishing characteristic of the class. Early naturalists viewed the metamorphosis of tadpoles as evidence that amphibians were intermediate in the scheme of creation between fishes and reptiles, since most species make the transition from water-breathing aquatic larvae to air-breathing terrestrial adults.

Although amphibians played an important role in classical embryology and our understanding of processes of development, the ecology and behavior of amphibian larvae, as independent organisms, was largely neglected until recently. R. Maxwell Savage, a pioneer student of tadpole biology, put it this way: "It often seems that the larvae receive less attention than the adults. This is curious, not only because larvae have a considerable interest in themselves, but because, in the study of the whole life history of an animal, it is often the larval stage that throws much light on features of the ecology that would otherwise remain incomprehensible." He advocated the study of tadpoles, "not as temporary animals in the process of becoming something else, but as animals whose life, although short compared to that of adults, is lived on an entirely different plane, and has called for special larval organs, habits, and responses, to be considered just as if the adult frog had never been discovered" (Savage 1961, p. 24).

This is the approach I have taken in this chapter. I begin by describing morphological adaptations of amphibian larvae for different environments, as well as adaptations for acquiring and processing food, since these are important for understanding other aspects of larval ecology and behavior. Finally, I conclude with a discussion of the social behavior of amphibian larvae and its relationship to population ecology, including the role of kin recognition in larval social behavior. Other aspects of larval biology are discussed elsewhere in the book. The physiological ecology of amphibian larvae was discussed in chapters two through five. Chapter 13 reviews the evolution and maintenance of a complex life cycle and ecological aspects of metamorphosis, particularly environmental and genetic influences on larval growth and development. Responses to predators and the ecology of larval communities are discussed in chapters 14 and 15.

The Origin and Evolution of Amphibian Larvae

A complex life history with an aquatic larval stage is thought to be the ancestral condition for all three groups of living amphibians, the caecilians, urodeles, and anurans. Indeed, this type of complex life history probably was inherited from the common ancestor of living amphibians (Hanken 1999a). Fossils representing several early tetrapod groups exhibit unmistakable larval features. These include dissorophoid temnospondyls (Boy 1974; Bolt 1977, 1979; Milner 1982; Schoch 1992; Boy and Sues 2000), which generally are considered the closest relatives to modern amphibians (see chapter 1). Fossil salamander and frog larvae resembling those of modern families or genera have been found in deposits as old as the Cretaceous (Estes, Spinar, and Nevo 1978; Naylor 1978; Wassersug and Wake 1995; S. Evans and Milner 1996; S. Evans, Milner, and C. Werner et al. 1996; Roček 2000; Roček and Rage 2000b). These fossils show that an aquatic larval stage is an ancient feature of amphibian biology, extending back at least 250 million years.

Morphology, Development, and Ecology of Caecilian Larvae

The ancestral mode of reproduction for caecilians is the production of eggs that hatch into aquatic larvae. This mode of reproduction is retained in the two most primitive families, the Rhinatrematidae and Ichthyophiidae, as well as some species in the more derived family Caeciliidae (chapter 10). The development of aquatic caecilian larvae is poorly understood compared to that of urodeles and anurans, and even less is known about their ecology. Only a few species in the family Ichthyophiidae have been studied in any detail (Sarasin and Sarasin 1887–1890; Breckenridge, Nathanael, and Pereira 1987; Himstedt 1991, 1996). Caecilian larvae look more like adults than do the larvae of either urodeles or anurans. They hatch at a relatively advanced stage of development, with lungs already present. The large external gills that are present in the developing embryo degenerate at hatching, but the larvae retain gill slits (either one or two pairs, depending on the family). The body is elongate and similar in form to that of adults, but aquatic larvae often have tail fins that enhance aquatic locomotion. In terrestrial species, the tail is lost at metamorphosis. At metamorphosis, the rather delicate chondrocranium of the caecilian larva undergoes extensive ossification to form the heavily reinforced skull of the burrowing adult (see chapter 1). There also are changes in the morphology of the hyobranchial skeleton and tongue that accompany the shift from aquatic suction feeding to capturing terrestrial prey with the jaws (M. Wake 1989a).

Some of the most significant changes that occur at metamorphosis are alterations of the sensory systems (Himstedt 1996). Caecilian larvae have well-developed lateral line systems with two kinds of receptors. The first are neuromasts, which are mechanical receptors similar to those of other aquatic vertebrates. Caecilians also have ampullary organs, which function as electroreceptors (Hetherington and Wake 1979; Fritzsch et al. 1985; Wahnschaffe, Fritzsch, and Himstedt 1985). These organs are sensitive to very weak electric fields, like those produced by living organisms, and probably aid in location of hidden prey in the water (Himstedt and Fritzsch 1990). Urodele larvae also have ampullary organs that are similar in morphology and function to those of caecilian larvae, but these organs are absent in anuran tadpoles, which lack the capacity for electroreception (Fritzsch 1981; Münz, Claas, and Fritzsch 1982, 1984; Fritzsch and Wahnschaffe 1983; A. Roth and Schlegel 1988). The lateral line system disappears in terrestrial adult caecilians.

Caecilians often are thought to be completely blind, but many species have functional eyes both as larvae and as adults (M. Wake 1985). The eyes are small relative to those of urodeles and anurans, and they do not increase in size as the body grows (Himstedt 1995). The muscles that move the eye in larvae assume a secondary function of retracting the tentacle, a chemosensory organ found only in adult caecilians (Billo 1986; Billo and Wake 1987; Himstedt 1996; see also chapter 1). In both larvae and adults, the eyes are covered with semitransparent skin and probably do not form images. Nevertheless, the eyes are sensitive to differences in the intensity of light and are involved in phototactic behavior. Larvae of the Asian caecilian *Ichthyophis kohtaoensis* exhibit positive phototaxis when they first hatch from the eggs, presumably because they use light cues to find their way out of the terrestrial burrow where the eggs were laid. Shortly after hatching, however, phototactic behavior reverses, suggesting that the larvae use negative phototaxis to locate suitable hiding places during the day (Himstedt 1995).

The ecology and behavior of caecilian larvae are almost completely unknown, but work on *Ichthyophis kohtaoensis* in Thailand has shown that the larvae are not strictly aquatic, as usually assumed, but are amphibious. During the day, they remain hidden in terrestrial retreat sites under rocks, logs, or vegetation at the edges of ponds, sometimes in groups, but emerge at night to forage in the water (Himstedt 1991). This amphibious mode of life is retained to some extent in the adults of this species, which are perfectly capable of swimming in the water, despite their morphological adaptations for burrowing (Crapon de Caprona and Himstedt 1985). Anecdotal evidence for other species of *Ichthyophis* and several other caecilians suggests that this type of amphibious behavior is relatively common in larval caecilians (Himstedt 1996). An analysis of stomach contents of juveniles of the aquatic caecilian *Typhlonectes compressicauda* showed that these animals eat earthworms, frog eggs, tadpoles, and both aquatic and terrestrial insects. These animals were observed foraging in shallow water, and may have captured terrestrial insects that fell into the water (Verdade, Schiesari, and Bertoluci 2000).

Morphology, Development, and Ecology of Urodele Larvae

Most discussions of urodele larvae emphasize the similarity of general body form of larvae and adults and the lack of dramatic changes at metamorphosis (Salthe and Mecham 1974; Duellman and Trueb 1986). Most salamanders have relatively extended larval periods, and in some stream-dwelling species, the larval period can last for more than a year. At the opposite extreme are amphiumas, which hatch at an advanced stage of development and lose their gills after only two weeks (Gunzburger 2003). Urodele larvae are more similar to adults than are anuran tadpoles, but there are several distinctive larval characteristics. These include a skeleton composed mostly of cartilage, flattened tail fins, external gills, open gill slits, and the absence of moveable eyelids (eyelids serve to clean and moisten the eyes in terrestrial amphibians, but do not serve a useful function in aquatic animals). Some or all of these features are retained in paedomorphic species (see chapter 13), but they change in other species at metamorphosis. Changes occur in many other characters, including modification of the head, mouth, and associated musculature. These changes accompany the switch from aquatic suction feeding to terrestrial prey capture (Lauder and Shaffer 1986, 1988; Lauder and Reilly 1988, 1990; Reilly and Lauder 1988; Shaffer and Lauder 1988; B. Miller and Larsen 1989; Reilly 1994, 1996).

Other changes at metamorphosis are less conspicuous, but no less important as the animals make the transition from aquatic to terrestrial life. The skin, for example, develops the glands that characterize adult skin (see chapter 2). Cell layers are added to the epidermis, which develops a distinct *stratum corneum,* the outer layer of the epidermis that provides some mechanical protection to the skin (H. Fox 1994; Warburg, Lewinson, and Rosenberg 1994). These morphological changes are accompanied by physiological changes in osmoregulation and ion transport (Burggren and Just 1992). Metamorphosing salamanders also develop adult urinary and reproductive systems. Changes in the digestive system and other visceral organs are less dramatic than in anuran tadpoles (see the following), because salamander larvae already are adapted to a carnivorous diet, as are adults, but there is some shortening of the gut (Tilley 1964). Finally, salamanders exhibit a number of changes in their sensory systems at metamorphosis (Just, Kraus-Just, and Check 1981; Burggren and Just 1992). These include loss of the lateral line system in terrestrial species, although this is retained in permanently aquatic, paedomorphic species, such as the European cave salamander (*Proteus anguinus;* Fritzsch and Wahnschaffe 1983; Istenic and Bulog 1984). The shift from aquatic to terrestrial habits also is accompanied by changes in the shape of the eye lens. Aquatic salamander larvae have spherical lenses in their eyes, which are best suited to seeing underwater. At metamorphosis, the lenses become more flattened, a change that enhances vision in air (Wilder 1925; Sivak and Warburg 1980). Highly aquatic species, such as newts of the genus *Triturus,* retain spherical lenses throughout life (Manteuffel, Wess, and Himstedt 1977).

Functional Morphology of Locomotion

Salamander larvae have the same thin, elongate body morphology found in adults. In contrast to anuran tadpoles, which have a tail with only a flexible notochord for an axial skeleton, salamander larvae have a fully developed vertebral column supporting the tail musculature (Wassersug 1989a). Larvae that live in ponds typically have very large tail fins that extend along the back. Mountain brook larvae have small, fleshy tail fins that do not extend beyond the tail itself; stream larvae are intermediate (fig. 12.1). In all salamander larvae, the front limbs develop before the hind limbs, the opposite of the pattern found in anurans. The timing of limb development varies, but most species have fully functional limbs for much of the larval period, in contrast to anurans, in which limbs emerge shortly before metamorphosis.

Pond-dwelling larvae, including many hynobiids, ambystomatids, and salamandrids, often have balancers when they hatch, but these are absent in sirenids, which also have pond-type larvae. Balancers are extensions of the mandibular arch that produce a sticky mucus secretion that helps to hold the larva in place before the front limbs develop. Once the limbs have developed, the balancers either break off, as in the ambystomatids, or are resorbed, as in the salamandrids. Larvae that live in flowing water typically lack balancers altogether, but hatch with both the front and hind limbs more fully developed. A phylogenetic analysis suggested that balancers evolved in the common ancestor of the derived salamander families, after the divergence of the Sirenidae, but were lost repeatedly in various lineages (Crawford and Wake 1998). It also is possible that balancers evolved twice, once in the Hynobiidae and again in the common ancestor of ambystomatids and salamandrids. Crawford and Wake (1998) argued that this was less likely, because the complexity of balancer morphology suggests a single origin of the structure.

The locomotion of salamander larvae has been described as anguilliform (eel-like) and involves lateral bending of both the body and tail (Hoff et al. 1989; Wassersug 1989a). Salamander larvae do not engage in extended bouts of sustained swimming, but instead move in short bursts, separated by periods of relative inactivity. This mode of locomotion is used both to escape from predators and to capture prey. The presence of large external gills and well-developed limbs increases drag as the animal moves. During rapid lunges toward prey,

salamander larvae fold their gills and forelimbs against the body, thereby reducing the amount of drag and increasing the speed of movement. They extend their limbs to slow forward movement (Hoff, Lannoo, and Wassersug 1985).

Pond-dwelling larvae often remain suspended in the water column when they are small, but gradually shift to a more benthic existence as they grow and develop limbs. Large larvae are stronger swimmers than are small larvae, but they also spend more time crawling on the bottom or through vegetation and less time swimming in open water than do small larvae (J. Anderson 1968a; Hassinger, Anderson, and Dalrymple 1970; Leff and Bachmann 1986; McWilliams and Bachmann1989a, b). Stream-dwelling larvae generally do not inhabit open water, but instead spend most of their time resting or crawling among rocks on the bottom. Most of their swimming is confined to lunges at prey or escapes from predators (M. Parker 1994).

Respiratory Structures

All salamander larvae have three sets of external gills, each consisting of a central stem (ramus) that supports the small respiratory structures, or fimbriae (fig. 12.1). The length of the rami and the number of fimbriae vary with the habitat in which the larvae are found (Valentine and Dennis 1964). Species that live in ponds or lakes with relatively low levels of dissolved oxygen generally have large, bushy gills with many fimbriae that provide a large surface area for gas exchange. Various species of *Ambystoma* have classic pond-type larvae, but similar larval morphology is found in other families as well, including the permanently aquatic proteids, salamandrids such as *Notophthalmus, Taricha,* and *Triturus,* and a few plethodontids such as *Hemidactylium* (fig. 12.1).

At the opposite extreme are larvae found in mountain brooks, where the water often is saturated with oxygen. These larvae have much reduced gills with only a few fimbriae (fig. 12.1). They include the North American genera *Rhyacotriton* and *Dicamptodon* and Asian hynobiids such as *Onychodactylus* and *Batrachuperus* (Valentine and Dennis 1964). Many salamanders, including some *Ambystoma* and plethodontids such as *Gyrinophilus, Pseudotriton,* and *Eurycea,* have intermediate gill morphology and are referred to as stream type larvae, although they may live in a variety of habitats, from fast-moving streams to rivers and still pools. Respiratory surface area exhibits some facultative response to the environment. Low levels of dissolved oxygen produce an increase in fimbrial area, whereas high oxygen levels cause a decrease (Bond 1960; Guimond and Hutchison 1976). Nevertheless, mountain brook and stream larvae never develop the very large gills of pond larvae and generally cannot survive at low oxygen levels. Many salamander larvae probably develop lungs relatively early, but only a few species have been examined in detail (Burggren and Just 1992). Larvae use both the skin and lungs to supplement oxygen uptake through the gills (see chapter 4). They also use the lungs to regulate buoyancy (Lannoo and Bachmann 1984b).

Functional Morphology of Feeding

Some terrestrial salamanders use inertial feeding to capture prey, grabbing the prey with the jaws and then moving the head forward while simultaneously releasing the prey (Bramble and Wake 1985). Other species capture prey by protruding the tongue from the mouth, in some cases for a considerable distance beyond the jaws (Özeti and Wake 1969; Lombard and Wake 1976, 1977; D. Wake 1982; see chapter 1). These modes of feeding are less effective in the aquatic environment, because the movement of the predator's head or tongue would displace the prey away from the mouth. Aquatic salamander larvae feed by suction, moving the snout close to the prey and suddenly opening the mouth while depressing the hyoid apparatus. This produces negative pressure in the mouth, which sucks in the prey (Shaffer and Lauder 1985a, b; Reilly and Lauder 1989; Gillis and Lauder 1994; Reilly 1995, 1996). Both the initial lunge toward the prey and the opening of the mouth can be extremely fast (Hoff, Lannoo, and Wassersug 1985). This mode of feeding is characteristic of all aquatic salamander larvae, and indeed, most aquatic ectothermic vertebrates (Lauder 1985; Wainwright et al. 1989; Sanderson and Kupferberg 1999).

In ambystomatid salamander larvae, the efficiency of suction feeding is greatly enhanced by the one-way flow of water into the mouth and out the open gill slits (fig. 12.2). At metamorphosis, the gill slits close, making a one-way flow of water impossible. The result is that metamorphosed adults are less effective at capturing prey in the water than are aquatic larvae (Lauder and Shaffer 1986). Lauder and Reilly (1988) experimentally tested the role of gill slits in enhancing aquatic feeding in adult axolotls (*Ambystoma mexicanum*), which retain both gills and open gill slits throughout life. They sutured the gill slits to prevent a one-way flow of water during suction feeding. This resulted in a decrease in aquatic feeding efficiency equivalent to that observed in metamorphosing *Ambystoma*. The closing of the gill slits is not solely responsible for the decrease in aquatic feeding efficiency of metamorphosed adults, however. There also are changes in the structure of the hyobranchial apparatus and size and strength of the muscles that open the mouth. The result is a decrease in buccal pressure and in the effectiveness of suction feeding at metamorphosis (Lauder and Reilly 1990).

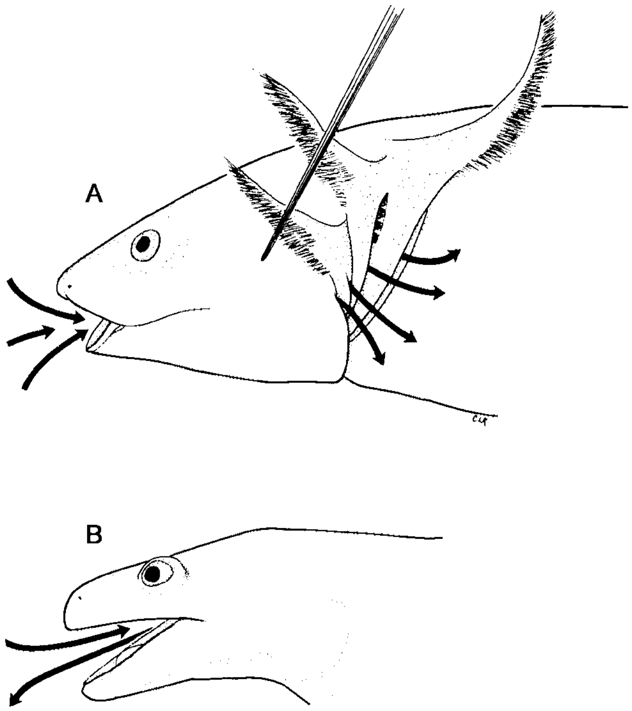

Fig. 12.2. (A) Diagram of one-way flow of water through gill slits of aquatic *Ambystoma tigrinum* larva during feeding. (B) Two-way flow of water in mouth of transformed adult. After Lauder and Shaffer (1985).

Decreased aquatic feeding performance also was observed in red-spotted newts (*Notophthalmus viridescens*) at metamorphosis. Terrestrial efts were less successful at capturing prey in the water than were aquatic larvae. In some populations of this species, some adults retain external gills into adulthood, but they lack open gill slits. The presence of the gills alone was not sufficient to increase aquatic feeding performance of branchiate adults over that of fully transformed individuals (Reilly and Lauder 1988). Nevertheless, both types of adults were much more successful at capturing prey in the water than were terrestrial efts. Fully transformed individuals of other salamandrid species that spend all or most of their adult lives in water also are very successful at capturing aquatic prey, even though all of these species lack open gill slits (B. Miller and Larsen 1989). This indicates that while a one-way flow of water may enhance aquatic feeding in some salamanders, it is not necessary for successful feeding in water. Adults of these aquatic species have morphological adaptations of the hyoid apparatus and

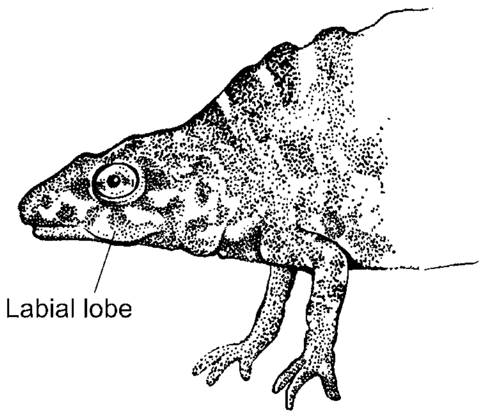

Fig. 12.3. Labial lobes in an adult *Triturus marmoratus,* an adaptation for aquatic feeding. Drawing by Mary Jane Spring from a photograph by Günter Diesener in Diesener and Reichholf (1986), p. 27.

mouth that enable them to continue feeding in much the same way as larvae.

The mouths of salamander larvae exhibit several adaptations for suction feeding. The tongue is little more than a glandular pad on the floor of the mouth, a condition that is retained in adults of highly aquatic species (Regal 1966; Özeti and Wake 1969). The mouth is relatively small, and large flaps of skin, or labial lobes, are present on the upper and lower jaws (fig. 12.1). These further reduce the size of the mouth opening and give it a rounded shape, thereby increasing the velocity of water flowing into the mouth and ensuring even acceleration of water moving around the edges of the mouth. The labial lobes also prevent water from flowing out of the mouth when it is closed (Matthes 1934; Özeti and Wake 1969; Lauder 1985). The lobes are lost at metamorphosis in terrestrial species, but may reappear in breeding adults of some species (fig. 12.3), enabling the animals to feed effectively in the water. The labial lobes are retained throughout life in adult salamanders that spend most of their time in water, and in some species, such as *Pachytriton brevipes,* the lobes are unusually large (B. Miller and Larsen 1989).

Feeding Ecology

All larval salamanders are carnivorous, as are adults. Most species are generalist predators on small invertebrates, and they can have a major impact on the structure and dynamics of freshwater invertebrate communities (Sprules 1972; Burton 1976; Holomuzki and Collins 1987; Taylor et al. 1988; Holomuzki 1989b; Petranka 1989a; Holomuzki, Collins, and Brunkow 1994; Blaustein et al. 1996). Salamander larvae, especially large individuals, also are important predators on anuran tadpoles and other salamander larvae (Metter 1963; Burton 1976; Caldwell, Thorp, and Jervey 1980; Stenhouse, Hairston, and Cobey 1983; Stenhouse 1985b; Cortwright 1988; Gustafson 1993; Griffiths, de Wijer, and May 1994; Morin 1995; Kiesecker 1996; Babik 1998; see also chapters 14 and 15). Larvae of at least one species (*Dicamptodon ensatus*) have been reported to feed on juvenile fish (M. Parker 1993). Most species are sit-and-wait predators that hang in the water column, rest on the bottom of a pond or stream, or hide under rocks and other debris. From these positions, the larvae make rapid lunges at passing prey animals (Hoff, Lannoo, and Wassersug 1985; Leff and Bachmann 1986; McWilliams and Bachmann 1989a, b; M. Parker 1994). In ponds where zooplankton is abundant, salamander larvae sometimes actively pursue prey as well (Hassinger, Anderson, and Dalrymple 1970). The tendency for salamander larvae to sit and wait for prey to come by produces a diet dominated by relatively active, mobile invertebrates. Cryptic, slow-moving invertebrates sometimes are underrepresented in the diet when compared to their abundance in the environment (M. Parker 1994).

Many species exhibit an ontogenetic shift in their diets, taking larger prey as they grow. In part, this is due to changes in the size of the mouth that enable large larvae to eat larger prey (Dodson and Dodson 1971; Collins and Holomuzki 1984; Petranka 1984c; Leff and Bachmann 1986; B. Taylor et al. 1988; M. Parker 1994; Sanderson and Kupferberg 1999). In pond-dwelling larvae, the shift in prey size also is related to the tendency for large individuals to spend most of their time crawling on the bottom rather than swimming in open water. Consequently, they feed mostly on benthic organisms that are larger than the zooplankton consumed by smaller individuals (Dodson and Dodson 1971; Leff and Bachmann 1986; McWilliams and Bachmann 1989a, b). Some pond-dwelling salamander larvae make daily vertical migrations in the water column in response to movements of their prey. Larvae also may change their daily patterns of activity or shift between microhabitats in response to movements of their prey or the activity of their predators (Efford and Mathias 1969; Dodson and Dodson 1971; Anderson and Williamson 1974; Sprules 1974b; L. Branch and Altig 1981; J. Taylor 1983a; Holomuzki 1986b; Leff and Bachmann 1986; McWilliams and Bachmann 1989a; Stangel and Semlitsch 1987; B. Taylor et al. 1988). There can be substantial variation in activity patterns, use of microhabitats, and prey selection among populations of the same species, and even among individuals in the same population (B. Henderson 1973; Efford and Mathias 1969; Collins and Holomuzki 1984; Zerba and Collins 1992). In general, stream-dwelling larvae do not exhibit pronounced ontogenetic shifts in microhabitat use or the type of prey consumed, but they sometimes shift activity patterns in the presence of predators. In most streams, open water areas lack prey that are suitable for salamander larvae, so the larvae tend to feed on benthic prey throughout development (Petranka 1984c; Nussbaum 1985; M. Parker 1994).

Cannibalism and Cannibalistic Morphs

As salamander larvae grow larger, they often attack smaller conspecifics, especially when population densities are high. Such attacks can produce serious injuries, including the loss of limbs and all or part of the tail. This type of aggressive interference competition can significantly reduce larval survivorship (R. N. Harris 1987b; Walls and Jaeger 1987; Petranka 1989a; Semlitsch and Reichling 1989; D. Scott 1990; C. K. Smith 1990; Van Buskirk and Smith 1991; Walls and Roudebush 1991; Hokit, Walls, and Blaustein 1996; Reques and Tejedo 1996). If size disparities between individuals are large enough, then aggressive attacks sometimes grade into full-scale cannibalism. Opportunistic larval cannibalism has been reported in several species of *Ambystoma* (Stenhouse, Hairston, and Cobey 1983; Lannoo, Lowcock, and Bogart 1989; Semlitsch and Reichling 1989; Walls and Roudebush 1991; M. Crump 1992; Nyman, Wilkinson, and Hutcherson 1993; Walls and Blaustein 1995; Brodman 1996), as well as *Dicamptodon* (C. Johnson and Schreck 1969; Nussbaum and Clothier 1973), *Pseudotriton ruber* (Gustafson 1993), *Salamandra salamandra* (Degani, Goldenberg, and Warburg 1980; Degani,1993), *Notophthalmus viridescens* (R. N. Harris 1987b), *Triturus cristatus* and *T. alpestris* (Babik 1998), and several species of *Hynobius* (Kusano, Kusano, and Miyashita 1985; Ohdachi 1994; Wakahara 1995; Nishihara 1996; Fu et al. 2003). Consumption of conspecifics can significantly increase growth rates of larvae and accelerate metamorphosis (Degani, Goldenberg, and Warburg 1980; Lannoo, Lowcock, and Bogart 1989; Warburg 1992; Degani 1993; Nyman, Wilkinson, and Hutcherson 1993; Wakahara 1995; Wildy et al. 1998; Kohmatsu, Nakano, and Yamamura 2001), an advantage that is particularly important for species that breed in temporary ponds.

In some populations, large cannibalistic individuals have proportionately larger heads than do noncannibalistic individuals, but the degree to which larvae develop into distinctive cannibalistic morphs varies among species. In ringed salamanders (*Ambystoma annulatum*), some populations of eastern tiger salamanders (*A. tigrinum tigrinum*), and some Asian salamanders in the genus *Hynobius,* cannibals are unusually large and have wide heads, but otherwise are not very different from noncannibals (Kusano, Kusano, and Miyashita 1985; Lannoo, Lowcock, and Bogart 1989; Nyman, Wilkinson, and Hutcherson 1993; Nishihara 1996). In contrast, populations of barred (*Ambystoma tigrinum mavortium*), blotched (*A. t. melanostictum*), Arizona (*A. t. nebulosum*), and eastern tiger salamanders (*A. t. tigrinum*), as well as long-toed salamanders (*A. macrodactylum columbianum*), sometimes have distinctive cannibalistic and noncannibalistic morphs. These differ not only in the size and shape of the head, but also in the size of the vomerine teeth (Powers 1903, 1907; Glass 1951; Gehlbach 1967, 1969; Rose and Armentrout 1976; Collins 1981; Pierce et al. 1983; Lannoo and Bachmann 1984a; Pedersen 1991; Collins, Zerba, and Sredl 1993; Walls et al. 1993; D. Pfennig, Ho, and Hoffman 1998; K. Larson et al. 1999). These large-headed morphs eat conspecifics much more frequently than do normal morphs (fig. 12.4), but they also eat large invertebrates, tadpoles, fishes, and other prey (Collins and Holomuzki 1984; D. Pfennig, Ho, and Hoffman 1998; K. Larson et al. 1999; Whiteman et al. 2003). In one population of *A. tigrinum* in South Dakota, cannibal morphs were found among both larvae and paedomorphic individuals (the latter are sexually mature individuals that retain larval gills and overwinter in the water before eventually metamorphosing; K. Larson et al. 1999). Paedomorphic cannibals also were described in the earliest study of cannibal morphs by Powers (1907), but in most other populations, the phenomenon is limited to sexually immature larvae. Cannibalistic morphs nearly always coexist in a pond with "typical" omnivorous morphs, with the frequency of cannibalistic morphs varying with environmental conditions (see Wakano, Kohmatsu, and Yamamura 2002, for a theoretical treatment of this phenonmenon).

The proximate determinants and ecological significance of cannibal morph development have been studied in considerable detail in the Arizona tiger salamander (*Ambystoma tigrinum nebulosum*). These salamanders typically are the top predators in the ponds where they live (Holomuzki and Collins 1987). When larval densities are high and competition for food is intense, individuals that develop into cannibals enjoy an advantage, because they have access to large prey, including conspecifics, which are not available to noncannibals (Maret and Collins 1997). This feeding advantage

Fig. 12.4. Cannibalistic morph of *Ambystoma tigrinum nebulosum* eating a conspecific. Photo by David Pfennig.

comes from an improved ability to handle large prey, which is related to the increased size of the head and vomerine teeth, and not to improved efficiency of suction feeding (Reilly, Lauder, and Collins 1992).

Larvae can be induced to develop into cannibals in the laboratory when reared at high density (Collins and Cheek 1983). A critical factor in controlling the expression of the cannibal phenotype is the availability of conspecifics as potential prey. When larvae were fed only invertebrates or tadpoles, or a combination of both prey types, they did not develop into cannibals if conspecifics were not present (Loeb, Collins, and Maret 1994). Nevertheless, the availability of tadpoles as prey does play an important role in the development of cannibalism. Salamander larvae that feed on tadpoles grow faster than do those that feed only on small invertebrates, and it is only the largest individuals that reach a size large enough to allow them to prey on conspecifics (Maret and Collins 1996). Similarly, individuals that feed on relatively large invertebrate prey grow faster than those that feed on smaller prey and are more likely to develop the cannibalistic morphology (Whiteman et al. 2003). Initial size differences among young larvae are magnified by interference competition among larvae, with the largest individuals inhibiting the feeding and growth of smaller larvae. This may result in part from avoidance of potentially cannibalistic large larvae by smaller ones, but it also could facilitate the development of cannibalistic behavior by increasing size differences among larvae in a pond (Ziemba and Collins 1999).

Development of cannibalistic morphs also is affected by the prevalence of an infectious bacterium (*Clostridium*), which often causes mass mortality in larval populations (Worthylake and Hovingh 1989). In natural populations, cannibalism is uncommon in lakes that are heavily infested with bacteria, and cannibals are disproportionately represented among dead and dying individuals (D. Pfennig, Loeb, and Collins 1991). Experimental work with another subspecies of tiger salamander, *A. t. tigrinum,* demonstrated that bacterial infections can be transmitted when cannibals eat diseased individuals, and in fact, cannibals were more likely to eat diseased larvae than healthy ones (D. Pfennig, Ho, and Hoffman 1998). Individuals that ate diseased conspecifics suffered reduced growth rates and increased mortality, effects that were not seen when larvae fed on infected individuals of another species. Cannibalism also can increase the probability of being infected by a deadly iridovirus that is known to cause mass mortality in tiger salamanders, but the salamanders do not appear to detect the presence of the virus in a population or avoid eating infected salamanders (Parris et al. 2005).

Cannibalistic salamander larvae actually preferred to feed on larvae of another species if given a choice. This suggests that there is a significant cost to intraspecific cannibalism in the form of increased likelihood of disease transmission, a cost that may account for the relative rarity of cannibalism in nature (D. Pfennig 1997), despite its obvious nutritional advantages (M. Crump 1992). Cannibalistic larvae of *A. t. nebulosum* tend to avoid eating close relatives if alternative prey is available. Such avoidance could be related either to inclusive fitness costs to eating close relatives, or to greater transmission of bacterial infections among close relatives (D. Pfennig, Sherman, and Collins 1994; for further discussion, see later section on “Kin Recognition, Cannibalism, and Aggression in Salamander Larvae”).

Experiments with the Asian salamanders in the genus *Hynobius* have shown that the mechanism for induction of cannibalistic morphs is similar to that in *Ambystoma tigrinum.* Cannibalistic morphs are most common in ponds with high densities of larvae and low food availability (Michimae and Wakahara 2001, 2002b; Fu et al. 2003). In ponds with low availability of small food items, larger individuals often feed on tadpoles, and these individuals are most likely to develop into the broad-headed cannibalistic morph (Michimae and Wakahara 2002a). These salamanders often breed very early in the spring in ponds where the only available food consists of relatively large prey such as tadpoles or conspecifics. Under such circumstances, broad-headed cannibals grow faster than do normal morphs. As in *Ambystoma tigrinum,* development of cannibalistic morphs is inhibited by the presence of a lot of closely related larvae (Michimae and Wakahara 2001).

Morphology and Development of Anuran Tadpoles

The basic internal and external anatomy of tadpoles has been reviewed in exhaustive detail by Altig and McDiarmid (1999), Cannatella (1999), Lannoo (1999), and Viertel and Richter (1999), so I will describe only the essential features of tadpole anatomy that relate directly to their ecology and behavior. In basic body morphology, anuran tadpoles and adults could scarcely be more different. Tadpoles are well adapted to aquatic locomotion, with rounded bodies and long tails with flattened fins. The transformation to a fully terrestrial tetrapod adapted for jumping, walking, or crawling on land and feeding on terrestrial prey is a remarkable one, involving major rearrangements of both internal and external morphology (Hourdry and Beaumont 1985; Wassersug 1997; Viertel and Richter 1999) and major changes in physiology (Burggren and Just 1992; Ultsch, Bradford, and Freda 1999). In tadpoles, the hind limbs emerge first, the opposite of the pattern seen in salamander larvae, with the front limbs appearing shortly before metamorphosis is complete. In many species, lungs develop well before metamorphosis and before the internal gills have been lost. In others, lung development is incomplete when the young frogs emerge onto land (Burggren and Just 1992). Lung development affects not only the mode of respiration in tadpoles (see chapter 4), but the regulation of buoyancy as well (Gee and Waldick 1995). In general, benthic tadpoles, which spend most of their time resting on the bottom of a pond or stream, develop and inflate their lungs later than do tadpoles that feed in the water column. Lung development often is delayed in stream-dwelling tadpoles compared to more generalized tadpoles, probably because the increased buoyancy provided by inflated lungs would be disadvantageous in flowing water (Wassersug and Heyer 1988; Nodzenski, Wassersug, and Inger 1989). Lung development also is delayed in some anurans that undergo rapid development in temporary ponds and emerge in a relatively underdeveloped state (see chapter 4).

Other major morphological alterations that occur during metamorphosis include development of an adult urogenital system and the rearrangement and ossification of skeletal elements (Duellman and Trueb 1986). The skin undergoes the same sorts of changes seen in metamorphosing urodeles, including addition of cell layers to the epidermis, development of a distinct *stratum corneum,* development of adult skin glands, and changes in the physiology of osmoregulation (Burggren and Just 1992; Fox 1994; Warburg, Lewinson, and Rosenberg 1994). There also are major changes in sense organs and other parts of the nervous system (Boatright-Horowitz and Simmons 1997; Lannoo 1999). In some cases, metamorphic changes involve loss of elements of the nervous system that function only in tadpoles, such as the loss of the lateral line system in terrestrial frogs. Other systems, such as an auditory system that can perceive airborne sounds, do not develop until metamorphosis. There also are changes in the sensitivity of some sensory systems as anurans make the transition from water to land. For example, the visual pigments of tadpoles in several different families have been shown to be most sensitive to wavelengths of light found in aquatic habitats. At metamorphosis, there is a shift toward wavelengths characteristic of terrestrial habitats (Hödl 1975).

The most dramatic changes are in the feeding apparatus and digestive system. Aquatic tadpoles are highly specialized for suspension feeding, and the tadpole chondrocranium is arranged to support a branchial skeleton that serves as a pump to move water into the mouth and across the gills (see the following). During metamorphosis, the transition to a terrestrial carnivore requires major reorganization of chondrocranial elements to form the ossified adult skull, loss of the larval mouthparts, and development of the adult jaws and tongue (De Jongh 1968; Wassersug and Hoff 1982; Burggren and Just 1992). Tadpoles have greatly elongated guts, but the morphology of the digestive system is relatively simple. Most tadpoles lack a functional stomach for digesting large food particles, although the larval stomach, the *manicotto glandulare,* is acidic and produces some digestive enzymes (I. Griffiths 1961; Viertel and Richter 1999). The gut lacks papillae or folds to increase absorptive surface area, as well as muscles to move food through the gut. A more distinct stomach develops during metamorphosis. The intestine becomes considerably shorter, but with increased internal surface area for nutrient absorption. At the same time, there are changes in the relative size of other visceral organs, such as the liver and pancreas. These morphological changes are accompanied by major changes in the physiology of digestive enzyme secretion, nutrient absorption, and the functioning of the muscles that move material through the digestive tract (Hourdry, l'Hermite, and Ferrand 1996; Wassersug 1997).

Functional Morphology of Locomotion

Tadpoles are unique among aquatic vertebrates in having an extremely short body and a relatively inflexible spine composed of a small number of vertebrae. The body of a tadpole is not streamlined like that of a fish, but is globular, with a clear division between the body and the tail (fig. 12.5). This unusual morphology is constrained by the developmental requirements of the terrestrial adult, in which a short, inflexible spine is essential for jumping locomotion (Wassersug 1989a, 1997; Hoff et al. 1999; Hoff and Wassersug 2000). The tail is supported only by a flexible notochord and, except at the base, lacks caudal vertebrae. Most tadpoles have tails that are tapered and pointed at the end, in contrast to the blunt or expanded tails of fishes. This appears to be the optimum design for a tail that is flexible rather than stiff, because the smaller surface area at the end of the tail reduces drag (Wassersug 1989a). The tail fin itself is little more than a double layer of skin, which lacks skeletal support. It has properties that allow it to remain relatively stiff while the tadpole is swimming, but it also is quite fragile (Hoff and Wassersug 2000). Tadpoles often suffer injury to their tails fins from predators, but their fragile tail fins may enable tadpoles to escape by preventing predators from getting a grip on the tail musculature (P. Doherty, Wassersug, and Lee 1998).

The design of a tadpole's body appears to be less suitable for aquatic locomotion than that of a fish, but fluid-dynamic models of tadpole locomotion have shown that they are relatively efficient swimmers (H. Liu, Wassersug, and Kawachi 1996, 1997). When a tadpole swims, the tip of the snout moves from side to side (Wassersug and Hoff 1985; Hoff and Wassersug 1986). These oscillations are under active

muscular control and may help to generate thrust (Hoff and Wassersug 2000). This seemingly awkward mode of locomotion also may increase the efficiency of swimming for an animal with a tadpole-shaped body, because it breaks up the boundary layer of fluid around the body. In contrast, a fish-shaped animal forced to swim like a tadpole would experience a substantial increase in drag compared to an animal swimming like a fish (Wassersug 1997).

In contrast to urodele larvae, most anuran tadpoles lose their external gills soon after hatching, before they reach the free-swimming stage. In *Agalychnis callidryas,* which has a plastic hatching period, tadpoles that hatch early lose their external gills within a day of hatching, whereas embryos of the same age that remain in the eggs retain their gills (Warkentin 1999b). Presumably the added surface area of external gills is important for embryonic respiration (see chapter 4), but become a handicap for hatchlings because they tend to increase drag and reduce swimming efficiency (Warkentin 2000b). Hatched tadpoles have plenty of other avenues for gas exchange, including the skin, internal gills, and eventually, the lungs. The internal gills are enclosed in a branchial chamber, an arrangement that provides a hydrodynamic advantage by reducing drag (fig. 12.5).

Tadpoles also differ from urodele larvae in the pattern of forelimb emergence. Most tadpoles develop their front legs inside the atrial chambers that house the gills. This prevents the forelimbs from increasing drag forces as the tadpole swims. Eruption of the legs is delayed until just before metamorphosis, thereby minimizing the amount of time the tadpole spends in the water when it has become a much less efficient swimmer (Wassersug and Sperry 1977; Wassersug 1989a; Dudley, King, and Wassersug 1991). Although the hind limbs emerge before the forelimbs, they nevertheless appear relatively late in development. Just as forelimbs would impede locomotion, the presence of hind limbs would reduce the efficiency of swimming by increasing drag (Gal and Blake 1987; Dudley, King, and Wassersug 1991). If legs appeared early in a tadpole's development, the animal might be much more vulnerable to aquatic predators because of reduced swimming performance. The hydrodynamic cost of having back legs is minimized by their position near the junction of the round body and the flat tail. The globose shape of the tadpole makes this a region of relatively low water flow that is unlikely to be affected by small increases in drag forces. In some tadpoles, the small hind limbs are kept folded against the body early in development, thereby reducing the effects of drag. Later, as the legs grow, they are held out to the sides of the body, and the effects of drag increase (Wassersug 1997).

Changes in the size and shape of a tadpole's body during development and the emergence of limbs may require tadpoles to change their modes of locomotion, especially when attempting to escape from predators. Both burst swimming speed and evasiveness have been shown to increase survival of tadpoles exposed to natural predators (Watkins 1996; see chapter 14). In at least some species of tadpoles, burst swimming speed increases with increasing body size, thereby reducing vulnerability to predators in larger tadpoles (R. Wilson and Franklin 2000a). This advantage can be reduced, however, as hind limbs develop. For example, wood frog tadpoles (*Rana sylvatica*) are relatively poor swimmers when they are small, but swimming performance increases as they grow. Swimming performance declines as the hind limbs develop and even more so once the front legs have appeared (R. Brown and Taylor 1995). This reduces the capacity of older tadpoles to escape from predators by outswimming them. Older tadpoles, especially those with all four legs present, tend to make more turns when subjected to attacks by a simulated predator. Brown and Taylor (1995) interpreted this behavior as a way to compensate for reduced swimming performance by emphasizing maneuverability over speed when escaping from predators. However, maneuverability is a measure of an animal's ability to make its way around obstacles, not simply a measure of turning frequency (R. Wassersug, personal communication). Changes in maneuverability of tadpoles as a function of developmental stage have not been investigated, nor have there been any comparative studies of differences in maneuverability among species.

Functional Morphology of Feeding

Tadpoles are essentially eating machines, and require a specialized feeding apparatus to maintain a constant intake of food (Wassersug 1975). Despite some adaptive modifications (see the following "Ecological Morphology of Tadpoles"), the basic mechanism is similar in most species and involves pumping water and suspended organic material across structures that trap the food. Water is pumped into the oral cavity with a buccal pump consisting of paired ceratohyals and associated hypobranchial and ceratobranchial structures (fig. 12.6). The ceratohyals articulate medially with the hypobranchial plates, which in turn support the branchial baskets. They also articulate near their distal (lateral) end with the palatoquadrates. When the muscles attached to the distal ends of the ceratohyals contract, those ends are elevated, and the ceratohyals rotate around the articulations with the palatoquadrates (fig. 12.7). This depresses the medial ends of the ceratohyals and expands the buccal cavity (the anterior part of the oral cavity), thereby drawing water into the mouth. When the ceratohyals return to their original position, water is forced from the buccal cavity into the pharynx (the posterior part of the oral cavity) and eventually exits through the spiracle. In most tadpoles, back flow of water is prevented by cyclic opening and closing of the mouth and by a transverse flap in the mouth, the ventral velum, which serves as a one-way valve between the buccal cavity and the pharynx (Wassersug 1972, 1976, 1980; Wassersug and Hoff 1979; Wassersug and Rosenberg 1979).

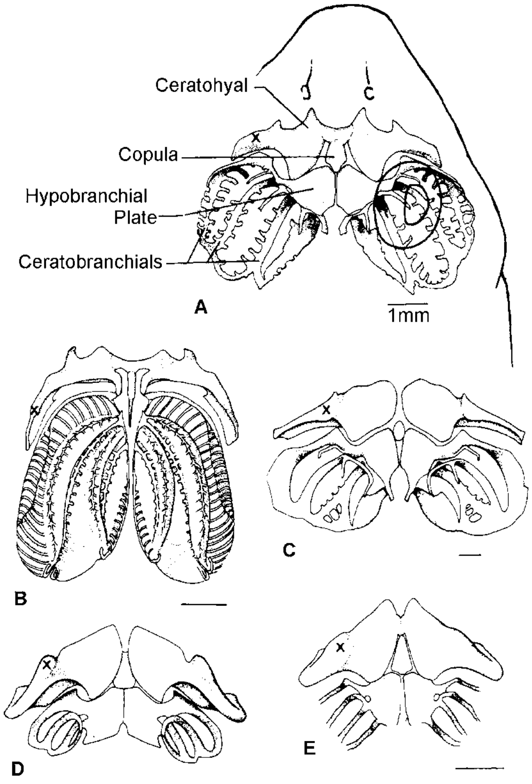

Fig. 12.6. Branchial skeletons of anuran tadpoles in dorsal view, showing elements of the buccal pump. The ceratohyals together make up the branchial basket that supports the gill filters. The "x" on each drawing indicates the point of articulation of the ceratohyal with the palatoquadrate bar (not shown). (A) *Rana pipiens* (Ranidae), a pond tadpole with a generalized diet. (B) *Gastrophryne carolinensis* (Microhylidae), an obligate midwater suspension-feeder with very large branchial baskets forming a fine seive. (C) *Heleophryne natalensis* (Heleophrynidae), a benthic tadpole that lives in rapidly flowing water. This tadpole has a suctorial mouth and grazes on periphyton attached to rocks. (D) *Anotheca spinosa* (Hylidae), an egg-eating tadpole that lives in bromeliads. The branchial baskets are reduced to short bars that intercept relatively large food particles. (E) *Hyla microcephala* (Hylidae), a pond tadpole that ingests large filamentous plant fragments and other large food particles. This species also has reduced branchial baskets typical of tadpoles with a macrophagous diet. After Wassersug and Hoff (1979).

As particles suspended in the water pass through the oral cavity, they are sorted by size. Large particles are channeled directly into the esophagus by papillae or ridges in the buccal cavity. Smaller particles pass into the pharynx, where they are entrapped in mucus secreted by the branchial food traps (fig. 12.6) or intercepted by gill filters born on the paired branchial baskets. The movements of cilia then transport cords of mucus and food particles into the esophagus (De Jongh 1968; Gradwell 1968, 1970, 1972a, b; Kenny 1969b, c; Wassersug 1972, 1975, 1980; Seale and Wassersug 1979; Wassersug and Hoff 1979; Wassersug and Rosenberg 1979; Seale, Hoff, and Wassersug 1982; Viertel 1982, 1984a, b, 1985, 1987, 1991; Inger 1985; Wassersug and Heyer 1988).

Although the pumping of water through the buccal cavity appears similar during irrigation of the gills for respiration and during feeding, these actions are not identical. Three muscles (hyoangularis, orbitohyoideus, and antrior interhyoideus) are involved in gill irrigation, but three additional muscles (intermandibularis, suspensorioangularis, and levator mandibulae longus superficialis) are used during feeding. These additional muscles are invoved in the opening and closing of the mouth (P. Larson and Reilly 2002). Tadpoles are unusual in that part of the neurocranium has been modified to function as an upper jaw, and this is powered by a set of muscles that in ancestral amphibians actually inserts on the lower jaw (Haas 2001). In addition, the lower jaw articulates with the condrocranium much farther forward than in other vertebrates, resulting in a feeding apparatus that is unique among tetrapods (Cannatella 1999; Haas 2001; P. Larson and Reilly 2002).

Ecological Morphology of Tadpoles

In contrast to the relatively minor variation in overall morphology of urodele larvae living in different habitats,

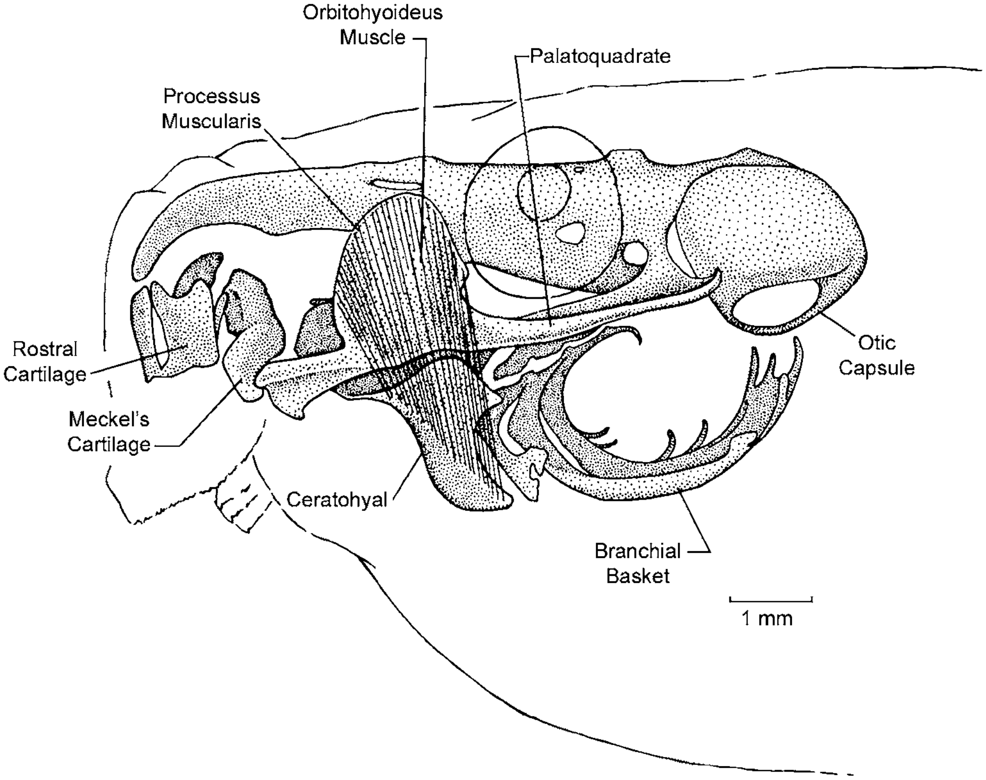

Fig. 12.7. Lateral view of the chondrocranium of a generalized pond tadpole (*Alytes obstetricans*). Contraction of the orbitohyoideus muscle causes the ceratohyal to rotate around its articulation with the palatoquadrate, thereby depressing the floor of the buccal cavity and drawing water into the mouth. Elevation of the buccal floor pushes water across the gill filters, located on the branchial baskets. After Wassersug and Hoff (1979).

anuran tadpoles exhibit a wide range of morphological variation that is correlated with differences in microhabitat use and feeding ecology. Most of this variation involves differences in the overall shape of the body, the size and shape of the tail fin, and the morphology of the oral disc, oral cavity, and branchial baskets. Many tadpoles have generalized body morphology and oral discs adapted for feeding on a variety of foods. These tend to be found mostly in ponds and quiet stream pools. Other species are specialized for particular habitats, such as streams, wet rocks, or bromeliads, or for particular types of food, such as microscopic algae, zooplankton, frog eggs, or other tadpoles. There also are tadpoles that do not feed at all, but complete development by drawing on stored energy in yolk reserves (Duellman and Trueb 1986). Some of these exhibit major morphological differences from aquatic tadpoles, whereas others do not (Candioti, Úbeda, and Lavilla 2005). Table 12.1 provides a summary of the major ecological types of tadpoles, based on the classification of Altig and Johnston (1989; see also Altig and McDiarmid 1999).

Despite the efforts of these authors to standardize the terminology used to describe ecological variation in tadpoles, there is some confusion in the literature. Some authors, such as Chou and Lin (1997), have adopted the classification of Altig and Johnston (1989). Others have used slightly different terminology. For example, Passmore and Carruthers (1995) distinguished "pelagic" from "nektonic" tadpoles, whereas Altig and Johnston (1989) used these terms as synonyms. Tadpoles of *Xenopus* were called "pelagic" by Van Dijk (1972), "nectonic filter-feeders" by Duellman and Trueb 1986, "suspension feeders" by Altig and Johnston (1989), and "nektonic" by Passmore and Carruthers (1995). Tadpoles of hylids and hyperoliids with laterally compressed bodies and wide tail fins, which live among dense vegetation, were called "pelagic/hydrophytophilic" by Van Dijk (1972) and "nektonic" by Altig and Johnston (1989). Duellman and Trueb (1986) simply treated them as a subset of pond-type tadpoles without giving them a specific name. Tadpoles that live in fast-flowing streams have been variously described as "rheophilic," "rhyacophilous," or "stream-adapted." Much of the confusion of terminology used to categorize tadpoles results from a lack of detailed behavioral and ecological information to support putative ecomorphological categories. Even the most detailed monographs on tadpoles usually include only brief ecological notes, mostly related to the types of sites where tadpoles

Table 12.1 Ecomorphological classification of anuran tadpoles

Tadpole type	Habitat and ecology	Morphology	Examples
I. Feeding tadpoles in nonflowing water (Lentic habitats)			
Benthic	Bottoms of ponds, either in shallow or deep water. Feed by rasping substrates or taking in particulate matter	Globular or somewhat flattened body. Eyes dorsal. Mouth ventral or anteroventral, with well-developed beak and tooth rows on oral disc. Tail fin not extending onto the body.	*Acris, Alytes;* some *Bufo, Colostethus, Dendrobates, Ptychadena, Rana, Smilisca*
Carnivorous	Ponds, especially temporary ponds	Similar to benthic tadpoles, but often with terminal mouth. Sometimes with enlarged mouth, beak, and jaw muscles (*Ceratophrys*) or enormous mouth with no oral disc (*Lepidobatrachus*). Some with no hard mouth parts, but with mouth that forms a tube for suction feeding (*Hymenochirus, Pipa carvalhoi*).	*Scaphiopus, Ceratophrys, Lechriodus, Lepidobatrachus, Hymenochirus, Pipa carvalhoi,* some *Hyla*
Macrophagous	Bottoms of ponds or in water column in vegetation	Body similar to other pond tadpoles. Oral disc small or absent, but large jaw sheathes present.	*Afrixalus, Cardioglossa, Occidozyga; Hyla leucophyllata, microcephala, parviceps* groups
Nektonic (Pelagic)	Live in open water of ponds, often moving through vegetation. Feed by scraping or rasping algae and other food off of rocks and other substrates	Body laterally compressed. Eyes lateral. Mouth anteroventral, with well-developed tooth rows on oral disc. Fins often high and sometimes extend onto body as far as head. Flagellum often present on tail tip.	Many *Hyla;* some *Scinax, Smilisca; Phyrnohyas, Trachycephalus*
Neustonic	Feed on organisms and organic matter in surface films of ponds	Similar in body form to other pond tadpoles, but with inverted, umbrella-like oral disc.	*Microhyla achatina*
Surface swimmer	Tadpoles swim near the surface of ponds and feed on floating vegetation, such as duckweed (*Lemna*). Can escape from predators by jumping out of water and skittering on surface	Body elongate, with top of head flat. Eyes large and lateral. Mouth terminal and small, bordered by flaplike labia with papillae. Serrated beak. Jaw muscles massive, but buccal muscles small. Long muscular tail with low dorsal fin, less-shallow ventral fin.	*Scarthyla ostinodactyla*
Suspension Feeder	Filter-feed on very small particles while hanging in water column	Flattened body with lateral eyes. Low tail fin with terminal flagellum often present. Hard mouth parts absent. Terminal mouth often small or slitlike. Barbels sometimes present at sides of mouth.	*Rhinophrynus, Silurana, Xenopus,* many microhylids (*Chiasmocleis, Ctenophryne, Gastrophryne, Hypopachus,* some *Microhyla, Phrynomerus*)
Suspension Rasper	Often feed on suspended particles in midwater, but also can rasp algae and other food from substrates. Often swim in head-up posture and form schools	Keratinized jaw sheathes and labial teeth present. Eyes lateral. Tail with wide fin and often with terminal flagellum.	Most *Agalychnis; Kassina, Pachymedusa,* most *Phyllomedusa*
Phytotelmonous	Tadpoles develop in water in bromeliads, tree holes, fallen logs, bamboo, seed pods, leaf axils, etc. May be carnivorous, obligate egg-eaters, or detritovores	Either elongate or short with stout body. Elongate tadpoles usually have thin tails with little or no tail fin. Mouth and oral cavity often specialized for feeding on large prey or frog eggs. Often obligate air-breathers with well developed lungs.	*Hoplophyrne, Anotheca, Hyla bromeliacia, Hyla zeteki, Osteocephalus oophagus, Osteopilus brunneus, Phrynohyas resinifictrix, Acxanthixalus, Nyctixalus;* some *Dendrobates, Mantidactylus*
II. Feeding tadpoles in flowing water (Lotic habitats)			
A. Tadpoles live in flowing portions of streams and rivers			
Clasping	Live in slow-flowing streams. Clasp substrate with oral disc and feed by rasping with labial teeth	Eyes small and dorsal. Oral disc usually large and ventral, with many marginal papillae. Muscular tail with low fin terminating at junction with body. Tail tip often rounded.	Some *Boophis; Natalobatrachus, Rana palmipes* and *R. pustulosa* groups

(*continued*)

Table 12.1 (continued)

Tadpole type	Habitat and ecology	Morphology	Examples
Adherent	Live in fast-flowing streams and rivers, sometimes in torrents. Maintain position with oral disc and feed by rasping substrates with labial teeth or catching food particles in current.	Often with very large oral discs with many marginal papillae and many labial tooth rows (*Plectrohyla, Ptychohyla*). Others have reduced or absent labial teeth and jaw sheathes that are not robust (*Hyla rufioculis, H. uranochroa, Taudactylus*). Belly sometimes flattened. Muscular tail with low fin and rounded tip.	Many *Hyla; Plectrohyla,* some *Ptychohyla,* some *Mantidactylus, Taudactylus*
Suctorial	Live in very fast-flowing streams and torrents. Cling to rocks with highly modified oral discs.	Large oral discs with many marginal papillae. In some species, fleshy flap forms extension of oral disc that enhances suction. Shape of body variable, but often flattened or with anterior end flattened. Muscular tail with low fin and rounded tip.	*Ascaphus, Bufo penangensis, B. torrenticola, Conraua, Heleophryne, Petropedetes, Scutiger, Trichobatrachus,* many hylids
Gastromyzophorous	Live in very fast-flowing streams and torrents. Cling to rocks with oral disc and belly sucker	Large belly sucker present, equipped with papillae or keratinized patches. Muscular tail with low fin, ending before junction with body. Tail rounded at tip.	*Amolops, Atelophryniscus, Atelopus,* some *Ansonia, Rana sauteri*
Psammonic	Lie buried in sandy bottoms of streams and feed on organisms in spaces between sand grains	Flattened body. Long, fanglike serrations in jaw that keep sand grains out of mouth. Long spiracular tube held with opening above sand layer in current. Oral disc reduced. Eyes dorsal.	*Otophryne robusta*
Semiterrestrial	Tadpoles live on wet rock faces, splash zones of waterfalls, and rivulets	Elongate, flattened body with dorsal eyes that are large and protuberant. Belly often flattened. Long thin tail with low find and sharp tip. Ventral mouth. Hind legs often develop early.	*Cycloramphus, Leptodactylus rugosus, Nannophrys ceylonensis, Rana beddomei, Thoropa, Werneria, Petropedetes*
B. Tadpoles live in still portions of streams and rivers			
Benthic	Bottoms of pools, either in shallow or deep water. Feed by rasping substrates or taking in particulate matter	Similar to generalized benthic pond tadpoles.	*Colostethus inguinalis, Hyla arenicolor,* some *Leptopelis, Oreolalax,* some *Rana, Strongylopus grayii*
Fossorial	Burrow into mud at bottom of stream pools or live in spaces between rocks	Thin, wormlike, flattened body. Long thin tail with low fin. Eyes dorsal. Small oral disc. Body often red from extensive cutaneous blood flow (in centrolenids).	Centrolenids, *Leptobrachium*
Nektonic (Pelagic)	Live in open water of pools	Similar to nektonic pond tadpoles, but with lower tail fins and less lateral eyes.	*Hyla miotympanum, Strongylopus fasciatus*
Neustonic	Feed on organisms in surface films of stream pools	Enlarged, umbrella-like oral disc oriented dorsally to funnel surface particles into mouth. Eyes lateral. Tail long with low fins.	*Colostethus flotator, Mantidactylus oviparus, Megophrys montana, Phyllomedusa guttata, P. jandaia*
III. Nonfeeding tadpoles develop in terrestrial nest or small body of water			
Nidicolous	Tadpoles hatch from eggs laid in moist terrestrial nests, tree holes, or bromeliads and complete development in nest without feeding, depending on yolk reserves. Aquatic microhabitats similar to those of feeding phytotelmonous tadpoles	Morphology variable, but often with tail fins, mouth parts, and pigment reduced. *Leiopelma hochstetteri, Mertensophryne,*	*Adenomera, Anodontohyla, Colostethus* (3 species), *Craspedoglossa, Eupsophus, Nectophrynoides malcomi, Paracophyla, Pelophryne, Philoria, Phrynodon, Platypelis, Plethodontohyla,* some *Rana, Syncope antenori, Synapturanus, Vanzolinius, Zachaenus*

Notes: Modified from Altig and Johnston (1989). Numbering system and order of tadpole types are different from those of Altig and Johnston.

were collected (e.g., Chou and Lin 1997). The behavior of tadpoles in the field is rarely described, and inferences have been drawn mostly from the morphology of the tadpoles.

Pond-Dwelling Tadpoles

Generalized pond tadpoles, which are found in most anuran families, typically have oval bodies with broad, muscular tails and wide tail fins. The mouth usually is oriented downward rather than forward. It is bordered by rows of papillae that may have a sensory function, may help to hold the mouth to the substrate, or both. The oral disc usually has several rows of keratinized labial teeth (denticles) used to anchor the oral disc and scrape algae and other organisms off of rocks and other substrates (Wassersug and Yamashita 2001). Usually there are horny jaw sheaths (often called a beak) as well, which are used to rasp food from substrates or bite through large or tough pieces of food (fig. 12.8). The branchial baskets are moderately well developed (fig. 12.6 A), with extensive gill filters and mucus-secreting areas on the food traps, which lie under the velum and above the gill filters. The buccal pump is well adapted for continuous pumping of water across the gills. Generalized pond tadpoles often have opportunistic feeding habits. They can extract phytoplankton and other suspended particles from the water column (Seale 1982a), but they also can feed on algae scraped off the substrate, on decaying animal matter, or on almost anything else that can be broken into small particles by the jaw sheaths and labial teeth. Some species become carnivorous and even cannibalistic under certain circumstances (see the following "Cannibalism and Morphological Polyphenism").

Benthic and Nektonic Tadpoles

Some pond tadpoles have become specialized for living in particular microhabitats or feeding on particular kinds of food. Many tadpoles are benthic in their habits, spending most of their time on the bottoms of ponds and relatively little time in the water column (table 12.1). These include tadpoles of many species in the families Bufonidae, Discoglossidae, Hylidae, Leptodactylidae, Megophryidae, Myobatrachidae, Pelobatidae, Ranidae, Rhacophoridae, and

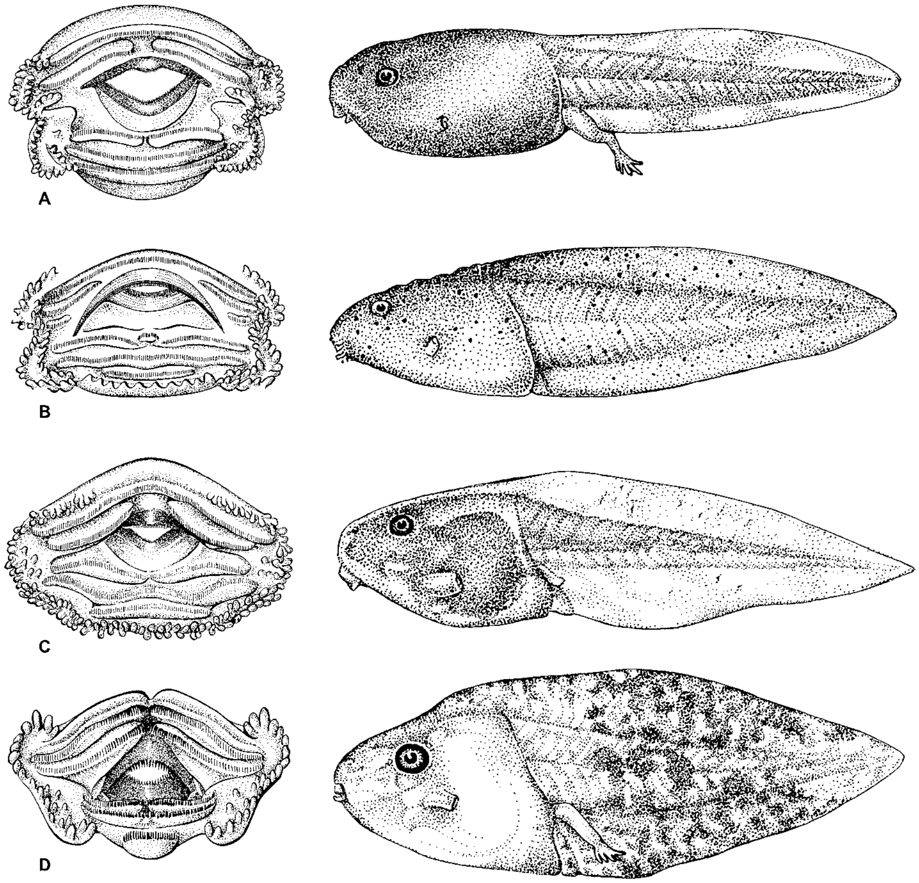

Fig. 12.8. Mouthparts and lateral views of pond tadpoles from several families. (A) *Bufo gargarizans* (Bufonidae). (B) *Rana catesbeiana* (Ranidae). (C) *Pseudacris clarkii* (Hylidae). (D) *Scinax boulengeri* (Hylidae). Drawings by Mary Jane Spring after C. Liu (1950; A), Stebbins (1951; B), David M. Dennis in Duellman (1970; C, D).

others (Wassersug 1980; Inger 1985; Wassersug and Heyer 1988). These tadpoles usually have the generalized morphology described previously. Other pond-dwelling tadpoles spend more time in the water column, often moving through patches of vegetation. These nektonic or pelagic tadpoles tend to have bodies that are more laterally compressed than those of benthic tadpoles, with the eyes on the sides of the head instead of the top. Nektonic tadpoles often have much taller tail fins than do benthic tadpoles, sometimes extending along the back all the way to the head (fig. 12.8 D). The tail usually tapers to a narrow point and may have a thin flagellum at the end, a structure that can move independently of the rest of the tail. Many tadpoles in the families Hylidae and Hyperoliidae have this type of morphology.

Midwater Suspension Feeders

Certain groups of pond-dwelling tadpoles are specialized for feeding in open water on very small particles, such as phytoplankton. These tadpoles typically are found in highly productive ponds in which the density of microscopic phytoplankton is sufficiently high to permit suspension feeding. Most pipid tadpoles (except *Hymenochirus*), tadpoles of the Mexican burrowing frog (*Rhinophrynus dorsalis*), and pond-dwelling microhylid tadpoles (fig. 12.9 B) lack keratinized structures on the oral disc and have become obligate suspension feeders. The morphology of the buccal pump allows large volumes of water to be drawn into the mouth and across the gills with each expansion and contraction of the buccal cavity. The branchial baskets are very large, with dense gill filters well adapted to extracting small particles from the water (fig. 12.6 B). The similarity in morphology and feeding styles in pipids and *Rhinophrynus* probably represents descent from a common ancestor, because these families are very closely related, despite striking differences in adult morphology (Ford and Cannatella 1993; Haas 2003). Midwater suspension feeding evolved independently in microhylids, which are among the most derived frogs and only distantly related to the other two families (Wassersug 1989b; Donnelly, De Sá, and Guyer 1990; Haas 2003). Tadpoles of hylid frogs in the subfamily Phyllomedusinae have hard jaw sheaths and labial teeth that are capable of scraping material from the substrate, but they often behave as midwater suspension feeders and have converged with the pipids and microhylids in the structure of the buccal pump (Wassersug and Hoff 1979). Altig and Johnston (1989) classified these tadpoles as suspension-raspers. Many of these midwater suspension feeders exhibit a strong tendency to form schools, probably as a means of protection against predators in areas that lack protected microhabitats (see the following "Social Behavior").

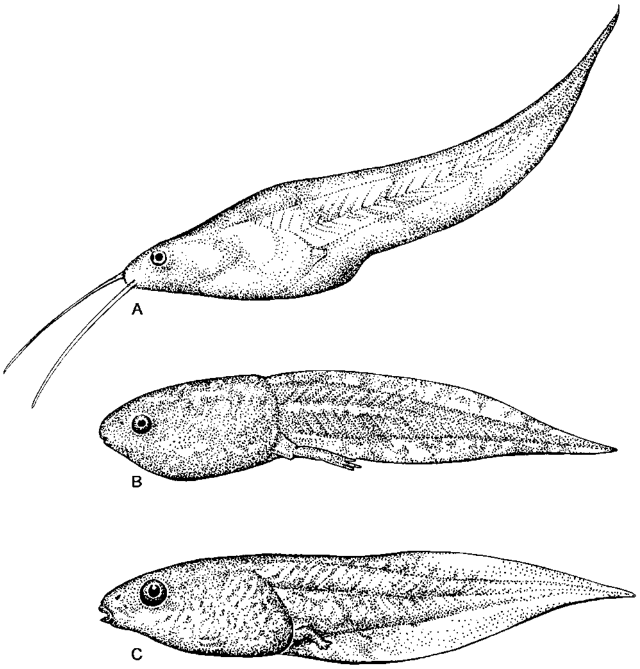

Fig. 12.9. Microphagous midwater suspension feeding tadpoles. (A) *Xenopus laevis* (Pipidae), showing typical head-down swimming posture. (B) *Kaloula rugifera* (Microhylidae). (C) *Agalychnis spurrelli* (Hylidae). (A) Drawing by Mary Jane Spring after Duellman and Trueb (1986). (B) After Liu (1950). (C) After David M. Dennis in Duellman (1970).

The morphology and ecology of suspension feeding have been studied in considerable detail in *Xenopus laevis,* which differs from most tadpoles in several respects (Wassersug 1996). *Xenopus* tadpoles spend most of their time feeding while suspended in the water column in a head-down position (fig. 12.9 A). They maintain this position by rapidly oscillating the tip of the tail (Hoff and Wassersug 1986). In contrast to most tadpoles, which have tail muscles composed entirely of relatively anaerobic white muscle fibers, *Xenopus* tadpoles have a band of red-muscle fibers outside the thicker white muscles (Muntz, Hornby, and Dalooi 1989). These more aerobic fibers have higher concentrations of mitochondria and lipids than do white fibers and are responsible for the continuous movements of the tip of the tail.

These tadpoles lack a ventral velum, the membrane that separates the buccal cavity from the pharyngeal cavity in most tadpoles. A one-way flow of water is made possible by valvelike action of the margins of the spiracle, which opens and closes as water is pumped into the mouth (Gradwell 1975). The combined buccopharyngeal cavity has a very large volume. *Xenopus* tadpoles take in much more water with each stroke of the buccal pump than do more generalized tadpoles of similar size (Seale 1982a). In most tadpoles, food trap areas that secrete mucus are found only in the pharynx, but in *Xenopus,* secretory ridges cover the whole floor of the buccopharyngeal cavity.

The modifications of the oral cavity make *Xenopus* tadpoles very efficient suspension feeders. They are capable of trapping extremely small food particles, some as small as viruses. They also can feed in water with particle concentrations that would be too low to allow more generalized tadpoles to extract sufficient energy by suspension feeding (Seale 1982a; Seale, Hoff, and Wassersug 1982; Viertel 1990, 1992). *Xenopus* tadpoles lack true gill filaments, but in well-oxygenated water, oxygen probably is taken up through the skin, the lining of the buccopharyngeal cavity, and the gill filters. The gill filters can become clogged with food when particle concentrations are high, thereby reducing surface area for respiration. The problem of maintaining aquatic respiration when food intake rates are high favors the early development of lungs and aerial breathing, and these tadpoles are obligate air-breathers during much of their development (M. Feder and Wassersug 1984; Feder et al. 1984; Pronych and Wassersug 1994; Orlando and Pinder 1995).

Surface Feeders

A few species of pond-dwelling tadpoles have unusual modes of feeding, some of which also are found in tadpoles that inhabit quiet pools in streams (see the following "Stream Tadpoles"). The tadpoles of several microhylid frogs from Southeast Asia, including *Microhyla achatina, M. borneensis,* and *M. heymonsi,* have inverted, umbrella-like oral discs that are held at the water's surface and used to capture microorganisms and organic material from the surface film (Altig and Johnston 1989; T. Leong and Chou 1999). These have been termed neustonic tadpoles (the neuston comprises the organisms found in surface films). Similar adaptations are found in tadpoles of some species of *Phyllomedusa* (Duellman and Trueb 1986) and in some stream-dwelling tadpoles (see the following). Another peculiar tadpole is that of an Amazonian hylid, *Scarthyla ostinodactyla* (Duellman and de Sá 1988). This tadpole has an elongate, somewhat flattened body with a very low dorsal fin and a muscular tail (fig. 12.10). It has powerful jaw muscles and an impressive serrated jaw sheath that probably is used to cut pieces of floating plants. It swims just below the surface and apparently feeds on surface vegetation such as duckweed (*Lemna*). It also has an unusual way of escaping from predators—it can use its muscular tail to jump out of the water and skitter across the surface very rapidly.

Fig. 12.10. Tadpole of *Scarthyla ostinodactyla* (Hylidae). This tadpole swims just below the water surface and feeds on duckweed (Lemna) and other surface vegetation. The muscular tail is used to jump out of the water and skitter across the surface to escape from predators. From Duellman and de Sá (1988).

Macrophagous Tadpoles

Some pond-dwelling tadpoles are adapted for feeding on large food particles and are termed *macrophagous* tadpoles (Duellman and Trueb 1986; Altig and Johnston 1989). The buccal cavity often is relatively large, enabling the tadpole to ingest large food items. The buccal pump is capable of generating strong suction for capturing food particles, but usually is not adapted for continuously pumping large volumes of water across the gills (Wassersug and Hoff 1979). Branchial baskets, gill filters, and branchial food traps are reduced and incapable of capturing small particles. Macrophagous feeding appears to be a derived trait in several anuran families, having evolved independently many times (Sokol 1975; Wassersug and Hoff 1979; Wassersug 1980).

Like most tadpoles, many macrophagous species are herbivorous. For example, Neotropical hylids such as *Hyla microcephala, H. phlebodes, H. ebraccata,* and other members of the *H. microcephala* and *H. leucophyllata* species groups apparently feed mainly on filamentous algae (Duellman and Trueb 1986; Duellman 2001), although *H. microcephala* tadpoles sometimes feed on small invertebrates as well (R. Wassersug, personal communication). These tadpoles have large ceratohyals and relatively large buccal cavities for dealing with large food particles, but the ceratobranchials and associated filter apparatus are reduced (fig. 12.6 E; Wassersug and Hoff 1979; Wassersug 1980). These species have rather simple mouths with strong horny jaw sheaths for breaking up filaments of algae (fig. 12.11). Macrophagous tadpoles can be either benthic or nektonic in their habits, and thus overlap in ecology with species that have more generalized diets. An example of a benthic macrophagous tadpole is that of *Occidozyga lima,* which has a flattened body and reduced tail fins, especially the ventral fin. In contrast, nektonic macrophagous tadpoles, like that of *Hyla microcephala,* have rounder bodies and much higher tail fins (fig. 12.11 A).

Carnivorous Tadpoles

Although the vast majority of tadpole species are entirely or primarily herbivorous, some pond tadpoles also feed on animal matter. Some of these can be considered macrophagous tadpoles that have morphological specializations for feeding on large food items, but others are generalized pond tadpoles that exhibit few adaptations for a macrophagous diet. For example, green frog (*Rana clamitans*) tadpoles, which are quintessential generalized pond tadpoles, are voracious predators on the eggs of wood frogs (*Rana sylvatica;* Petranka and Kennedy 1999). Tadpoles of the Neotropical frog *Leptodactylus pentadactylus* feed on algae scraped from the substrate (Vinton 1951), but they also can be major predators on the eggs and larvae of other anurans (Heyer, McDiarmid, and Weigmann 1975; Wells 1979).

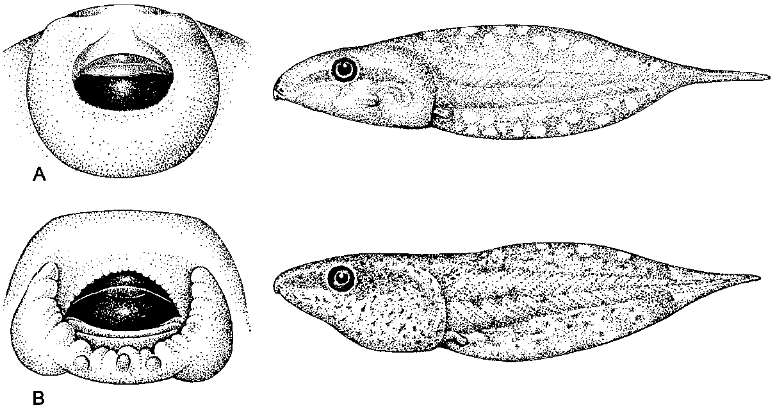

Fig. 12.11. Mouthparts and lateral views of pond tadpoles that feed mainly on filamentous algae. (A) *Hyla microcephala.* (B) *Hyla ebraccata.* Drawings by Mary Jane Spring after David M. Dennis in Duellman (1970).

Both the external mouthparts and internal oral structures of this species lack obvious specialization for a carnivorous diet and are characteristic of generalized pond-dwelling tadpoles (Wassersug and Heyer 1988). A variety of other generalized tadpoles in the tropics are opportunistic predators on the eggs or larvae of other species (Hero and Galatti 1990; Magnusson and Hero 1991; Silva, Giaretta, and Facure 2005), as are tadpoles of various species of *Bufo, Rana, Pelobates,* and *Pelodytes* (Heusser 1970; Banks and Beebee 1987b; Tejedo 1991; see chapter 14). Opportunistic carnivores sometimes are cannibalistic, consuming eggs, larvae, or transforming individuals of their own species (see the following "Cannibalism and Morphological Polyphenism"). Tadpoles of *Bufo crucifer* in Brazil ate crustacean eggs, although they did so only when feeding in aggregations, and the eggs did not make up a large proportion of the diet (Eterovick 2000).

Specialized macrophagous carnivores include tadpoles of the Neotropical genus *Ceratophrys,* which are active predators with large heads and massive, serrated jaw sheaths (Fernandez and Fernandez 1921; Noble 1931; La Marca 1986; fig. 12.12). The digestive tract of this species is shorter than those of most herbivorous tadpoles, but it is not known whether the anterior portion of the digestive tract functions like a true stomach or produces pepsin and other enzymes that digest protein (Fry and Kaltenbach 1999). Asian and African ranids in the genus *Hoplobatrachus* also are specialized carnivores that readily prey on eggs and tadpoles of other species or on conspecifics. They have massive serrated jaw sheaths similar to that of *Ceratophrys,* as well as needle-like labial teeth. The branchial baskets and gill filters are reduced in size, and the esophageal opening is very large (Chou and Lin 1997; Grosjean, Vences, and Dubois 2004).

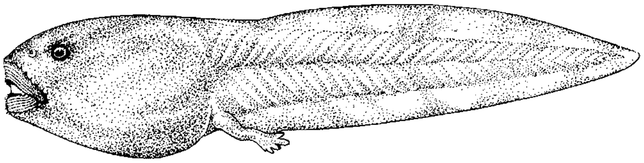

Fig. 12.12. A carnivorous, macrophagous tadpole (*Ceratophrys dorsata*) (Leptodactylidae). The well-developed rows of labial denticles are used to rasp flesh from tadpoles and other prey. Drawing by Mary Jane Spring after Noble (1931).

Tadpoles of South American frogs in the genus *Lepidobatrachus,* which is closely realted to *Ceratophrys* (Haas 2003), have enormous heads, wide mouths, and large buccal cavities for ingesting large prey, but lack hard mouthparts for tearing their food. They feed mainly on small invertebrates and tadpoles that are swallowed whole and sometimes are cannibalistic (Cei, 1968; Wassersug and Hoff 1979). Many features of their anatomy are unusual for tadpoles. The stomach is more clearly differentiated from the intestine and the gut is much shorter than in typical tadpoles. The stomach begins to produce pepsin as soon as the tadpoles begin to feed (E. Carroll, Seneviratne, and Ruibal 1991). Many features of the oral apparatus and digestive tract in these tadpoles appear to be more like those of adult frogs than of tadpoles, features that are correlated with their adultlike diet. These frogs breed in ephemeral pools that often dry up quickly. Larval development is accelerated, with some tadpoles leaving the water in only 20 days (Ruibal and Thomas 1988).

The African pipid frog *Hymenochirus boettgeri* has an unusual tadpole adapted for feeding on small invertebrates. Like all pipids, these tadpoles lack keratinized mouthparts. The front of the mouth is modified to form an oral tube when the jaws are depressed, quite unlike the mouths of *Xenopus* tadpoles (fig. 12.13). The ceratohyals are greatly enlarged, but the ceratobranchials are much reduced and lack any trace of a filter apparatus. There is a common buc-

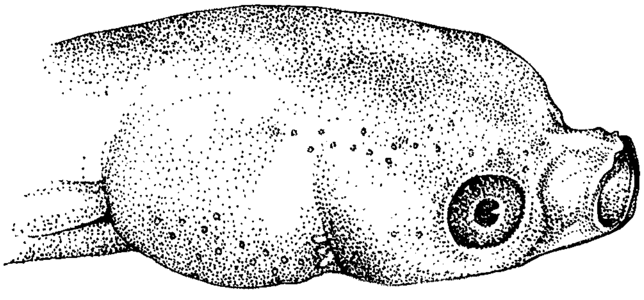

Fig. 12.13. The carnivorous tadpole of *Hymenochirus boettgeri* (Pipidae) with a mouth modified into a feeding tube for sucking in zooplankton. Drawing by Mary Jane Spring after O. Sokol (1962).

copharyngeal chamber, and the effective buccal volume is large, allowing the tadpole to ingest large prey whole (Sokol 1962; Ueck 1967; Wassersug and Hoff 1979). The tadpoles actively pursue small invertebrates and suck them into the mouth by rapidly expanding the buccal cavity. The pumping mechanism is similar to that of a microphagous filter feeder, such as *Xenopus,* and clearly is derived from it. The tadpole does not maintain a constant current of water through the buccopharyngeal cavity, but instead pumps water only when a prey animal is encountered. The narrow oral tube apparently serves to accelerate the flow of water into the mouth by constricting it into a small space, while the round opening enhances suction feeding by ensuring even acceleration around the edges of the mouth (Sokol 1962; Deban and Olson 2002).

Cannibalism and Morphological Polyphenism

Generalized pond tadpoles that normally eat plant material or detritus sometimes kill and eat conspecific eggs or tadpoles (see also chapter 14). There are field observations of cannibalism of either eggs or larvae in *Hymenochirus boettgeri* (Sokal 1962), *Rhinophrynus dorsalis* (Starrett 1960), *Lechriodus fletcheri* (J. Moore 1961), *Ceratophrys* (Cei 1980), *Leptodactylus* (Hero and Galatti1990; Magnusson and Hero 1991; Silva, Giaretta, and Facure 2005), *Rana temporaria* (Heusser 1970, 1971b), *R. sylvatica* (Petranka and Thomas 1995), *Euphlyctis cyanophlyctis* (McCann 1932), *Hoplobatrachus* (McCann 1932, Grosjean, Vences, and Dubois 2004), *Hyla pseudopuma* (Crump 1983), and *Spea* and *Scaphiopus* (S. Ball 1936; Bragg 1957a, 1964, 1965; Pomeroy 1981). There are observations of cannibalism in the laboratory for several other species (M. Simon 1984). Opportunistic cannibalism often is associated with reproduction in ephemeral pools, where food can be scarce, and drying of pools places a premium on rapid development (M. Simon 1984; Polis and Myers 1985; Crump 1992; see also Heusser 1970, 1971b; Kluge 1981; Crump 1983, 1986b; Petranka and Thomas 1995). Usually cannibalistic tadpoles prey on smaller conspecifics, but in some species, tadpoles prey on metamorphosing individuals, especially when the latter have developed all of their legs but have not yet lost their tails. This type of cannibalism has been observed in a Neotropical hylid, *Osteopilus septentrionalis* (Crump 1986b) and in several species of spadefoot toads (*Scaphiopus* and *Spea;* Ball 1936; Bragg 1957a, 1964, 1965; Pomeroy 1981).

Some spadefoot toads in the genus *Spea* also exhibit diet-induced changes in morphology and feeding habits. In three species, *S. bombifrons, S. intermontana,* and *S. multiplicata,* tadpoles exhibit two distinct phenotypes (fig. 12.14). Most individuals are generalized omnivores that feed mainly on organic detritus on the bottoms of temporary desert rain pools. Others develop into carnivores, with enlarged jaw musculature and heavy, serrated jaw sheaths for attacking prey (Bragg 1946, 1956, 1957a, 1962, 1964, 1965; Bragg and Bragg 1959; Pomeroy 1981).

This type of polyphenism has been studied in considerable detail in *Spea multiplicata* (D. Pfennig 1990a, 1992a, b; D. Pfennig, Mabry, and Orange 1991; D. Pfennig and Frankino 1997). In contrast to the situation observed in some species of *Ambystoma,* a high density of conspecifics in the pond is not the main trigger that induces the carnivorous morph in spadefoot toads. Instead, the carnivorous morph develops in response to high densities of tiny freshwater shrimp that are found in ephemeral desert pools. Frequencies of carnivorous tadpoles are correlated with shrimp densities in natural pools, and shrimp density, in turn, is negatively correlated with pond persistence (D. Pfennig 1990a). Feeding shrimp to omnivorous tadpoles induces development of these morphs (D. Pfennig 1992b). The precise physiological mechanism that induces the carnivorous morph is not clear, but it does not appear to be due to increased intake of thyroid hormones in the prey (Storz 2004). In at least some species, the morphology of the tadpoles is reversible; carnivorous tadpoles given only a diet typical of omnivorous tadpoles quickly revert to the omnivore phenotype. The carnivorous tadpoles feed mostly on shrimp, but some-

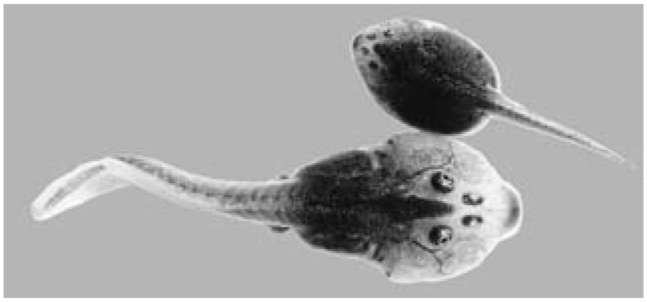

Fig. 12.14. Omnivorous (top) and carnivorous (bottom) morphs of the tadpoles of *Spea bombifrons.* Photo by David Pfennig.

times take other species of tadpoles or conspecifics as well. Thus, they tend to be more opportunistic cannibals than are the cannibalistic morphs in *Ambystoma.* Tadpoles of the carnivorous morph are much more likely to eat conspecifics than are typical morph tadpoles (D. Pfennig and Frankino 1997). Both the behavior of carnivorous tadpoles and the initial development of the carnivore phenotype are mediated by kinship relationships among individuals in a pond (see "Kin Recognition and Cannibalism in Tadpoles" in a later section).

The development and ecology of carnivorous morphs also is influenced by interactions among species. Tadpoles of *Spea bombifrons* are more effective predators on shrimp than are tadpoles of *S. multiplicata,* whereas *S. multiplicata* tadpoles are superior competitors when feeding on detritus. When both species are present in the same pond, tadpoles of *S. bombifrons* are more likely to become carnivorous than when that species is found alone. Conversely, tadpoles of *S. multiplicata* are less likely to become carnivorous in the presence of *S. bombifrons* than in single-species ponds (D. Pfennig and Murphy 2000). Across a range of natural ponds with different densities of the two species, *S. multiplicata* tadpoles were increasingly omnivore-like as the abundance of *S. bombifrons* increased, whereas *S. bombifrons* tadpoles became increasingly carnivore-like as the density of *S. multiplicata* increased. Similar results were obtained when the tadpoles were reared in the laboratory with different numbers of heterospecific tadpoles (D. Pfennig and Murphy 2002).

The adaptive significance of this type of phenotypic plasticity appears to be the same as in cannibalistic *Ambystoma.* Carnivores grow faster and metamorphose earlier, an advantage in pools that dry out quickly. Omnivores, on the other hand, do better in longer lasting ponds, because they reach metamorphosis with larger fat reserves (D. Pfennig 1992a). In *Spea multiplicata,* age and size at metamorphosis are negatively correlated, the reverse of the pattern seen in most anurans (see chapter 13). This is largely because the highest quality food used by these tadpoles, small shrimp, is rapidly depleted. When the first tadpoles begin to metamorphose, the remaining individuals do not enjoy a release from food competition that often occurs in species that feed on algae or bacteria, which continue to increase in abundance over time (e.g., R. Newman 1989). Consequently, late-metamorphosing individuals actually are smaller than are those that leave the pond early (D. Pfennig, Mabry, and Orange 1991).

Phytotelmonous Tadpoles

Some tadpoles live in water that accumulates in bromeliads, leaf axils, tree holes, hollow logs, seedpods, and other plant parts (Lehtinen 2004). Some of these tadpoles hatch from eggs deposited in these small pools (see chapter 10), but in dendrobatid frogs and some hemiphractine hylids (*Flectonotus*), a parent carries tadpoles to these sites (see chapter 11). These phytotelmonous tadpoles (*phyto* [G.] = plant; *telma* [G.] = pool) have a variety of feeding habits. Some do not feed at all (see the following "Nonfeeding Tadpoles"). Others feed on organic detritus that collects in the water, or they may prey on small invertebrates such as mosquito larvae, and even on conspecific tadpoles (K. Summers 1990; Caldwell 1993; Caldwell and de Araújo 1998). Still others feed opportunistically or entirely on anuran eggs deposited in the same body of water. The South American hylid *Trachycephalus resinifictrix,* which breeds in tree holes, appears to be an opportunistic egg-eater (Schiesari, Grillitsch, and Vogl 1996), as are some species of *Dendrobates* tadpoles (Weygoldt 1987).

Specialized egg-eaters include Neotropical hylids such as *Anotheca spinosa, Osteopilus brunneus, Osteocephalus oophagus,* and *Hyla zeteki* (Dunn 1926a, 1937; E. Taylor 1954; Duellman 1970; Lannoo, Townsend, and Wassersug 1987; Jungfer and Schiesari 1995; Jungfer 1996; Schiesari, Grillitsch, and Vogl 1996; Thompson 1996). Tadpoles of the African microhylid *Hoplophryne uluguruensis,* several Asian rhacophorids (*Chirixalus eiffingeri, Philautus, Theloderma*), and several species of *Dendrobates* also feed largely or exclusively on frog eggs (Noble 1929a; Wassersug, Frogner, and Inger 1981; Ueda 1986; Weygoldt 1987; Kam, Chuang, and Yen 1996). In the case of *Osteopilus brunneus, Osteocephalus oophagus, Anotheca spinosa, Chirixalus eiffingeri,* and some *Dendrobates,* the mother provides the tadpoles with trophic eggs (see chapter 11 for further discussion of this form of parental care). In *Chirixalus eiifingeri,* tadpoles compete with one another in their bamboo pools, and may scavenge dead tadpoles, but they do not cannibalize living tadpoles and appear to be entirely dependent on eggs provided by the mother (Y. Chen et al., 2001; Kam et al. 2001).

Egg-eating tadpoles typically have terminal mouths with large jaw sheaths but reduced labial teeth, relatively large heads, and large buccal cavities (fig. 12.15). Structures associated with a microphagous diet often are reduced (fig. 12.6 D), although this is not true for some egg-eating dendrobatid tadpoles (Weygoldt1987; Caldwell and de Araújo 1998). Tadpoles of *Osteopilus brunneus* do not maintain a continuous flow of water through the buccopharyngeal cavity, but suck food in as it is encountered. Consequently, there is not a continuous stream of moving water to aerate the gills. The lack of gill aeration, together with the low levels of oxygen in water-filled bromeliads, makes aerial respiration obligatory for these tadpoles (Lannoo, Townsend, and Wassersug 1987).

(A) *Anotheca spinosa.* (B) *Hyla zeteki.* These species are not closely related, but have converged in the evolution of diet and morphology. Drawings by Mary Jane Spring after David M. Dennis in Duellman (1970).

Stream Tadpoles

In areas where ponds and other bodies of standing water are scarce, such as mountainous regions, streams and rivers provide the principal breeding habitats for aquatic-breeding frogs. Streams offer a variety of microhabitats for tadpoles, from deep, quiet pools that are not very different from small ponds, to rapidly flowing riffles and torrents. Different species of stream-dwelling tadpoles have evolved morphological and behavioral adaptations for particular stream microhabitats and often are precluded from living in other microhabitats (Inger, Voris, and Frogner 1986; S. Richards 2002). Indeed, tadpoles living in different stream microhabitats display much greater morphological diversity than do pond-dwelling tadpoles, and tadpoles in different families often exhibit striking convergence in overall morphology and feeding structures (Lamotte and Lescure 1989a, b; Haas and Richards 1998). Some stream tadpoles are fossorial, spending most of their lives buried in gravel, sand, or mud at the bottom of streams. Fossorial life probably is not possible for most pond-dwelling tadpoles, especially those living in warm climates, because of the lack of oxygen on the bottoms of many ponds (see chapter 4).

Benthic, Nektonic, and Neustonic Stream Tadpoles

Many stream tadpoles are confined to relatively quiet pools and backwater areas, where they are not exposed to the direct action of flowing water. These tadpoles resemble pond-dwelling tadpoles in their morphology and exhibit only minor adaptations to stream habitats. For example, various species of *Rana* in the southwestern United States can be found in stream pools, while others are found mostly in ponds. Tadpoles that live in streams tend to have slightly thicker, more muscular tails and thicker tail fins than do those found in ponds, but otherwise are similar to pond-type tadpoles (Hillis 1982; N. Scott and Jennings 1985; Jennings and Scott 1993). Pond-dwelling ranids sometimes breed in quiet pools of streams, and their tadpoles sometimes exhibit minor variation in body shape and tail morphology, but it is not clear whether such differences have a genetic basis or are due to phenotypic plasticity (Jennings and Scott 1993). Some stream-dwelling ranids in other regions, such as *Rana angolensis* in Africa, *Limnonectes blythii* and its relatives in Borneo and Southeast Asia, and the Neotropical species *Rana palmipes,* have benthic tadpoles that are not much different from pond-dwelling species (Inger 1985; Altig and Johnston 1989; T. Leong and Chou 1999).

Benthic ranid stream tadpoles tend to have generalized feeding habits. They can grow even when feeding on relatively nutrient-poor stream sediments (Flecker, Feifarek, and Taylor 1999), but do better when feeding on more nutritious food, such as diatoms that grow on filamentous algae (Kupferberg, Marks, and Power 1994; Kupferberg 1997a, b). Benthic stream tadpoles can have a major effect on total community structure. Their feeding activities remove significant quantities of diatoms or sediments that tend to inhibit the growth of filamentous algae, and they can have a negative effect on grazing invertebrates that feed on diatoms (Kupferberg 1997a; Flecker, Feifarek, and Taylor 1999).

In addition to ranids, many other anurans have benthic tadpoles that live on the bottoms of quiet stream pools. These include some bufonids (*Bufo asper, B. fastidiosus*), dendrobatids (*Colostethus pamamensis*), hylids (*Hyla arenicolor, Pseudacris regilla*), hyperoliids (*Leptopelis*), leptodactylids (*Alsodes, Telmatobius*), megophryids (*Leptobrachium, Ore-*

olalax), myobatrachids (*Mixophyes*), rhacophorids (*Polypedates colletti, Rhacophorus gauni*), and others (Inger 1985; Wassersug and Heyer 1988; Altig and Johnston 1989; Zhao et al. 1994; Lips and Krempels 1995; T. Leong and Chou 1999). Most of these tadpoles are very similar to benthic pond-dwelling tadpoles, but may have somewhat more flattened bodies and shallower tail fins.

Tadpoles that live in open water are less common in streams than in ponds, probably because submerged vegetation and other sources of food are scarce in these habitats. Tadpoles of some South African stream frogs in the genus *Rana* (sometimes placed in the genus *Strongylopus*) are nektonic, or intermediate between nektonic and benthic (Altig and Johnston 1989; Passmore and Carruthers 1995), as are tadpoles of the *Hyla miotympanum* group from Central America (Duellman 1970). These tadpoles lack the very high tail fins of nektonic pond tadpoles (Altig and Johnston 1989).

Midwater suspension feeders usually are not found in streams, although Neotropical frogs such as *Agalychnis callidryas* sometimes place their eggs over quiet pools in streams and their tadpoles subsequently develop in those pools. Some stream-dwellers are neustonic feeders. These include several species of *Colostethus* that have funnel-shaped mouths that are oriented upward. Presumably these tadpoles feed either on organisms in the surface film, or perhaps from the undersides of rocks (fig. 12.16 B). Several megophryid frogs in the genus *Megophrys* and *Ophryophryne* from Asia have very peculiar mouthparts adapted to feeding on surface films. The mouth has wide lips forming an upturned funnel (fig. 12.16 C). There are very few labial teeth and no horny jaw sheaths. The tadpoles are found in pools under cascades in small mountain streams, suspended from the surface by the funnel mouth, with the opening directed into the current to catch floating particles (M. A. Smith 1926; Liu 1950; Inger 1985, 1986; Nodzenski, Wassersug, and Inger 1989; T. Leong and Chou 2000; Grosjean 2003).

Fossorial and Psammonic Tadpoles

Centrolenid tadpoles have a very different set of adaptations for stream life. They have elongated bodies with muscular tails and reduced tail fins (fig. 12.17 A). They burrow into gravel or under leaves in streams, and also have been observed burrowed in mud or wet leaves some distance from flowing water. These tadpoles have poorly developed eyes until just before metamorphosis and lack extensive pigmentation in the skin, features that are consistent with their fossorial habits (Villa and Valerio 1982; Mijares-Urrutia 1990; Jaramillo et al. 1997). They often appear to be bright red because of the extensive blood flow through the skin, which may facilitate cutaneous gas exchange.

The tadpoles of some Asian megophryid frogs of the genera *Leptobrachium, Leptobrachella,* and *Leptolalax* also are fossorial (Altig and Johnston 1989). These tadpoles have elongated bodies that are superficially similar to those of centrolenid frogs fig. 12.17 B). They spend most of their time in the spaces between rocks and gravel in quiet stream pools (Liu 1950; Inger 1966, 1985; Inger, Voris, and Frogner 1986). Tadpoles of some species in these genera are more robust

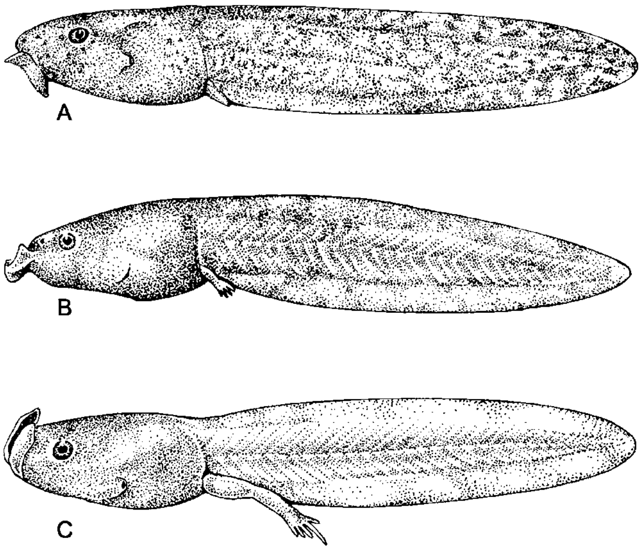

Fig. 12.16. Stream tadpoles with funnel mouths. (A) *Duellmanohyla rufioculis* (Hylidae), which is adapted for feeding on the bottoms of quiet pools. (B) *Colostethus nubicola* (Dendrobatidae), with an upturned funnel for feeding from the undersides of rocks, (C) *Megophrys minor* (Megophryidae), with an upturned funnel for feeding from the water's surface. (A) Drawing by Mary Jane Spring after David M. Dennis in Duellman (1970). (B) After Duellman and Trueb (1986). (C) After C. Liu (1950).

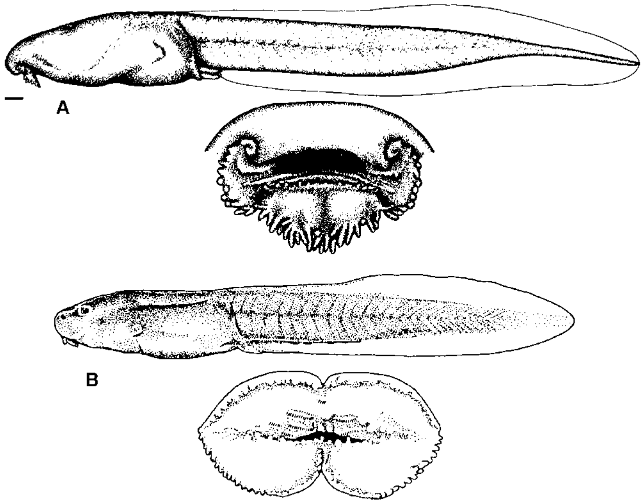

Fig. 12.17. Two fossorial tadpoles, showing convergent evolution in body and tail morphology. (A) *Hyalinobatrachium uranoscopum* (Centrolenidae). (B) *Leptolalax gracilis* (Rhacophoridae). (A) After Heyer (1985), and (B) after Lamotte and Lescure (1989a).

and live in more open habitats, such as the bottoms of quiet pools. One fossorial species, *Leptolalax gracilis,* has a relatively smaller gut and liver than do more generalized tadpoles, probably because of space constraints imposed by their elongate body form. These tadpoles also develop lungs relatively late. This not only alleviates the space constraints for internal organs, but also keeps the tadpoles negatively buoyant (Nodzenski, Wassersug, and Inger 1989).

One of the most bizarre of all tadpoles is that of the South American microhylid *Otophryne pyburni.* The tadpole was first described as that of *O. robusta* by Pyburn (1980b), but the population that he studied is now considered to be *O. pyburni* (J. A. Campbell and Clarke 1998). This tadpole has sharp, needlelike teeth on both the upper and lower jaws (fig. 12.18). Pyburn (1980b) thought the teeth indicated a carnivorous diet, but subsequent work showed this to be incorrect. In fact, these tadpoles appear to be specialized for burrowing into the sandy bottoms of streams, where they are passive filter feeders on organic material in the sand. The teeth appear to be adaptations for preventing sand grains from entering the mouth (Wassersug and Pyburn 1987). The fossorial tadpoles of a centrolenid frog, *Hyalinobatrachium ignioculus,* have somewhat similar serrations on the jaw sheaths, but the function of these structures is not known (Noonan and Bonett 2003). Another unusual feature of the *Otophryne* tadpole is an unusually long spiracle tube (fig. 12.19). Wassersug and Pyburn (1987) speculated that the opening of the tube is held above the sand surface when the tadpole is buried (fig. 12.19 B). Currents passing by the opening would draw water out of the tube, thereby allowing for passive movement of water into the mouth without active pumping. These were called psammonic tadpoles by Altig and Johnston (1989; *psamm* [G.] = sand).

Tadpoles Adapted to Fast-Flowing Water

Tadpoles in several families are associated with rapidly flowing streams or torrents. In such habitats, both suspended plankton and larger organic particles are rare, and tadpoles often depend primarily on food attached to the substrate. They face the dual problem of maintaining a position in the current and removing algae that is tightly attached to rocks

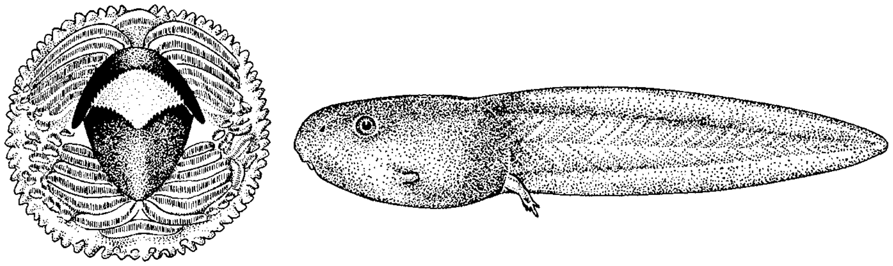

Fig. 12.20. Mouthparts and lateral view of *Oreolalax popei* (Microhylidae), a Chinese stream tadpole with a partially carnivorous diet. Drawing by Mary Jane Spring after C. Liu (1950).

(Lamotte and Lescure 1989a, b; S. Richards 2002). Tadpoles that live in rapid currents typically have elongated or flattened bodies, muscular tails, and reduced tail fins. The elongated body places constraints on the development of the feeding apparatus. These species generally have relatively small heads, which precludes having large buccal cavities and macrophagous feeding habits (Wassersug and Hoff 1979). However, some species are predatory. For example, Chinese megophryids of the genus *Oreolalax* live in mountain streams and eat insect larvae and tadpoles in addition to algae; they have powerful, serrated jaws for capturing prey (fig. 12.20).

Many stream-dwelling tadpoles have evolved special morphological adaptations for adhering to rocks, either with enlarged mouthparts and sucking discs, or suction discs on the belly. Altig and Johnston (1989) and Altig and McDiarmid (1999) classified tadpoles that cling to rocks with their mouthparts into several subcategories, including clasping, adherent, and suctorial forms (see table 12.1). These categories reflect apparent differences in the ability of tadpoles to cling to rocks in increasingly fast currents, determined mainly from observed differences in morphology. These categories tend to grade into one another, however, so that even relatively closely related species in the genus *Hyla* may fall into different categories (Duellman 1970).

Tadpoles that live in slow-moving currents may clasp rocks or other substrates and often have somewhat enlarged oral discs. They maintain their position in the current mostly by swimming with their muscular tails. These clasping tadpoles include some petropedetids, such as the South African kloof frog (*Natalobatrachus bonebergi*). Some mantellid treefrogs from Madagascar in the genus *Boophis* also have clasping tadpoles (other tadpoles in this genus live in ponds or quiet stream pools; Altig and Johnston 1989; Lamotte and Lescure 1989b; Glaw and Vences 1994; Passmore and Carruthers 1995).

Stream tadpoles in several families, including hylids, myobatrachids, and mantellids, have enlarged, umbrella-shaped oral discs that enable them to cling to rocks in faster currents. These so-called adherent tadpoles include many species of *Hyla, Duellmanohyla, Plectrohyla* and *Ptychohyla* (fig. 12.21) from South and Central America (Duellman 1970, 2001; Lamotte and Lescure 1989b; Duellman and Campbell 1992). Tadpoles with enlarged oral discs also are characteristic of some Australian hylids in the genus *Litoria,* myobatrachids in the genera *Taudactylus* and *Crinia* (*C. riparia*), and some mantellid frogs from Madagascar in the genus *Mantidactylus* (Altig and Johnston 1989; Lamotte and Lescure 1989b; Davies 1991; Tyler and Davies1993; Glaw and Vences 1994). There also are tadpoles with upturned, funnel-shaped mouths that live in flowing water and apparently use their mouths to adhere temporarily to the undersides of rocks. These include several species of *Phyllomedusa* (Hylidae), *Mantidactylus* (Mantellinae), *Colostethus* (Dendrobatidae), and *Megophrys* (Megophryidae; Lamotte and Lescure 1989b).

Tadpoles that live in even faster currents often have the oral disc developed into a powerful sucker that enables them to cling to rocks more or less continuously. Oral suckers have evolved independently in the North American tailed frog (*Ascaphus truei*) (fig. 12.22 A), South African frogs in the genus *Heleophryne,* many Neotropical species of *Hyla* (fig. 12.22 B–D), hylid frogs from Australia and New Guinea (*Litoria, Nyctimystes*), a number of species of *Bufo,* Asian bufonids in the genus *Ansonia,* Asian megophryids in the genus *Scutiger,* and several genera of ranid, petropedetid, and astylosternid frogs (*Conraua, Petropedetes, Trichobatrachus;* Lutz and Orton 1946; Duellman 1970; Duellman and Trueb 1986; Altig and Johnston 1989; Iwasawa and Saito 1989; Lamotte and Lescure 1989a, b; Inger 1992; Tyler and Davies 1993; Passmore and Carruthers 1995; Haas and Richards 1998; Altig and McDiarmid 1999; S. Richards 2002).

In *Ascaphus,* there is an extensive system of lymphatic canals that provides a hydraulic framework to support the front and sides of the sucker. This allows for tight attachment to the substrate while suction is generated by negative pressure in the buccal cavity. An oral valve that closes when

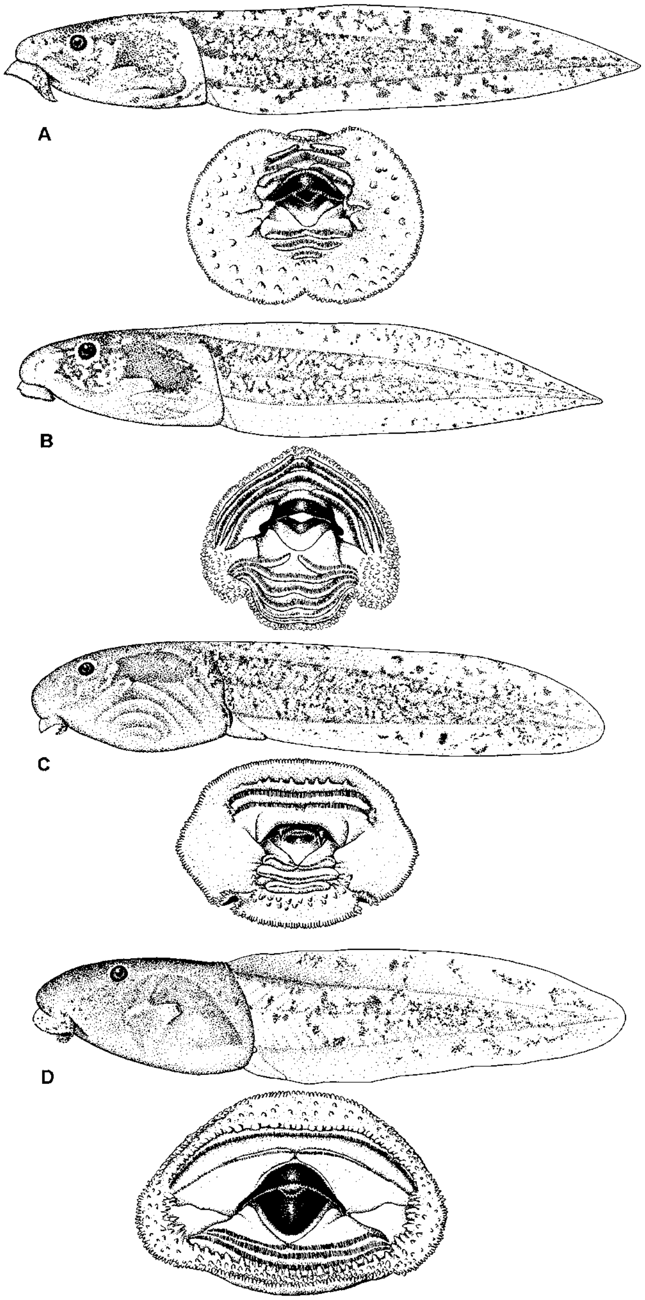

Fig. 12.21. Hylid stream tadpoles with adherent mouthparts. (A) *Duellmanohyla schmidtorum.* (B) *Ptychohyla euthysanota.* (C) *Plectrohyla matudai.* (D) *Plectrohyla guatemalensis.* The precise morphology of the mouthparts varies among genera and even within the genus *Plectrohyla,* but all have converged on a morphology that allows the tadpoles to hold onto rocks in flowing water. After drawings by David M. Dennis in Duellman (1970).

the sucker is engaged prevents water flow into the buccal cavity and allows the tadpole to remain attached to rocks for long periods of time without continuous buccal pumping. These tadpoles have an unusual tendon connection between the muscles of the trunk and tail and the lower jaw cartilages, which allows for coordinated movement of the jaw and tail musculature during "suctorial crawling" across the surface of rocks (Gradwell 1973). Suctorial tadpoles in other families appear to move in a similar fashion (Gradwell 1975; C. Taylor and Altig 1995). Feeding in species with suctorial mouths is accomplished by scraping algae off of rocks, and these tadpoles often have well-developed horny jaw sheaths and extra rows of labial teeth on the oral disc (Duellman 1970, 2001; Duellman and Trueb 1986; Lamotte and Lescure 1989a, b; fig. 12.22). The way in which suspended particles are transported through the oral cavity is not entirely clear. One possibility is that the sucker is loosened periodically to allow water to flow into the oral cavity and move food particles into the pharynx (Gradwell 1971; Haas and Richards 1998). Water flow over the gills for respiration is maintained by inflow of water through the nostrils (Altig and Brodie 1972; Gradwell 1971, 1975).

Suctorial tadpoles in several different families exhibit remarkable convergence in morphology, not only of the oral sucker, but also in features on the chondrocranium and muscle system. Haas and Richards (1998) compared the cranial morphology of suctorial tadpoles in the Australian hylid subfamily Pelodryadinae (*Nyctimystes* and the *Litoria nannotis* species group) with that of closely related pond-type tadpoles. Many of the differences in cranial morphology reflect alterations in the position and relative proportions of cranial elements, rather than entirely new structures. The heads of suctorial tadpoles are much wider at the front than are those of pond-type tadpoles, providing a base of attachment for the large oral sucker and the muscles associated with it. Suctorial tadpoles also have relatively smaller branchial baskets, but large ceratohyals. The *rectus abdominis* muscle, which runs along the belly of the tadpole, has a more anterior insertion in suctorial tadpoles. This probably enables the tadpole to draw its body forward after securing a hold with the sucker. Many of the morphological features seen in suctorial hylid tadpoles from Australia are very similar in Neotropical suctorial tadpoles, such as *Hyla armata,* in *Heleophryne* tadpoles from southern Africa, and in mantellid tadpoles of the genus *Boophis* from Madagascar. These groups are not closely related, so the similarity in structure reflects convergent adaptations to similar flowing-water habitats. The basic structure of the cranium also is similar in *Ascaphus,* but this species has some unique morphological features that reflect its much greater phylogenetic distance from other species with suctorial tadpoles, all of which are in neobatrachian families.

Some stream-dwelling tadpoles have an enormous disc posterior to the mouth and extending over much of the ventral surface of the body (fig. 12.23). These so-called gastromyzophorous tadpoles are found in two genera of

Dennis in Duellman (1970; B, C, D).

Neotropical bufonids, *Atelopus* and *Atelophryniscus,* one species of Asian bufonid in the genus *Ansonia,* Asian ranids in the genus *Amolops,* and the Asian ranid *Rana sauteri.* The abdominal sucker enables these tadpoles to adhere to rocks in very strong currents under cascades in mountain streams (Noble 1929a; Hora 1930; Liu 1950; Starrett 1967; Duellman and Lynch 1969; Lescure 1981; P. Gray and Cannatella 1985; Inger 1985, 1992; Duellman and Trueb 1986; Lamotte and Lescure 1989b; Chou and Lin 1997). Hora (1922) reported that an *Amolops* tadpole lifted out of the water by its tail could support a rock attached to its ventral disc that was 60 times the mass of the tadpole. This extraordinary suction is not created by negative pressure in the buccal cavity, but by action of abdominal and branchial muscles. Large pads of connective tissue, to which muscles are attached, support the flaps of skin that form the disc. When the muscles contract, the central part of the disc is elevated while the edges remain attached to the substrate, thereby creating a vacuum inside the disc (Noble 1929a). A similar set of muscles is found in the one species of *Ansonia* that has an abdominal sucker (Inger 1992). The way in which suction is generated by *Atelopus* tadpoles has not been reported. Tadpoles of this genus have less developed keratinized mouthparts than do *Amolops* tadpoles, suggesting that their feeding ecology is different or that they live on different kinds of rocks (Wassersug and Heyer 1983).

Semiterrestrial Tadpoles

Tadpoles of two genera of leptodactylids, *Cycloramphus* and *Thoropa,* are found on wet rocks along streams in the forests of southeastern Brazil (fig. 12.24 A, B). In most species, tadpoles are adapted for adhering to the surface of rocks splashed by waterfalls or covered by a film of water from seepage areas (Heyer 1983; Heyer and Maxson 1983; Wassersug and Heyer 1983). Their bodies are greatly elongated, with reduced tail fins. The venter is flattened, and in *Cycloramphus,* there is a shelf-like projection extending beyond the body that provides increased area for adhesion to the substrate by means of surface tension, but there is no

specialized suction apparatus. The branchial baskets of these tadpoles are relatively flattened and lack the dense filter apparatus needed for feeding on plankton (Wassersug and Heyer 1983). Evidently they feed by scraping algae off of rocks, but their ecology is poorly known.

Some tadpoles in several other families exhibit ecological and morphological adaptations similar to those of *Thoropa* and *Cycloramphus*. For example, some species in the African genus *Petropedetes* have flattened bodies and sometimes adhere to rocks in the splash zones of waterfalls (fig. 12.24 C). These tadpoles apparently spend much of their time out of the water, and even have been observed moving about on the forest floor with only their back legs fully emerged (Lawson 1993; see also fig 9.6 in Hoff et al. 1999). In contrast to the leptodactylids, however, *Petropedetes* tadpoles also have large suctorial oral discs characteristic of other tadpoles found in fast-flowing streams (Lamotte and Lescure 1989a). Some Asian ranid tadpoles in a different subfamily have similar habits and body morphology, and these also have suctorial oral discs. These include *Indirana beddomii* and *Nannophrys ceylonensis* (Lamotte and Lescure 1989a; Wickramasinghe et al. 2005). Finally, there are some West African bufonid tadpoles with similar habits, flattened bodies, and moderately to well developed suctorial oral discs. These include *Bufo perreti* and some species of *Werneria* (Altig and Johnston 1989; Lamotte and Lescure 1989a, b).

Nonfeeding Tadpoles

Tadpoles in several families of anurans complete development in an enclosed nest, sometimes attended by a parent (see chapters 10 and 11). These were termed nidicolous tadpoles by Altig and Johnston (1989; *nid* [L.] = nest; *-colous* [L.] = inhabiting). Many of these tadpoles do not feed, but live entirely on yolk reserves. For example, tadpoles of *Cycloramphus stejnegeri* develop in a terrestrial nest attended by the female (Heyer and Crombie 1979). They lack the flattened venter characteristic of aquatic members of the genus, as well as most feeding structures (Heyer 1983). Oral structures have been lost or reduced to varying degrees in other tadpoles that complete development in an enclosed nest, but in others, such as *Eupsophus calcaratus,* are not dramatically different from generalized feeding tadpoles (Candioti, Úbeda, and Lavilla 2005). Nidicolous tadpoles are known from species of bufonids, dendrobatids, leiopelmatids, leptodactylids, microhylids, myobatrachids, and ranids (Lutz 1947; Lescure 1973, 1975a, 1979; Salthe and Mecham 1974; Blommers-Schlösser 1975a; Lamotte and Lescure 1977; Altig and Johnston 1989; Junca, Altig, and Gascon 1994; Kaiser and Altig 1994; Caldwell and Lima 2003; see also chapter 10). This type of reproductive mode is somewhat intermediate between aquatic development and fully terrestrial eggs with direct development (see chapter 10). In the case of dendrobatids in the genus *Colostethus,* nidicolous tadpoles probably have evolved independently several times from an ancestral mode of transporting tadpoles to water (Caldwell and Lima 2003). A complete phylogenetic analysis of the genus and its close relatives is needed to test this hypothesis, however,

Some tadpoles that either hatch in or are carried to small pools of water in plant parts, such as bromeliads, leaf axils, and seed husks (phytotelmata), complete development with little or no independent feeding (see also the previous "Phytotelmonous Tadpoles"). For example, the hemiphractine hylid frog *Flectonotus goeldii* carries eggs in a dorsal brood pouch (see chapters 10 and 11). After the eggs have hatched, the mother deposits tadpoles in bromeliads, where they complete their development. The tadpoles appear to be capable of completing development without feeding, although they have been observed to ingest undeveloped eggs and

dead or dying tadpoles in captivity (Weygoldt 1989b; Weygoldt and de Carvalho e Silva 1991). Tadpoles of *F. goeldii* lack keratinized labial teeth on the oral disc. The branchial baskets are small and poorly developed, and some branchial muscles are weakly developed or missing. The tadpoles also lack the branchial food traps and gill filter rows that are characteristic of free-living tadpoles in the closely related genus *Gastrotheca* (Haas 1996). The morphological features that are missing or poorly developed in *F. goeldii* are those that normally appear late in the development of *Gastrotheca* tadpoles, suggesting that development has been truncated in *Flectonotus*.

Social Behavior of Amphibian Larvae

Adult amphibians show little evidence of true sociality, and virtually all behavioral interactions between them, except for courtship and mating, are competitive (see chapters 8 and 9). Most amphibian larvae are relatively solitary as well, and many appear to actively avoid contact with other individuals. This is especially true of salamander larvae, which tend to be aggressive toward other larvae and sometimes are cannibalistic (Mathis et al. 1995; Blaustein and Walls 1995; see also the earlier "Cannibalism and Cannibalistic Morphs"). In some anuran tadpoles, however, there is evidence of social attraction, coordinated behavior among individuals, and even limited cooperation. Often these interactions are mediated by recognition of close kin (Blaustein and Walls 1995; Hoff et al. 1999).

The Natural History of Tadpole Aggregations

The occurrence of dense aggregations of anuran tadpoles in temporary ponds was reported by a number of early workers (e.g., Abbott 1884; S. Ball 1936; Richmond 1947), but it was mainly the work of Arthur N. Bragg on spadefoot toads in Oklahoma that called attention to the social behavior of tadpoles. In a long series of papers starting in the early 1940s, Bragg described a number of types of aggregations in several species of spadefoot toads (summarized in Bragg 1965). Some of these aggregations were enormous, containing hundreds of thousands of tadpoles. In one pond, for example, he observed a feeding aggregation nearly 7 m long, 1 m wide, and several centimeters deep, with the entire mass of tadpoles moving slowly in the same direction along the bottom of the pond (Bragg 1957a). He also described huge aggregations of thousands of metamorphosing juveniles emerging synchronously from the receding waters of temporary pools (Bragg 1965). Later work revealed that species in at least 10 families of anurans have tadpoles that form aggregations (table 12.2 and reviews by Lescure 1968; Wassersug 1973; Caldwell 1989; Blaustein and Walls 1995).

Much of the early literature on tadpole aggregations

Table 12.2 Examples of social aggregations in anuran tadpoles.

Species (source no.)	Pond type	Tadpole color	Type of aggregation
Pipidae			
Xenopus laevis (11, 20)	Permanent and temporary	Light, nearly transparent	Polarized midwater schools; coordinated filter feeding
Rhinophrynidae			
Rhinophrynus dorsalis (5)	Temporary	Light, nearly transparent	Polarized schools on pond bottom; coordinated movement in feeding swarms
Microhylidae			
Chiasmocleis ventrimaculata (25)	Permanent and temporary	Gray	Flat, wide schools on surface; regular spacing and parallel orientation
Hamptophryne boliviana (25)	Permanent and temporary	Dark brown above; gray below	Flat, wide schools on surface; regular spacing and parallel orientation
Phrynomantis annectens (9, 14)	Permanent and temporary	Black and gold	Polarized midwater school; parallel orientation and coordinated movement
P. microps (32)	Temporary	Black and gold	Aggregations of different sizes; tadpoles not always segregated by size; some parallel orientation in windy conditions
Pelobatidae			
Scaphiopus and *Spea* (2, 3, 6)	Temporary	Black	Stationary aggregations of thousands of tadpoles on bottom; parallel orientation and coordinated movement in feeding swarms
Bufonidae			
Bufo americanus (12, 16, 17, 23)	Temporary	Black	Large stationary aggregations on bottom with random spacing; some coordinated movement when feeding
B. boreas (27)	Permanent	Black	Huge stationary aggregations on bottom; some coordinated movement when feeding
B. crucifer (36)	Temporary	Black	Dense moving aggregations in shallow water
B. maculatus (35)	Temporary	Black	Dense stationary aggregations in shallow pools and large moving aggregations in deeper water, with some parallel orientation
B. rufus (33)	Temporary	Dark brown	Stationary or moving aggregations of variable size
B. woodhousii (21)	Temporary	Black	Large stationary or slow-moving aggregations; some parallel orientation and size segregation
Schismaderma carens (7, 9)	Temporary	Black	Densely packed tadpole "balls" in midwater; lower density feeding groups on bottom
Hylidae			
Hyla geographica (8, 10, 18, 29, 37)	Permanent	Black	Densely packed tadpole "balls" or flat aggregations; rolling or swarming movement without parallel orientation; segregation by size
Phyllomedusa vaillanti (24)	Permanent	Gold	Dense, highly mobile polarized schools in midwater, on surface, or on bottom; segregation by size
Leptodactylidae			
Leptodactylus insularum (28)	Temporary	Brown and gold	Densely packed swarms with coordinated movement led by mother
L. chaquensis (18)	Temporary		Dense aggregations
L. melanonotus (11)	Temporary	Black	Dense aggregations
L. ocellatus (13)	Temporary	Brown	Densely packed swarms with coordinated movement led by mother
L. wagneri (25)	Temporary	Dark	Polarized aggregations on bottom with parallel orientation and coordinated movement

(*continued*)

Table 12.2 (continued)

Species (source no.)	Pond type	Tadpole color	Type of aggregation
Ranidae			
Pyxicephalus adspersus (4, 9)	Temporary	Black	Dense aggregations with coordinated movement accompanied by father
Rana cascadae (27)	Permanent and temporary	Brown	Small stationary aggregations on bottom
R. heckscheri (1, 18)	Permanent	Black and gold	Dense schools with coordinated rolling movement
R. sylvatica (26)	Temporary	Dusky, greenish gray	Usually not aggregated; occasional polarized schools at high density
R. temporaria (34)	Temporary	Brown to black	Moving or stationary aggregations of variable size
Rhacophoridae			
Philautus cherrapunjiae (11)		Black	Compact, irregular schools

focused on the proper nomenclature for these groups. Bragg (1965) distinguished between asocial and social groups. The former resulted from tadpoles aggregating in response to some feature of the environment, such as temperature gradients or a temporary concentration of food; the latter resulted from the mutual attraction of individual tadpoles. Other workers have used a variety of terms to describe tadpole groups, and Wassersug (1973) attempted to standardize the terminology. He classified groups as simple aggregates and biosocial aggregates, which were equivalent to Bragg's categories. He further subdivided them into polarized and nonpolarized groups, the former being those in which individuals show parallel orientation in the same direction. Wassersug restricted the term "school" to biosocial aggregates showing some degree of coordinated group movement, but the degree of polarization in schools can vary considerably. Some ichthyologists have used the term "shoal" to refer to aggregations of fishes, restricting the term "school" to polarized groups exhibiting coordinated movement (Pitcher and Parrish 1993).

The diversity of tadpole aggregations is evident from table 12.2. This is not an exhaustive list; other species are briefly described in natural history accounts as being gregarious, but the details of group formation and behavior are unknown. The groups that most closely resemble schools of fishes are the highly polarized midwater schools formed by planktivorous tadpoles of *Xenopus* (Wassersug 1973; L. Katz, Potel, and Wassersug 1981; Wassersug, Frogner, and Inger 1981). These form groups characterized by rather even spacing of individuals, parallel orientation, and coordinated movement in one direction. Very similar behavior occurs in the African microhylid *Phrynomantis annectans,* also a midwater planktivore (Van Dijk 1972; Channing 1976b). Other microhylid tadpoles, including *Chiasmocleis ventrimaculata, Hamptophryne boliviana,* and *Phrynomantis microps,* typically hang just below the surface in large aggregations with regular spacing between individuals (Schlüter 1984; Rödel and Linsenmair 1997). Tadpoles of the Mexican burrowing frog, *Rhinophrynus dorsalis,* are morphologically similar to those of *Xenopus* and sometimes form polarized schools. Apparently they feed mostly on small particulate matter, but can feed on small invertebrates as well (Starrett 1960; L. Stuart 1961; Wassersug 1973 and personal communication).

Hylid tadpoles in the subfamily Phyllomedusinae also are similar to *Xenopus* tadpoles in morphology and feeding ecology, being adapted for swimming and hovering in the water column (Wassersug 1973). At least some species also are gregarious. For example, *Phyllomedusa vaillanti* of Amazonian Brazil lays eggs on leaves overhanging ponds. Tadpoles tend to hatch synchronously (Schlüter 1984) and remain in the spot where they land in the water until a group is formed (L. Branch 1983). They travel in polarized schools that are segregated by size and therefore may represent groups of siblings from single egg clutches. Sometimes schools merge during feeding bouts, but quickly separate. This species exhibits a variety of feeding modes, including grazing on the bottom, midwater filter-feeding, and feeding from the surface film, but in all cases tadpoles are gregarious and exhibit coordinated movements (L. Branch 1983).

Tadpoles of spadefoot toads (*Scaphiopus* and *Spea*) and many true toads (*Bufo*) form stationary aggregations on the bottom of shallow ponds; these groups range in size from a few dozen to hundreds of thousands of individuals (fig. 12.25 A). Groups of spadefoot toad tadpoles tend to reach very high densities because they typically breed in ephemeral rain pools that rapidly decrease in size (Bragg 1965). Individuals in stationary aggregations often show little regular-

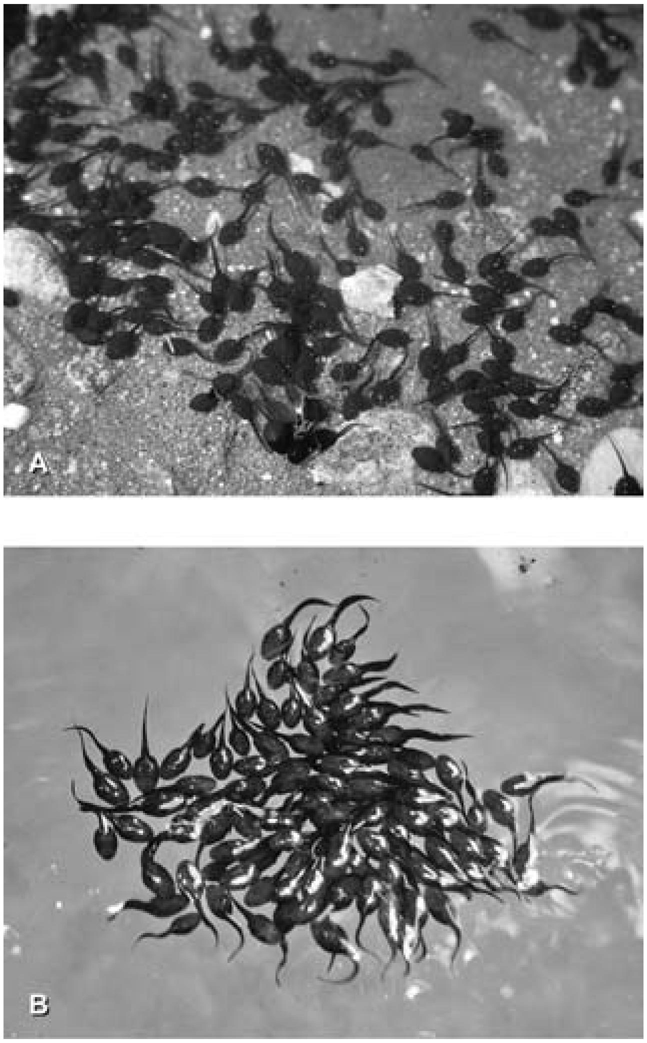

Fig. 12.25. (A) Aggregation of American toad tadpoles (*Bufo americanus*) in a shallow pond. These tadpoles often form dense aggregations in shallow water during sunny weather, but then move to deeper water at night. (B) School of *Hyla geographica* tadpoles in a river in Trinidad. These tadpoles form tight balls and swim together in a coordinated manner, probably for protection against predators. Photos by Kentwood D. Wells.

ity in spacing or orientation. In some species, there is a statistical tendency for similar-sized individuals to be associated with one another and to orient in the same direction, but this is not obvious from simple observation (Wassersug, Frogner, and Inger 1981; Breden, Lum, and Wassersug 1982). In both groups, polarized schools are formed when the tadpoles are actively feeding. Usually this involves substrate feeding, with the entire mass of tadpoles moving in the same direction, churning up the pond bottom (Richmond 1947; Bragg 1965; Beiswenger 1975), but occasionally they will feed on suspended particles or plankton in the water column (Bragg 1965; Test and McCann 1976). Many species also are highly gregarious immediately before and immediately after metamorphosis (Bragg 1948, 1950, 1952, 1965; Bragg and Brooks 1958; Black and Black 1969; Lillywhite and Wassersug 1974; S. Arnold and Wassersug 1978).

Some of the most impressive social groups of tadpoles are the densely packed tadpole balls formed by some bufonids and hylids. In these groups, tadpoles do not show parallel orientation, but instead form a seething mass that tends to roll through the water. Often the tadpoles are in direct bodily contact, forming an impressive aggregation that is very conspicuous in open water. This type of aggregation has been described in the African toad *Schismaderma carens* (sometimes placed in the genus *Bufo;* Wager 1965; Van Dijk 1972). Very similar aggregations occur in *Hyla geographica* (fig. 12.25 B; Kenny 1969a; Duellman and Lescure 1973; Duellman 1978; Caldwell 1989). Aggregations of this species observed by Caldwell (1989) in Brazil usually contained tadpoles in a relatively narrow range of sizes, suggesting that each group represents a single clutch of eggs, or offspring of several clutches that hatched at about the same time. When swimming in midwater, the tadpoles form tight balls, but they sometimes spread out into flat schools on the surface. Often the tadpoles in these aggregations were facing inward toward the center of the group, as if trying to swim toward the middle. I have observed similar behavior in the same species in a river in Trinidad. These tadpoles sometimes spread out into a flat school while feeding on the bottom, but formed balls in open water (my unpublished observations).

Several species of leptodactylid frogs have gregarious tadpoles (table 12.2), and in several species, parents accompany the schools. Tadpoles of *Leptodactylus insularum* often form very dense schools with individuals in close bodily contact. These schools are attended by the female, which actively leads the tadpoles through shallow pools, communicating with them by means of tactile or chemical cues (Wells and Bard 1988; see further discussion in chapter 11). Female *L. ocellatus* accompany groups of gregarious tadpoles, and females also have been observed directing the movements of tadpole schools (Vaz-Ferreira and Gehrau 1975; J. Caldwell, personal communication). Tadpoles of the closely related species *L. chaquensis* also are gregarious (Cei 1980), but parental attendance has not been reported. Very similar behavior has been described in the African ranid, *Pyxicephalus adspersus,* with the male rather than the female accompanying the tadpole school (Kok, du Preez, and Channing 1989).

Although most other ranid tadpoles seem to be solitary, there is evidence of limited sociality in some species. Tadpoles of *Rana cascadae* often are found in small stationary aggregations, although there is little indication of coordinated behavior or complex spatial organization (O'Hara and Blaustein 1985; Blaustein and O'Hara 1986). Wood frog (*Rana sylvatica*) tadpoles generally are not gregarious, but Waldman (1984) reported that they sometimes form polarized feeding schools in ponds with very high population densities. The most social North American ranid species appears to be the river frog, *Rana heckscheri*, which forms dense schools and has coordinated feeding behavior (Altig and Christensen 1981; Punzo 1991, 1992). A. Wright (1932), who first described this species, reported that the behavior of the tadpoles was more similar to that of *Bufo* tadpoles than to that of other species of *Rana*. At least two Old World ranids, *Rana chalconota* and *Aubria subsigillata*, are reported to form compact schools (Schiøtz 1963; Wassersug 1973), as do tadpoles of an Asian rhacophorid, *Philautus cherrapunjiae* (Roonwal and Kripalani 1961).

Despite considerable variation in the details of social behavior, gregarious species have several characteristics in common. Most obvious is that many are visually conspicuous, often being either black or bright gold (table 12.1). The exceptions are the midwater schoolers, which tend to have light coloration or are nearly transparent. Some degree of size segregation has been reported in several species (*Bufo woodhousii, Hyla geographica, Phyllomedusa vaillanti*) suggesting a tendency for siblings from the same clutch to group together (see the following discussion). Finally, some species tend to be more gregarious during the day than at night. For example, tadpoles of *Bufo americanus, Phyllomedusa vaillanti, Phrynomantis annectans,* and *Phrynomantis microps* are highly social during the day, but are randomly distributed throughout the pond at night (Channing 1976b; Beiswenger 1977; L. Branch 1983; Rödel and Linsenmair 1997). Aggregation behavior in *Phrynomantis* is affected by water clarity, with larger and denser aggregations occurring in clear water, where tadpoles probably are most vulnerable to predators (Spieler 2003). Other species exhibit tighter parallel orientation or more even spacing during the day than at night (L. Katz, Potel, and Wassersug 1981; Wassersug, Frogner, and Inger 1981). This is not universally true, however. Bragg (1948) observed dense feeding schools of spadefoot toad tadpoles at night, and *Hyla geographica* tadpoles are reported to remain gregarious at night as well (L. Branch 1983). *Leptodactylus* tadpoles attended by a parent also are highly gregarious at all times (Vaz-Ferreira and Gehrau 1975; Wells and Bard 1987).

Benefits of Aggregation Behavior

Many authors have speculated on the adaptive significance of tadpole aggregations, but evidence for any hypothesis is scarce. Some explanations seem rather implausible. For example, both R. Savage (1961) and Bragg (1965) proposed that grouping is advantageous because large stationary aggregations reduce the oxygen and increase the carbon dioxide content of the water near the tadpoles, and this in turn may help to repel predators such as water beetles. However, the costs of reduced oxygen levels to the tadpoles themselves were not considered. Richmond (1947) suggested that schooling helps reduce the frequency of collision between swimming tadpoles, but the advantage of this is unclear. Most explanations have been more reasonable, focusing on benefits such as increased feeding efficiency or protection against predators, the same benefits proposed for group-living fishes (Pitcher and Parrish 1993).

Feeding Benefits

The benefits of cooperative feeding often are invoked to explain the polarized substrate-feeding schools observed in species such as *Bufo, Spea,* and *Scaphiopus*. Such schools frequently form when tadpole densities are high and pond productivity low. In temporary rain pools, macrophytic plants and phytoplankton often are scarce, and the only organic matter available to the tadpoles is in the bottom mud. Cooperative schools might enhance feeding efficiency by churning up the substrate and exposing food not available to individual tadpoles (Richmond 1947; Bragg 1954b, 1965; Bragg and King 1960; L. Stuart 1961; Beiswenger 1975; Waldman 1984, 1991; Blaustein and Walls 1995). Aggregation also might be favored if it enabled tadpoles to displace competing species that do not aggregate. There are anecdotal reports, for example, of small groups of *Pseudacris regilla* tadpoles being displaced by large aggregations of *Bufo boreas* tadpoles (Blaustein and Walls 1995). A similar explanation for schooling behavior has been proposed for some coral reef fishes (Robertson et al. 1976).

Although the hypothesis that aggregation enhances feeding seems reasonable, there is little experimental evidence to either support or refute it. Wilbur (1977a) did find that increased densities of *Bufo americanus* tadpoles had a positive effect on size at metamorphosis, but only at rather low initial densities. In laboratory experiments, tadpoles of this species had the largest mass at metamorphosis when all individuals in a tank had access to a common food resource (Breden and Kelly 1982). This could have been due to social facilitation in breaking up large food particles or to nutritional benefits derived from the feces of other individuals (Steinwascher 1978b). Similar enhancement of growth in interacting tadpoles compared to isolated ones has been observed in *Xenopus laevis* (L. Katz, Potel, and Wassersug 1981) and *Rhynophrynus dorsalis* (Foster and McDiarmid 1982). These experiments do not directly demonstrate that large aggregations enhance feeding efficiency under natural conditions, but they do suggest that limited social interactions benefit individuals even in the absence of predators. Punzo (1991) reported that both learned avoidance of noxious stimuli and coordinated swimming were enhanced in social groups of *Rana heckscheri* tadpoles, but he did not directly address the question of facilitated feeding behavior, which has been suggested, but not demonstrated experimentally for this species (Altig and Christensen 1981). In a study of *Bufo crucifer* tadpoles in Brazil, Eterovick (2000) found that the tadpoles ate more heterotrophic organisms (protozoans, ciliophores, and crustacean eggs) when feeding in aggregations than when feeding alone, but the nutritional benefits of this change in feeding behavior, if any, are not known.

Protection against Predators

Protection against predators is perhaps the most common explanation for the formation of schools, flocks, and herds by animals (Wittenberger 1981; Pitcher and Parrish 1993). Several types of antipredator benefits have been proposed for tadpole aggregations, but again, there is little experimental support for any of these ideas. Some authors have simply suggested that predators are reluctant to enter tadpole schools, although the reasons for this are not clear. For example, Black (1970) reported that beetle larvae commonly fed on tadpoles of *Spea bombifrons* on the periphery of schools, but they were not seen to enter the aggregations themselves. Bragg (1965) observed beetle larvae turning away when they reached the edge of a tadpole school. Carpenter (1953a) thought that aggregation by *Rana pretiosa* tadpoles might reduce attacks by leeches or somehow facilitate their removal. Both Bragg (1965) and Black (1970) proposed that aggregations provide protection against intraspecific cannibalism, because cannibalistic tadpoles were observed feeding on isolated conspecifics, but not on those in aggregations. This hypothesis seems at odds with other data showing that cannibalism is most likely to occur when population densities are high (see the following "Cannibalism and Kin Recognition").

Some tadpoles form more cohesive aggregations in the presence of predators or chemical cues derived from predators. For example, when tadpoles of European common toads (*Bufo bufo*) were presented with chemical cues from predatory fishes, they formed more cohesive groups than in the absence of such cues (Watt, Nottingham, and Young 1997). Tadpoles of the African microhylid *Phrynomantis microps* formed aggregations in the presence of dangerous predators, such as aquatic insects, but not in the presence of harmless insects or other species of tadpoles (Rödel and Linsenmair 1997). Aggregation behavior also was induced by presenting tadpoles with chemicals derived from injured conspecifics, suggesting a form of alarm response in this species. In another African species, *Bufo maculatus,* tadpoles formed aggregations only in response to both chemical stimuli from injured conspecifics and mechanical stimuli produced by movements of predators (Spieler and Linsenmair 1999). In many other tadpoles, the typical reaction to chemicals released by injured tadpoles is to flee from the source of the chemical or reduce swimming activity, but not to form aggregations (Hrbâçek 1950; Kulzer 1954; Pfeiffer 1966, 1974; Hews and Blaustein 1985; Hews 1988; Nicieza 1999; see chapter 14 for further discussion of alarm responses to predators). *Bufo maculatus* tadpoles showed similar avoidance responses to injured tadpoles in the absence of mechanical stimuli from swimming predators.

Aggregated animals sometimes benefit from a "selfish herd" effect, or from satiation of local populations of predators (W. D. Hamilton, 1971). The best evidence for such an effect in tadpoles is the study by Watt, Nottingham, and Young (1997) of *Bufo bufo* tadpoles. They found that attacks by predatory fish increased as the size of a tadpole aggregation increased, but the per capita attack rate declined (fig. 12.26). Unfortunately, because of ethical concerns, they were not able to observe actual predation rates on groups of different sizes, but the inference from the experiment is that individual tadpoles are safer in larger groups. Kehr and Schnack (1991) reported that tadpoles of *Bufo arenarum* were least vulnerable to predation by giant water bugs (*Belostoma*) at high tadpole densities, but it was not clear whether this was due to predator satiation or an effect of aggregation by tadpoles on prey capture success by the predators.

Aggregated tadpoles might benefit from more rapid detection of predators or confusion effects. Schooling tadpoles approached by a predator typically fan out and swim in several directions, although some degree of coordinated movement is maintained (L. Branch 1983; personal observations on *Hyla geographica*). Tadpoles near the center of an aggregation might benefit from rapid transmission of a fright reaction initiated by those at the periphery swimming away from a predator (Treherne and Foster 1981). In some species, the benefits of grouping may continue beyond metamorphosis. It has been proposed that synchronized metamorphosis

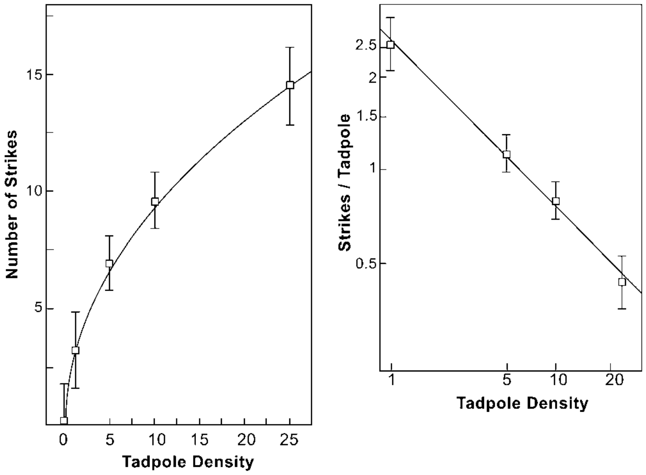

Fig. 12.26. The effect of group size on attack frequency by predators of *Bufo bufo* tadpoles. The number of predator attacks increased with increasing tadpole density (left), but per capita risk decreased with increasing density (right). After P. Watt, Nottingham, and Young (1997).

and postmetamorphic aggregations in some species serve to swamp predators and thereby reduce individual risk (Beiswenger 1975; Arnold and Wassersug 1978).

Finally, if tadpoles are distasteful, then aggregation might enhance protection against predators by providing a more conspicuous aposematic signal (Wassersug 1973; Peterson and Blaustein 1991). The conspicuously black coloration of many social tadpoles (table 12.1) has been cited as support for this hypothesis, but direct evidence for an aposematic function of black coloration is scarce. Certainly *Bufo* tadpoles are distasteful to some predators, although the effectiveness of noxious chemicals depends on the developmental stage of the tadpole (Formanowicz and Brodie 1982; Glandt 1984) and the feeding behavior of the predator (chapter 14). The palatability of most schooling tadpoles is not known (Wassersug 1973), but there is little evidence that tadpoles of spadefoot toads are distasteful. In fact, they appear to be preferred prey for some natural predators, and their best protection is for females to lay eggs in temporary ponds where predators are scarce (Woodward 1983).

Physiological Benefits

Some species of tadpoles tend to aggregate in the warmest parts of ponds, except when temperatures reach lethal values (Mullally 1953; Brattstrom 1962c; Karlstrom 1962; Bragg 1965; Beiswenger and Test 1966; Beiswenger 1977). Brattstrom (1962c) found that a pan of water containing a large group of tadpoles heated more quickly in the sun than a pan with water alone, leading him to suggest that aggregation serves a thermoregulatory function, which would be enhanced by the black color of many species. However, Brattstrom's experiment is not convincing, because it did not allow for convective cooling resulting from water currents or movements of the tadpoles themselves. Beiswenger (1977) found that screened enclosures in ponds with tadpoles actually heated more slowly than did empty enclosures because of the currents set up by moving tadpoles. Bragg (1962) and Black and Black (1969) also proposed physiological benefits to explain the formation of metamorphic aggregations. They suggested that clustering might reduce desiccation of tadpoles emerging from exposed ponds. Lillywhite and Wassersug (1974) considered this unlikely, but did not present data to refute the hypothesis; they concluded that aggregation in juveniles might be a nonadaptive continuation of larval behavior patterns.

Costs of Aggregation Behavior

Most authors have given scant attention to the possible costs of group living in tadpoles. In any animal, the frequency of group formation, the sizes of groups, and the spatial and social relationships within groups represent a balance between conflicting selective pressures (Bertram 1978; Pulliam and Caraco 1984; Magurran and Bendelow 1990; Richardson 1994). Furthermore, the costs and benefits of group living often are two sides of the same coin. For example, schooling can be an effective defense against certain types of predators, but it also can increase exposure to other predators or induce a compensating change in their behavior (e.g., Major 1977, 1978). Group foraging may increase feeding efficiency under some circumstances, but result in increased competition if the distribution of resources changes. Consequently, it is impossible to evaluate the costs and benefits of group living solely on the basis of casual natural history observations; careful experimental studies are needed as well. The key issue is whether the per capita benefit to individuals increases with increasing group size, even if larger groups attract predators or suffer increased competition for food.

Competition for Resources

One potential cost of group living is increased competition for resources, including oxygen and food. As aquatic oxygen levels decrease, tadpoles switch to aerial respiration (see chapter 4). Synchronized aerial breathing, with many tadpoles swimming simultaneously to the surface, has been reported in a number of social species (L. Stuart 1961; Wager 1965; Wassersug 1971, 1973; L. Branch 1983). However, it is not clear that a social aggregation would deplete the oxygen in a pond more quickly than would an equally large number of dispersed tadpoles. Similarly, the effects of social aggregation on competition for food is not well understood. Increased population density often leads to decreased individual growth rates and smaller size at metamorphosis (see chapter 13). Presumably this is due largely to exploitative competition for food, although there is limited evidence for interference competition as well. For example, large tadpoles may push smaller tadpoles aside and interfere with their feeding (R. Savage 1952; Gromko, Mason, and Smith-Gill 1973; John and Fenster 1975; Wilbur 1977a; Faragher and Jaeger 1998). Probably the total density of tadpoles in a pond affects the intensity of exploitative competition, but not necessarily by the degree of aggregation. In contrast, interference competition probably is most intense in aggregating species (R. Griffiths and Foster 1998).

Risk of Predation

The second major cost of group living is likely to be an increased risk of predation. Although aggregation may decrease the risk of predation under some circumstances, conspicuous groups also could attract more predators, and this would be particularly costly if the tadpoles are not distasteful to all types of predators. Information bearing on this point is largely anecdotal. For example, with reference to *Schismaderma carens,* Wager (1965, 110) stated that "Predators love this gregarious habit: dragonfly larvae dive into the mass and emerge immediately with a struggling victim; a bird such as a Hammerhead will eat hundreds in a single meal, and a Water Tortoise will take them by the mouthful." I once observed a turtle feeding on a dense aggregation *of Leptodactylus insularum* tadpoles in Panama (unpublished observations), and several authors have reported predation by birds on conspicuously aggregated tadpoles (Wassersug 1971; Ideker 1976; Beiswenger 1981). In *Pyxicephalus adspersus* and *Leptodactylus ocellatus,* attending parents are reported to attack vertebrate predators (B. Balinsky and Balinsky 1954; Vaz-Ferreira and Gehrau 1975). Such behavior could be an evolutionary response to the increased vulnerability of aggregated tadpoles.

Cannibalism by conspecifics tends to occur mostly in tadpoles that form aggregations (see previous discussion of "Cannibalism"), but it is not clear that this represents a cost of aggregation per se. Black (1970) reported that cannibalistic *Spea bombifrons* tadpoles were present only in ponds where tadpoles were in large feeding schools. He interpreted this as evidence that schools were formed as protection against cannibals. However, it also is possible that cannibalism is an opportunistic response to the availability of densely aggregated prey, or that both cannibalism and schooling are independent responses to food shortage or high population density (see D. Pfennig 1992a, b).

Kin Recognition in Tadpoles

The occurrence of size-specific schools of tadpoles in species such as *Hyla geographica* and *Phyllomedusa vaillanti* strongly suggests that schools are formed from single egg clutches, and this almost certainly is the case for *Leptodactylus* tadpoles attended by the mother and *Pyxicephalus* tadpoles attended by the father. However, direct evidence that tadpoles can recognize close kin comes not from these tropical species, but from work on North American ranids, bufonids, and pelobatids. Kin recognition was first demonstrated in *Bufo americanus* tadpoles by Waldman and Adler (1979) and subsequently described in several other species by Waldman, Blaustein and O'Hara, and several other investigators. Much of the work by these authors has involved rearing tadpoles under various conditions in the laboratory and testing their ability to distinguish siblings from nonsiblings. Most investigators have used some measure of spatial association to determine whether tadpoles can recognize their kin. In Waldman's early experiments, sibships were colored with different vital stains and then placed in equal numbers in a single tank. Kin recognition was tested by analysis of the spatial distribution of the colored tadpoles. In most other studies, individual tadpoles were placed in a tank with groups of different sibships in chambers at either end. Kin recognition was tested by measuring the amount of time the tadpoles spent in each end of the tank. Later studies included tests for kin association in more realistic field conditions (Waldman 1982b; O'Hara and Blaustein 1985; Hokit and Blaustein 1997), as well as investigations of kin recognition in relation to cannibalism by tadpoles (D. Pfennig, Reeve, and Sherman 1993; D. Pfennig and Frankino 1997; D. Pfennig 1999). There have been several comprehensive reviews of kin recognition in tadpoles (Waldman 1986a, 1991; Blaustein, Beckoff, and Daniels 1987a, b; Blaustein 1988; Blaustein and Waldman 1992; Blaustein and Walls 1995; Hoff et al. 1999). I will give only a brief summary of this work here.

Development of Kin Recognition

In all of the species that exhibit any sort of kin recognition, tadpoles raised exclusively with siblings associated preferentially with sibs over nonsibs, although in *Rana aurora* this was true only for very young tadpoles. In a few species, including *Pseudacris crucifer, P. regilla, Rana pipiens,* and *R. pretiosa,* tadpoles reared only with siblings did not exhibit any tendency to associate with close relatives (O'Hara and Blaustein 1988; Fishwald et al. 1990). None of these species is known to aggregate with conspecifics in the field.

The effect of exposure to nonsibs during development varies. In *Bufo americanus,* tadpoles reared in mixed groups did not show a preference for familiar sibs over familiar nonsibs in laboratory tests, but did exhibit such preferences in the field (Waldman 1981, 1982b). When tadpoles of *B. americanus* were exposed to sibs before being reared in a mixed group, they retained their ability to recognize siblings. In contrast, when tadpoles were exposed first to mixed groups and later to siblings, they did not exhibit a preference for siblings over familiar nonsibs. These results suggest that experience early in the larval period affects kin recognition. One might predict that when the eggs of several different females are laid in close proximity, as sometimes occurs in this species, tadpoles would exhibit weaker preferences for siblings than those that hatch from isolated egg clutches. Exposure to siblings is not essential for kin recognition, however, because tadpoles reared in isolation also exhibited a preference for associating with sibs (Waldman 1981). In *Bufo boreas,* tadpoles exposed only to siblings exhibited a preference for familiar sibs over unfamiliar nonsibs. In contrast to *B. americanus,* however, subsequent exposure to mixed groups of tadpoles eliminated this preference (O'Hara and Blaustein 1982). This species often occurs in aggregations of hundreds of thousands of individuals, many of which are not related to each other, so it seems unlikely that tadpoles of this species commonly associate with close relatives in the field. Tadpoles of a toad from India, *Bufo melanostictus,* exhibited a preference for associating with sibs in laboratory experiment and could recognize both familiar and unfamiliar kin regardless of rearing conditions (Saidapur and Girish 2000).

The development of kin recognition in two ranids, *Rana cascadae* and *R. sylvatica,* appears to be somewhat different from that seen in the toads. *Rana cascadae* tadpoles could distinguish unfamiliar sibs from unfamiliar nonsibs when reared only in sib groups, in mixed groups, or in social isolation (Blaustein and O'Hara 1981, 1982a, 1983). In laboratory tests, tadpoles reared in mixed groups did not distinguish between sibs and nonsibs from their own rearing groups (O'Hara and Blaustein 1981), but they did exhibit a tendency to associate with familiar sibs over familiar nonsibs in field trials (O'Hara and Blaustein 1985). Taken together, these results suggest that early exposure to siblings is not required for kin recognition, and exposure to nonsibs does not eliminate a preference for associating with sibs. Tadpoles collected from natural aggregations in the field preferred to associate with members of their own aggregations rather than tadpoles from other aggregations (Blaustein and O'Hara 1987). This species forms relatively small aggregations that tend to remain in the same general area for long periods of time. Genetic relationships in these aggregations have not been determined, but it is possible that they are composed largely of siblings from the same egg clutch.

Tadpoles of *R. sylvatica* differ from those of *R. cascadae* in their social behavior. They seldom form aggregations in the field, and when they do so, the aggregations often are composed of large numbers of individuals that could not all be from the same clutch (Waldman 1984). Nevertheless, tadpoles of this species did exhibit some tendency to associate with sibs in laboratory tests, whether they were raised only with sibs or in mixed groups (Waldman 1984; Cornell, Berven, and Gamboa 1989; Fishwald et al. 1990; Rautio et al. 1991). These tadpoles also tended to associate more with familiar sibs with whom they had been reared than with unfamiliar sibs reared in separate tanks (Waldman 1984). These results suggest that familiarity with certain individuals can affect the way in which tadpoles associate with other individuals. Developmental stage can affect kin recognition as well. Rautio et al. (1991) found that 10-day-old *R. sylvatica* tadpoles did not exhibit kin recognition, whereas tadpoles that were at least 17 days old did. These authors also found evidence that tadpoles were positively attracted to siblings, but did not avoid nonsiblings. This contrasts with another set of tests conducted by Waldman (1986a). He observed spacing patterns of *R. sylvatica* tadpoles in laboratory pools and found that they seemed to avoid unrelated conspecifics, rather than being attracted to closely related individuals.

There is limited evidence for some species that kin recognition persists in postmetamorphic anurans. When *Rana cascadae* juveniles were tested in a Y-tube apparatus, they tended to move toward the odors of siblings than toward nonsibs. This preference persisted for up to 47 days after metamorphosis (Blaustein, O'Hara, and Olson 1984). In *R. sylvatica,* juveniles tested within 24 hours of metamorphosis exhibited a tendency to move toward siblings (Cornell, Berven, and Gamboa 1989), but this apparent preference for siblings was not evident several days after metamorphosis (Waldman 1989).

Sensory Mechanisms of Kin Recognition

It seems clear that chemical cues are the principal means of kin recognition in all of these species. Tadpoles probably use visual cues from other swimming tadpoles to locate aggregations of conspecifics and especially to form polarized schools (Wassersug and Hessler 1971; Wassersug 1973; Foster and McDiarmid 1982). Nevertheless, there is no evidence that visual cues provide sufficient information to enable tadpoles to identify close relatives. In laboratory tests with *Bufo americanus, Rana cascadae,* and *R. aurora,* tadpoles moved preferentially toward water containing siblings, even when all visual cues were excluded (Blaustein and O'Hara 1982a; Waldman 1985a; Blaustein et al. 1993). All of the tests of kin recognition in metamorphosed juveniles also were done with an apparatus that excluded all but chemical cues.

The role of chemical cues in the formation of kin aggregations was revealed indirectly in studies of kin recognition in spadefoot toad tadpoles. In *Spea multiplicata,* tadpoles associated preferentially with siblings over nonsiblings, but they also preferred to associate with nonsiblings that had been raised on the same type of food to siblings raised on different food (D. Pfennig 1990b). These results suggested that tadpoles use chemical cues to select preferred feeding patches in a pond. An apparent preference for aggregating with close kin could be due, in part, to this type of habitat selection. Siblings are likely to remain near where they hatched and feed on similar foods, thereby acquiring chemical cues from their food or surroundings. In an experiment with *S. intermontana,* J. A. Hall et al. (1995) found little evidence that tadpoles tend to aggregate with siblings, but they did find a preference for aggregating with tadpoles raised on the same type of food.

The importance of chemical cues from the environment in the development of kin recognition is supported by some unpublished experiments reported by Waldman (1991). Eggs of *Rana sylvatica* were injected with either lemon or orange extract early in development. Tadpoles hatching from these egg clutches subsequently exhibited a preference for the odors to which they initially had been exposed. Waldman also injected eggs with different cultures of algae, which sometimes grow commensally with the eggs of *R. sylvatica.* Again, tadpoles exhibited a preference for the odors of familiar algal cultures. Hence, even though *R. sylvatica* tadpoles exhibit a preference for siblings when they have not been raised with them, it is clear that environmental cues can affect the choices made by tadpoles in laboratory tests.

How Often Do Tadpoles Associate with Kin?

Although the evidence for kin-recognition abilities in tadpoles seems compelling, the importance of such behavior in the field is less clear. Waldman (1982b) and O'Hara and Blaustein (1985) reared sibships of *Bufo americanus* and *R. cascadae* separately in the laboratory, colored them with vital stains, and released them together into natural ponds. Analyses of the spatial distribution of colored tadpoles revealed a tendency to associate with sibs. Such experiments have not been performed with other species. The genetic composition of naturally occurring aggregations of tadpoles or juveniles is not known for any species. Since different sibships cannot be distinguished visually in the field, a genetic analysis using DNA fingerprinting or other molecular techniques would be required to investigate this problem. This would be difficult in species that form aggregations containing individuals from many eggs clutches, because any kinship associations are likely to be manifested as slight statistical differences in spatial distribution within a group. Species that form size-specific aggregations, such *as Hyla geographica* and *Phyllomedusa vaillanti,* would be ideal subjects for such studies, as would species in which schools of tadpoles are attended by a parent. These are species that are mostly likely to live in aggregations consisting mostly or entirely of siblings.

Although tadpoles apparently make fine-scale distinctions between conspecifics, the choices made by tadpoles are not perfect. Indeed, they generally do not approach the level of discrimination exhibited by frogs in species recognition tests using acoustic cues (see chapter 7) or salamanders in sex or species recognition tests using chemical cues (chapter 8). In many of those experiments, nearly 100% of individuals being tested make the correct choice. In contrast, tadpoles being tested for sibling recognition often spent only about 55–58% of their time on the sibling side of a test aquarium (O'Hara and Blaustein 1981, 1982; Blaustein and O'Hara 1982a, 1986). These results are statistically significant with large sample sizes, but do not provide evidence of robust or unanimous preferences for associating with siblings. In field tests with *B. americanus,* about two-thirds of the aggregations sampled differed significantly from a random distribution of sibships. In most of these groups, about 60–70% of the individuals were from the same sibship; none was a pure sibling group (Waldman 1982b). In groups of *R. cascadae* tadpoles that differed significantly from a random distribution of sibships, the average proportion of the more common one was about 72%, and pure sibship aggregations were rare (O'Hara and Blaustein 1985). Thus, even in species with well-developed abilities to recognize kin, individual tadpoles are likely to be in contact with both relatives and nonrelatives under natural conditions. In species such as *Bufo boreas,* which form enormous aggregations of hundreds of thousands of individuals, tadpoles probably have few opportunities to interact with siblings in the field, and kin recognition may not be very important in normal social interactions. The same probably is true for species such as *Phrynomantis microps,* which forms swarms composed of many different sizes of tadpoles. Tadpoles of this species readily aggregate with unrelated individuals in the laboratory (Rödel and Linsenmair 1997).

Grafen (1990b) argued that many examples of apparent kin recognition in tadpoles and other animals actually are a by-product of other recognition systems, such as species or group recognition. His argument is that animals use cues emanating from conspecifics to recognize them as conspecifics or members of a social group. They are attracted to conspecifics for protection against predators, enhancement of foraging, or to locate mates. Animals learn the chemical signatures of other individuals early in their development, or they compare cues coming from their own bodies with those of other individuals (phenotype matching). In either case, close relatives are likely to be more similar to one another than are distantly related individuals. Even in the absence of selection for kin recognition per se, responses to such cues could result in apparent kin recognition in laboratory and spatial associations between siblings in the field. Grafen's paper generated some debate (see Blaustein et al. 1991; Byers and Beckoff 1991; R. Stuart 1991; and replies by Grafen 1991a, b, c), but Blaustein et al. (1991) agreed that it often would be difficult to distinguish true kin recognition from recognition that is a by-product of species recognition. Grafen's argument is consistent with the relatively weak kin recognition observed in several species of tadpoles, and the lack of evidence for pure-sibling groups in natural aggregations. His interpretation also is consistent with the results of studies with spadefoot toad tadpoles that suggest that aggregation with kin is a by-product of habitat selection.

Why Aggregate with Close Kin?

Explanations for the preferential aggregation of tadpoles with siblings generally have involved kin-selection models in which group formation itself is favored by kin selection. However, some species exhibit a preference for siblings in the laboratory, but have few opportunities to preferentially associate with kin in the field (e.g., O'Hara and Blaustein 1982; Blaustein and O'Hara 1986), so such models must be treated cautiously. Most authors have assumed that any benefits realized by individuals living in groups will be enhanced by aggregating with kin, but actual fitness benefits of such behavior have not been well documented (Blaustein 1988; Blaustein et al. 1991; Waldman 1991; Blaustein and Walls 1995). It also has been proposed that an ability to recognize siblings developed in the tadpole stage might carry over into adulthood, possibly to be used in avoiding mating with close relatives (Blaustein, O'Hara, and Olson 1984). Convincing evidence to support this hypothesis is lacking, although other types of kin recognition by adult anurans are possible (Waldman, Rice, and Honeycutt 1992).

Antipredator Benefits

Two principal kin-selection models of tadpole aggregation both relate to protection from predators. One hypothesis is that distasteful tadpoles benefit from grouping with close kin, because even those individuals sampled by predators will benefit if close relatives are saved (Wassersug 1973; Waldman and Adler 1979; Waldman 1982b; J. Peterson and Blaustein 1991). Alternatively, it has been proposed that tadpoles enjoy inclusive fitness benefits by transmitting warnings of predator attacks to close relatives. This could either occur through physical transmission of a fright reaction, or through release of "warning pheromones" (Blaustein and O'Hara 1981; O'Hara and Blaustein 1981, 1985; Waldman 1982b; Hews and Blaustein 1985). The only rigorous test of this hypothesis with a relatively social species of tadpole was work by Hokit and Blaustein (1995) on *Rana cascadae* tadpoles. They failed to find any evidence for an alarm response to injured tadpoles. The alarm reaction hypothesis assumes that chemical substances eliciting a fright reaction in tadpoles are pheromones that evolved specifically as warning signals. If so, then tadpoles would gain greater fitness benefits if these signals were directed toward relatives. Another possibility is that tadpoles have evolved a behavioral reaction to any chemicals released from injured skin, but the chemicals have other functions and are not produced specifically as warning pheromones. In that case, a kin selection model is not required, because there is no cost associated with production of the signal. At present, the nature of the alarm pheromone in tadpoles is unknown.

Another way of looking at this problem is to assume that aggregation per se has not evolved through kin selection, but when selective pressures such as predation and a shortage of food favor group life, then aggregating with kin may minimize the costs of such behavior. When the benefits of group life greatly exceed the costs, then one might expect tadpoles to form large aggregations of both relatives and nonrelatives, as undoubtedly occurs in many species of *Bufo*. In these species, the ability to recognize kin may not be fully utilized (e.g., *Bufo boreas;* O'Hara and Blaustein 1982). When there are few selective pressures favoring group formation, then any tendency to associate with siblings in laboratory tests are expected to be relatively weak, because the tadpoles derive few benefits from such behavior (e.g., *Rana aurora;* Blaustein and O'Hara 1986).

When selection favors group formation, there can be distinct advantages to aggregating with individuals of a similar size. As pointed out by L. Branch (1983), size-specific schooling is very common in other organisms such as fishes. Individuals that differ in size from most of their companions are more conspicuous to predators. They also are at a disadvantage in fleeing from predators if they cannot move at the same speed (e.g., Mueller 1971, 1975; Milinski 1977; Hobson 1978; N. Wolf 1985; Ranta and Lindström 1990; Ranta, Lindström, and Peuhkuri 1992; Pitcher, Magurran, and Edwards 1985; Pitcher, Magurran, and Allan 1986; Peuhkuri 1997; Peuhkuri, Ranta, and Seppä 1997). There also could be advantages in grouping with similar-sized individuals if large tadpoles out-compete smaller ones through behavioral interference (Faragher and Jaeger 1998).

One way for tadpoles to insure size-specific aggregation is to associate preferentially with conspecifics, which are likely to be more similar in size than are members of other species. Indeed, multispecies aggregations of tadpoles have not been reported in the field, even in situations in which several species live in the same pond. Griffiths and Denton (1992) reported that tadpoles of *Bufo bufo,* a relatively social species, were attracted to tadpoles of both *B. calamita* and *Rana temporaria* in laboratory tests when no other tadpoles were present, but exhibited a somewhat greater attraction to conspecific tadpoles. Nevertheless, when given a choice between an aggregation of conspecifics and one containing *R. temporaria* tadpoles, the *B. bufo* tadpoles did not exhibit a clear preference for conspecifics, even though the *Rana* tadpoles were considerably larger. When given a choice between conspecifics and *B. calamita* tadpoles, the *B. bufo* tadpoles actually showed a slight preference for heterospecific tadpoles. Tadpoles of *B. calamita* are somewhat smaller than are those of *B. bufo,* so the reason for this preference is unclear. Griffiths and Denton (1992) did not present any evidence of mixed-species aggregations in nature.

Given that most tadpoles seem to aggregate mainly with conspecifics, then they could further increase the probability of aggregating with tadpoles of similar size if they associated with siblings from the same egg clutch, because these tadpoles are likely to have hatched at the same time. Preferences for siblings observed in laboratory and field tests could be the result of individuals avoiding nonsiblings because they are more likely to be of a different size, and might have little to do with a preference for kin per se. In a laboratory test of chemical cues used in kin recognition, Waldman (1985b) found that *B. americanus* tadpoles showed no preference for sibling odor over pure water, but preferred pure water to nonsibling odor. This indicates that they are repelled by nonsiblings, but are not necessarily strongly attracted to siblings. Chemical cues need not provide information about size per se. A preference for sibling odors could develop simply if this is most likely to result in tadpoles finding themselves with individuals of similar size.

If preferential aggregation with siblings is mainly a strategy to ensure size-specific grouping, then one might expect kin preferences to be weakly developed in many explosive breeders, because most tadpoles in a pond will be of similar size. Such abilities might be more strongly developed in tadpoles of prolonged breeders, which would be exposed to conspecifics of various sizes. This might explain the relatively imperfect discrimination of many of the species tested to date, most of which are explosive breeders. Unfortunately, in North America, schooling tadpoles tend to be most common among explosive breeders that use ephemeral breeding sites, so these predictions are difficult to test. Again, some of the tropical species that have prolonged breeding seasons and form size-specific aggregations, such as *Hyla geographica,* would be the most appropriate ones for testing this hypothesis.

If predation is the major force favoring group formation, then size-specific aggregation, and possibly kin recognition, also should be most strongly developed in permanent-water species exposed to visually hunting predators that actively search for prey, such as fishes. *Hyla geographica,* which breeds in permanent lakes and rivers with predatory fishes, is one possible example. If the major predators on tadpoles are sit-and-wait predators that do not necessarily select prey by size, then size-specific aggregation may not be favored. For example, tadpoles of the African frog *Phrynomantis microps* are preyed upon mostly by insects, and these tadpoles tend to form aggregations that are not sorted by size (Rödel and Linsenmair 1997). Unfortunately, possible antipredator benefits of size-specific aggregation have not been tested experimentally with tadpoles. For example, there have not been any studies comparable to those with fish to determine whether predators preferentially select the "odd" tadpole in a group. Instead, most studies of predation on tadpoles have focused on the effect of tadpole size or developmental stage on vulnerability to predation, with tadpoles of similar size being presented to predators simultaneously (see chapter 14 for further discussion).

Effect of Kin Association on Growth and Development

Various authors have suggested that tadpoles aggregate with kin because of beneficial effects on growth and development. Unfortunately, it is difficult to predict exactly how aggregating with kin will affect growth and development toward metamorphosis. Waldman (1991) suggested that in dense aggregations of tadpoles, as might occur in a temporary pond in the process of drying up, smaller tadpoles might gain inclusive fitness benefits by aggregating with kin and allowing their own growth to be stunted in favor of larger, faster growing siblings. Other authors have argued that aggregating with kin might ameliorate the effects of intraspecific competition, thereby allowing all individuals in an aggregation to grow more rapidly or reach a larger size at metamorphosis. In fact, experimental studies of the effect of kin association on growth and development have produced evidence of both positive and negative effects of living with kin.

In a study of chorus frog tadpoles (*Pseudacris triseriata*), a species not known to form kin-based aggregations, D. C. Smith (1990) found that tadpoles reared with siblings grew more rapidly than did those raised with nonsiblings. Similar results were obtained in a study of *Bombina variegata* tadpoles, another species not known to form kin-based aggregations (Jasienski 1988). In contrast, tadpoles of *Rana arvalis,* a species that sometimes forms aggregations of unknown composition, grew larger when reared with nonsiblings than with siblings (Shvarts and Pyastolova 1970a). A preliminary study of *Rana cascadae,* a species that sometimes aggregates with close relatives, showed that siblings raised together at high density had lower body mass than did nonsiblings raised under the same conditions (Hokit and Blaustein 1994). Later, a more thorough study of the same species in which tadpoles were raised in field enclosures revealed complex interactions between the effects of kinship, type of substrate, and larval density on growth and development. Under some conditions, tadpoles reared with siblings had higher survivorship than did those raised with nonsiblings, but they also tended to be smaller, especially at high densities (Hokit and Blaustein 1997). Pakkasmaa and Aikio (2003) found relatively weak effects of kinship on growth and development of *Rana temporaria* tadpoles, and the effect of kinship interacted with density. Tadpoles of an Indian frog, *Rana temporalis,* had faster growth rates and reached larger metamorphic size when reared in single sibships than when reared in mixed groups, but only at high density (Girish and Saidapur 1999a). Sib groups also had shorter larval periods and were more likely to reach metamorphosis at high density than were nonsib groups (Girish and Saidapur 2003). In contrast, developmental and metamorphic traits of another Indian frog, *Tomopterna breviceps,* were unaffected by kinship (Gramapurohit et al. 2004). Waldman (1986b) reported both positive and negative effects of kin association on growth rates of *Bufo americanus* tadpoles, with some families experiencing enhanced growth and others retarded growth. Taken together, these studies demonstrate that kinship can affect the growth and development of tadpoles, but in ways that depend on other ecological factors and on larval density. These studies do not provide convincing evidence that species of tadpoles that form aggregations consistently benefit from aggregating with close relatives.

Kin Recognition and Cannibalism in Tadpoles

Studies of kin association among tadpoles have produced relatively little clear evidence that tadpoles derive fitness advantages from aggregating with close relatives, as opposed to forming aggregations with randomly related individuals. One type of behavioral interaction for which the benefits of kin recognition seem more predictable is cannibalism by conspecifics. Kin selection theory clearly predicts that when tadpoles or salamander larvae cannibalize other members of their population, they are likely to derive inclusive fitness benefits from recognizing close relatives and refraining from eating them (D. Pfennig 1997). In addition, there are direct benefits from not eating close relatives, such as reduced chances of transmitting diseases through cannibalism.

D. Pfennig, Reeve, and Sherman (1993) tested for kin recognition in tadpoles of *Spea bombifrons,* one of the species that sometimes develops a carnivorous morph. In a test of kin association, omnivores spent about 60% of their time close to siblings, compared to 43% for carnivores. These results suggest that carnivores actually avoid being in close proximity to their relatives. Carnivores that consumed other tadpoles were much more likely to eat nonsiblings (77% of the tadpoles consumed) than siblings (23%). The tendency to avoid eating siblings broke down, however, if the carnivores were very hungry. Subsequent work showed that carnivores of this species are much more likely to eat conspecifics than are omnivores, so the carnivores clearly represent a greater danger to their own siblings than do omnivores (D. Pfennig and Frankino 1997). Tadpoles of *S. bombifrons* also were more likely to develop into carnivores when they were raised alone than when they were raised with siblings, but they were not more likely to do so than when raised in mixed groups of siblings and nonsiblings. Tadpoles of another species, *S. multiplicata,* were more likely to develop into carnivores when reared in mixed groups rather than pure sibling groups.

Tadpoles of *S. bombifrons* exhibit a greater tendency to develop into carnivores than do tadpoles of *S. multiplicata,* and the former also exhibit a stronger avoidance of kin as prey (D. Pfennig 1999). Different sibships *of S. multiplicata* also vary in their propensity to become carnivores. Members of sibships that showed a strong tendency to become carnivores also exhibited the strongest avoidance of kin as prey. When some of these carnivores reverted to the omnivore morph, however, they no longer avoided eating siblings, but as omnivores, they were much less likely to eat any tadpoles, and therefore represented a less serious threat to their relatives. Taken together, these results suggest that the expression of kin recognition in spadefoot toad tadpoles is context-dependent and varies according to the danger that individual tadpoles pose to their relatives.

Kin Recognition, Cannibalism, and Aggression in Salamander Larvae

Salamander larvae differ from many tadpoles in being relatively solitary and actively avoiding contact with conspecifics, so aggregations of closely related larvae are not expected, except in situations where dispersal from a nest site is minimal (e.g., R. N. Harris et al. 2003). The antisocial behavior of salamander larvae probably is related to widespread aggressive competition among larvae of many species of salamanders, as well as opportunistic cannibalism and the formation of specialized cannibalistic morphs in some populations. As with cannibalistic tadpoles, kin selection is expected to favor kin recognition in aggressive or cannibalistic salamander larvae, because the larvae derive inclusive fitness benefits from directing aggression or cannibalism differentially toward nonrelatives (D. Pfennig 1997). Cannibalistic larvae of *Ambystoma t. nebulosum* recognize close relatives and prefer to feed on unrelated individuals if they are available (D. Pfennig, Sherman, and Collins 1994). The presence of close relatives also can inhibit the development of cannibalistic morphs (D. Pfennig and Collins 1993).

There are two possible advantages to preying preferentially on nonrelatives. The first is a reduction in the inclusive fitness cost that would be incurred if relatives were consumed (the kin selection hypothesis). The second is the possibility that larvae are more susceptible to pathogens carried by close relatives, perhaps because they share similar immune systems (D. Pfennig, Ho, and Hoffman 1998; the disease avoidance hypothesis).

D. Pfennig, Collins, and Ziemba (1999) performed a series of experiments to distinguish between the kin selection and disease avoidance hypotheses for the evolution of kin recognition in tiger salamanders. Contrary to expectation, they found that cannibals were more likely to contract disease after eating nonrelatives than after eating relatives. Larvae did not show any tendency to avoid diseased prey, and in fact, preferred such prey because they were easier to catch. Finally, larvae from populations where disease was prevalent did not exhibit any greater kin discrimination than did those from disease-free populations. All of these results indicate that disease avoidance does not favor the evolution of kin recognition. In contrast, those individuals that did discriminate between kin and nonkin as prey had more surviving siblings than did nondiscriminators, indicating that kin recognition is favored by kin selection. The cost of kin discrimination was low, because growth and survival were similar in discriminators and nondiscriminators.

Kinship influences the behavior of other species of salamander larvae as well, but not always in the way observed in *A. tigrinum nebulosum.* Larvae of *Ambystoma opacum* were less aggressive and more submissive toward siblings of a similar size than toward nonsiblings (Walls and Roudebush 1991). The ability to recognize siblings persisted after metamorphosis, but degree of familiarity with other individuals appeared to have a greater impact on aggressive interactions than did kinship (Walls 1991). Later studies showed that larvae of this species actually preferred to eat siblings rather than nonsiblings when they were much larger than their prey (Blaustein and Walls 1995), but the reason for this unexpected preference is unclear. A complex laboratory experiment did reveal that kinship did not, by itself, influence either aggression between larvae or larval performance, but interactions between kinship, larval density, and food availability did have a significant effect (Hokit, Walls, and Blaustein 1996). These results indicate that the expression of kin recognition and the effect of kinship on larval fitness depend on ecological context, but the fitness consequences of kin recognition in *A. opacum* are less clear than for highly cannibalistic populations of *A. tigrinum.* When larvae were raised in field enclosures, kinship did not affect larval performance, even though growth and size were affected by density (Walls and Blaustein 1994). Another species, *A. gracile,* did not exhibit clear evidence of kin recognition (Blaustein and Walls 1995). Larvae of this species are aggressive toward conspecifics, but cannibalism is relatively rare.

Summary and Conclusions

Larval amphibians essentially function as independent organisms with adaptations quite different from those of adults. This is particularly true of anuran tadpoles. Although the basic morphological structure of larvae is well known for most groups of amphibians, the study of larval ecology and behavior is still in its infancy. The work of Wassersug and others has shown how much can be learned about the ecology of tadpoles from considerations of functional morphology. Tadpoles adapted for generalized suspension feeding, midwater plankton feeding, or feeding on large food particles exhibit strikingly different configurations of the buccal pump and associated feeding structures. However, many of the inferences about relationships between morphology and feeding ecology are based on anecdotal accounts of feeding behavior. Detailed observational and experimental studies of tadpole feeding behavior in the field and laboratory are needed to supplement the wealth of information available on tadpole morphology. This is particularly true for some of the tropical species with unusual morphological adaptations.

A striking feature of anuran tadpole evolution is the frequent occurrence of convergent evolution of similar morphology in tadpoles from distantly related families that live in similar environments. Striking examples include the repeated evolution of very similar suction devices to hold onto rocks in fast-moving water (Lamotte and Lescure 1989a, b; Haas and Richards 1998), the evolution of similar body and tail fin morphology in nektonic tadpoles in different families (Altig and Johnston 1989), and the repeated reduction of mouthparts and other structures in egg-eating tadpoles that live in bromeliads and other phytotelmata (Lannoo, Townsend, and Wassersug 1987; Schiesari, Grillitsch, and Vogl 1996). Ecomorphological studies of tadpoles also have shown that tadpole morphology can be relatively plastic and can evolve rapidly in response to differences in larval habitats. For example, stream-dwelling tadpoles often exhibit morphological adaptations for life in fast-moving water that are absent in closely related members of the same genus (Iwasawa and Saito 1989; Inger 1992). Similar divergence is seen in egg-eating tadpoles when compared with pond-breeding relatives (Schiesari, Grillitsch, and Vogl 1996). Even within species, there can be considerable morphological plasticity, ranging from relatively minor differences between pond- and stream-dwelling populations (Jennings and Scott 1993) to within-population differentiation of omnivorous and carnivorous morphs and variation among populations in the frequency of these morphs (D. Pfennig and Frankino 1997).

Because salamander larvae are less diverse in their morphological and ecological adaptations, their ecology has received less attention than that of tadpoles. However, the idea that salamander larvae are simply aquatic equivalents of adults because they are at the same trophic level (Duellman and Trueb 1986) is clearly an oversimplification. While it is true that both larval and adult salamanders are carnivorous, the larvae often undergo ontogenetic changes in diet as they grow. In addition, the shift from an aquatic to terrestrial habitat often is accompanied by rather dramatic changes in prey selection. For example, larval *Gyrinophilus porphyriticus* feed mainly on aquatic invertebrates, whereas adults prey on adult salamanders of other species (Bruce 1979, 1980; see chapter 13 for further discussion). In part, this shift in diet reflects the availability of prey in different microhabitats. However, it also is related to morphological differences that make larvae better at capturing prey in water, whereas transformed individuals are more adept at capturing prey on land (Lauder and Shaffer 1986). Additional studies of ontogenetic changes in microhabitat selection and feeding behavior of both urodele and anuran larvae would add considerably to our understanding of their ecology.

The study of social behavior in larval amphibians, particularly anuran tadpoles, also is just beginning. There are now many descriptive accounts of aggregations and schooling behavior in tadpoles, as well as abundant speculation about the functions of such groups, but careful experimental studies of the effects of grouping on feeding behavior and predator avoidance are almost nonexistent. There is intriguing evidence that interaction among close relatives is an important component of tadpole social behavior. The nature of cues used to recognize close relatives, as well as the ontogeny of kin recognition, are now partially understood for a few species, but the prevalence of kin recognition in the thousands of species of tadpoles around the world is completely unknown. Many of the species studied to date have only moderately social tadpoles; tropical species that appear to exhibit close aggregation of kin groups many provide more interesting examples of kin recognition in the future. As in the case of grouping behavior in general, the adaptive significance of kin recognition for tadpoles in the field is poorly understood. Several speculative hypotheses have been proposed, related either to enhanced growth or protection from predators, but as yet there are few definitive tests of these ideas. The most convincing evidence for an adaptive advantage to kin recognition comes from studies of kin discrimination in relation to cannibalism in both tadpoles and salamander larvae.

Chapter 13 Complex Life Cycles and the Ecology of Amphibian Metamorphosis

Amblystoma*'s a giant newt who rears in swampy waters*
As other newts are wont to do, a lot of fishy daughters:
These Axolotls, having gills, pursue a life aquatic,
But, when they should transform to newts, are naughty and erratic.

They change upon compulsion, if the water grows too foul,
For then they have to use their lungs, and go ashore to prowl:
But when a lake's attractive, nicely aired, and full of food,
They cling to youth perpetual, and rear a tadpole brood.

And newts Perennibranchiate have gone from bad to worse;
They think aquatic life is bliss, terrestrial a curse.
They do not even contemplate a change to suit the weather,
But live as tadpoles, breed as tadpoles, tadpoles altogether.
—Walter Garstang, "The Axolotl and the Ammocoete" (1985)

WALTER GARSTANG'S verse nicely illustrates both the complexity and variability of amphibian life cycles. Indeed, amphibians are unique among tetrapods in the complexity of their life cycles and the degree to which their life cycles vary in response to environmental conditions. Amphibians are not so unusual, however, when all groups of animals are considered. Werner (1988) estimated that at least 80% of all animals have complex, multistage life cycles, including the most successful lineages of insects and most marine invertebrates (see also B. Hall and Wake 1999). Most amphibians have a standard life cycle in which eggs are laid in water and hatch into aquatic larvae. These larvae then feed, grow, and develop in the water until they eventually metamorphose into terrestrial or semiaquatic adults. Yet, as discussed in chapter 10, many amphibians have abandoned the aquatic stages of their life cycles and have evolved reproductive modes that make them more or less independent of water. Other species, like the axolotl described in Garstang's poem (the current name for this animal is *Ambystoma*), have lost the terrestrial portion of the life cycle and retain at least part of their larval morphology as sexually mature adults. This variability in amphibian life histories suggests that the advantages of a complex life cycle vary with environmental conditions. In this chapter, I begin by considering the evolution and maintenance of a complex life cycle from an ecological perspective, including interspecific variation in the length of the larval period in relation to environmental conditions. Next, I discuss proximate determinants of larval life history traits, including growth rates, the timing of metamorphosis, and size at transformation. I also discuss the importance of phenotypic plasticity as an adaptive response to variable environments. Finally, I consider the evolutionary loss of metamorphosis in paedomorphic amphibians and the adaptive significance of this type of life history.

The Adaptive Significance of Complex Life Cycles

In the previous chapter, I reviewed a number of morphological and behavioral adaptations of amphibian larvae, particularly as they relate to feeding ecology. A key question that needs to be considered is why amphibians have a larval stage at all. Certainly part of the answer is related to the evolutionary history of amphibians. A complex life cycle with a free-living aquatic larva is considered by most investigators to be the ancestral condition in all three major lineages of amphibians (Hanken 1999a; R. N. Harris 1999; Reiss 2002). Nevertheless, the course of larval evolution has diverged in these three clades. Both urodeles and caecilians have larvae that resemble adults in basic morphology. The larvae undergo gradual developmental changes as they make the transition from aquatic larvae to terrestrial adults, but they do not undergo the very dramatic metamorphosis seen in anurans. This lack of dramatic metamorphosis is related to the absence of a major shift in diet from the larval stage to the adult. In both of these groups, larvae and adults are carnivorous, very likely the ancestral condition for all amphibians. Individuals often exhibit ontogenetic shifts in size or type of prey as they grow, but the basic diet remains the same. Most anurans, on the other hand, undergo a relatively rapid and dramatic change from a largely herbivorous diet to an entirely carnivorous one. This major shift in diet in turn requires a major rearrangement of organ systems and external morphology.

Caecilians, urodeles, and anurans also differ in their tendency to exhibit evolutionary loss of a complex life cycle. Most caecilians have evolved a specialized lifestyle as terrestrial, burrowing animals. The most successful lineages have lost the aquatic larval stage altogether, shifting either to direct development of terrestrial eggs or to viviparity (see chapter 10). In those caecilians that retain a complex life cycle, the larvae often are not very different from adults ecologically. Most species hatch at a relatively advanced stage of development, and the larvae of some species have become amphibious like the adults, rather than being strictly aquatic (see chapter 12). Urodeles exhibit two opposing evolutionary trends. Among plethodontids, loss of the aquatic larval stage and the evolution of direct development occurred several times, and the lineages that are most successful in terms of numbers of species all have direct development (see chapter 10). Other urodeles have gone in the opposite direction, eliminating the terrestrial adult stage and becoming paedomorphic, retaining at least some larval features throughout life. Direct development has evolved many times among anurans as well. Some lineages have become very successful, possibly as a result of losing the aquatic larval stage (e.g., *Eleutherodactylus*). A few species have become viviparous (see chapter 10). Nevertheless, most anurans have retained a complex life cycle, even in species in which feeding by larvae has been reduced or eliminated. What accounts for the widespread persistence of aquatic larvae in anurans?

The anuran tadpole almost certainly represents a derived type of larval morphology, although a relatively ancient one. The ancestors of modern frogs are assumed to have had a larva much more like that of urodeles, with gradual morphological changes rather than rapid and dramatic metamorphosis (Wassersug and Hoff 1982; R. N. Harris 1999; Reiss 2002). Nevertheless, tadpoles with morphology like that of modern forms have been around at least since the Cretaceous, and probably evolved much earlier (Hanken 1999a). The marked difference in morphology and diet of tadpoles and adult anurans suggests that anurans actually have evolved a more complex life cycle, with selection having favored morphological and ecological divergence of larvae and adults.

In an influential paper, Istock (1967) argued that complex life cycles are inherently unstable. He assumed that populations of larvae and adults were independently regulated, and he developed a model of population growth rates derived from the logistic equation and incorporating information on age-specific mortality and fecundity. He argued that if factors regulating either larval or adult populations are relaxed, then selection should favor the loss of one stage or the other. In the case of amphibians, life histories would tend to move either toward loss of the larval stage and direct development (chapter 10) or retention of a permanent larval morphology (paedomorphosis). Hence, he considered the maintenance of complex life cycles in many amphibians, especially anurans, to be a paradox.

Istock's model was criticized on a number of grounds relating to both the mathematical treatment and its biological assumptions (Bryant 1969; Slade and Wassersug 1975; Wassersug 1975; Strathmann 1978; Wilbur 1980; Werner 1988; Ebenman1992). A number of amphibian biologists have argued that complex life cycles are maintained because of the unique ecological role of the aquatic larval stage, particularly in anurans. Their conclusions are based in part on an analogy with many holometabolous insects, in which nearly all of an individual's growth takes place in the larval stage, with the adult serving mainly for dispersal and reproduction. For example, Wassersug (1975) argued that typical anuran tadpoles are essentially eating machines adapted for rapid utilization of food sources that undergo rapid seasonal fluctuations. Complex life cycles are therefore most likely to be maintained under a regime of short-term environmental fluctuations (e.g., alternating cold and warm or wet and dry seasons). Loss of one stage of the life cycle is more likely when either the aquatic or terrestrial environment becomes more stable. Because morphological constraints prevent the development of a functional reproductive system in an anuran tadpole, only the larval stage can be lost in this group. Similarly, Wilbur (1980) argued that amphibian larvae are adapted for exploiting opportunities for rapid growth by taking advantage of seasonal flushes of primary productivity in aquatic environments. Adults, on the other hand, were viewed as being adapted for survival through unfavorable seasons and dispersal to new breeding sites (see also Wilbur and Collins 1973).

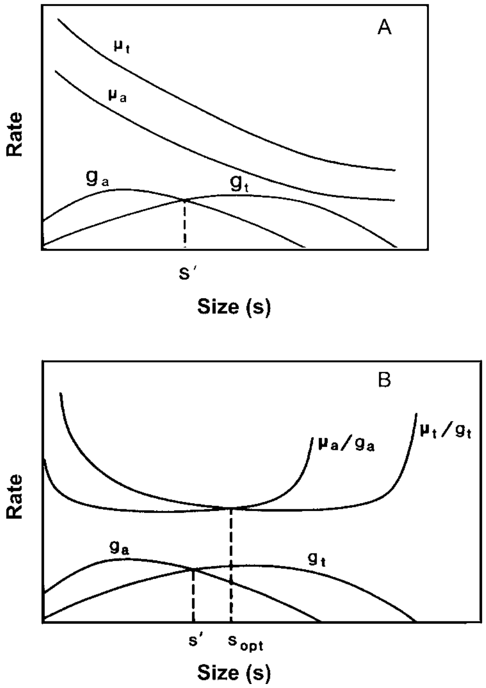

Fig. 13.1. Werner's model of amphibian metamorphosis as an ontogenetic niche shift. (A) Hypothetical size-specific rates of growth (g) and mortality (μ) in the aquatic (a) and terrestrial (t) habitats. The size at metamorphosis that maximizes growth across the entire life history is given as s′. (B) Ratios of mortality to growth (μ/g) in the aquatic (a) and terrestrial (t) environments. The optimum size at metamorphosis (s_{opt}) is shifted to the right toward a larger size than s′ and represents the size at which the ratio of mortality to growth in the aquatic environment surpasses the ratio in the terrestrial environment. After Werner (1986).

Amphibian Metamorphosis as an Ontogenetic Niche Shift

The Wassersug-Wilbur model is an appealing one, and for some time was the standard explanation for the maintenance of complex life cycles in amphibians (e.g., Duellman and Trueb 1986). It is, however, heavily influenced by work on frogs that breed in temporary ponds, and probably oversimplifies the evolution of complex life cycles in general. It is not clear, for example, that all larval habitats experience an initial flush of productivity, as originally proposed by Wassersug (R. N. Harris 1999). Furthermore, Werner (1986, 1988) pointed out that most of an individual's growth to adult size usually takes place after metamorphosis, not before. For example, *Rana catesbeiana* has one of the longest larval periods and the largest size at metamorphosis of any North American frog, yet a transforming juvenile is only 4% of the mass of an adult. Werner estimated that in most anurans, more than 90% of growth occurs in the terrestrial phase. So common is this pattern that one species that does complete most of its growth in the tadpole stage has been named the "paradox frog" (*Pseudis paradoxa;* Emerson 1988b). Werner also cited examples of metamorphosed juveniles actually growing more rapidly than aquatic larvae. Hence, the strict dichotomy between larval growth and adult dispersal stages does not seem to apply to most amphibians.

Building on the arguments of Wassersug (1975), Wilbur (1980), and others, Werner (1986, 1988) focused attention on the shift in an amphibian's ecological niche as it makes the transition from the larval to the terrestrial stage. This type of ontogenetic niche shift is widespread even among animals that increase in size during development, even those that do not change habitats or undergo dramatic metamorphosis (Werner and Gilliam 1984). In contrast to previous models of complex life cycles, which focused on the effects of age-specific mortality and growth, Werner proposed a model based on changes in size-specific mortality and growth, because both of these variables tend to be more affected by size than by age in amphibians.

Werner proposed that the costs and benefits of living in the water or on land depend on the size-specific growth and mortality rates experienced in both habitats. If the timing of metamorphosis was simply a function of growth rate, then larvae should transform when size-specific growth rates in the terrestrial environment are expected to exceed those in the aquatic environment (fig. 13.1 A). However, if size-specific mortality rates vary in the two environments as well, then the optimum time for metamorphosis changes, depending on the trade-off between growth and mortality rates (fig. 13.1 B). Werner's model indicates that lifetime fitness is maximized for prereproductive individuals when the ratio of mortality to growth rates is minimized. Therefore, an individual should remain in the larval habitat as long as this ratio is lower in the water, and metamorphose at the size at which this ratio first becomes lower for the terrestrial habitat (fig. 13.1 B). This prediction is independent of the source of mortality. For example, if breeding sites are highly ephemeral, then selection will favor early transformation because the ratio of mortality to growth in the aquatic environment will exceed that in the terrestrial environment, even at small body sizes (i.e., all larvae will perish if they remain in the pond). On the other hand, larvae in a more permanent pond might have prolonged larval periods if aquatic predators are scarce, but short larval periods and smaller sizes at transformation if size-specific predation rates in the aquatic environment exceed those in the terrestrial environment.

Several authors have modified and expanded upon Werner's original model. Jackson and Semlitsch (1993), in a study of paedomorphosis in *Ambystoma talpoideum,* criticized Werner's (1986) model and earlier ones for not including tradeoffs in reproduction. This is particularly relevant to paedomorphic species, which sometimes can reproduce earlier by staying in the water as paedomorphic adults instead of transforming and moving onto land (see subsequent discussion of paedomorphosis). Ludwig and Rowe (1990) and L. Rowe and Ludwig (1991) expanded Werner's model to include consideration of reproduction in species that always metamorphose, such as anurans. They explored the effects of time constraints on the timing of metamorphosis and the optimum size at metamorphosis. In essence, they argued that metamorphic timing and optimum size should vary, depending on the time between metamorphosis and reproduction. In species with short breeding periods that occur at a fixed time after metamorphosis, individuals that metamorphose at a small size probably will not have time to catch up with those that metamorphose at a large size before reproducing. When reproduction is prolonged, on the other hand, metamorphosing at a small size to escape aquatic predators or enhance growth rates might not be a disadvantage, because small individuals eventually reach a large size before reproducing. As in Werner's model, however, the precise point at which metamorphosis is favored depends on the balance of size-specific growth and mortality rates in aquatic and terrestrial habitats.

Ebenman (1992) incorporated genetic correlation between larval and adult morphological traits into a model of life-history evolution based on ecological niche shifts. His main focus was the initial evolution of a complex life cycle with pronounced metamorphosis, like that of anurans, from a life cycle with less dramatic morphological change between stages. He argued that when larvae and adults make use of very different resources in different habitats, their ability to use resources efficiently often is constrained by genetic correlation between larval and adult morphology. Such constraints are evident in the feeding behavior of salamanders, for example, because morphological features of the hyoid apparatus that are required for suction feeding in water limit the evolution of tongue projection in adults (D. Wake 1982). Ebenman (1992) showed that selection can favor the disruption of such constraining genetic correlation, leading in turn to divergence in larval and adult morphology. Once evolved, this type of complex life cycle, with morphologically distinct larvae undergoing dramatic metamorphosis into adults, is thought to be more stable than the type of life cycle seen in urodeles. Hence, this type of life cycle is less likely to evolve toward reduction or elimination of either the larval or adult stage (see R. N. Harris 1999, for a somewhat similar model). From a mechanistic point of view, the evolution of complex life cycles like those of anurans can result in different developmental programs guiding the formation of larval and adult morphology (Alberch 1987, 1989; Elinson 1990; Hanken, Jennings, and Olsson 1997; Hanken 1999a). From an evolutionary perspective, a complex life cycle with metamorphosis can be seen as an adaptation that permits independent responses of different life history stages to selective pressures in different environments (Werner 1988, Ebenman 1992; R. N. Harris 1999).

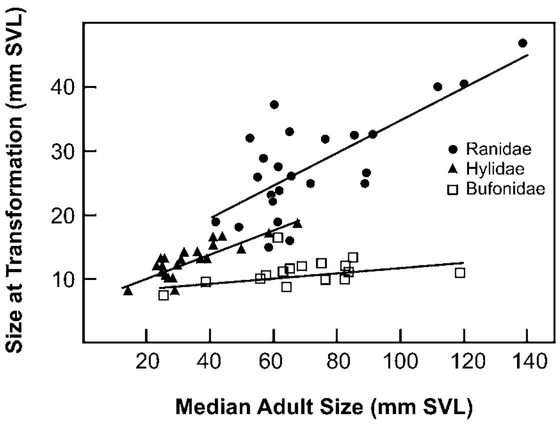

Fig. 13.2. Size at metamorphosis as a function of median adult size for three families of North American anurans. Ranids transform at a relatively large size compared to adult body size, and size at metamorphosis is positively correlated with adult body size. Bufonids always transform at a very small body size, regardless of adult body size. Hylids are intermediate. After Werner (1986).

Interspecific Variation in Length of the Larval Period

Ontogenetic niche shift models are particularly useful in explaining interspecific differences in the length of the larval period and the size of individuals at metamorphosis. They also can be applied to different populations of a species, because selection can favor different life history strategies in different environments. Werner (1986) pointed out that North American ranid frogs show a positive correlation between adult body size and size at metamorphosis (fig. 13.2). The largest ranids tend to breed in permanent water and remain in the larval stage for more than a year (e.g., Collins 1979a). Tadpoles of many large ranids appear to be unpalatable to aquatic predators (Walters 1975; Kruse and Francis 1977; Formanowicz and Brodie 1982; Morin 1983a; Woodward 1983; Kruse and Stone 1984) and eventually grow to a size that allows them to escape most predators. They also exhibit behavioral responses to predators that reduce the chances of being eaten (see chapter 14). On the other hand, they are vulnerable to a variety of predators on land and will be subjected to the physical stresses of a terrestrial environment. Selection will favor remaining in the larval stage as long as the mortality/growth ratio in the aquatic environment is lower than in the terrestrial environment. Smaller species, such as wood frogs (*Rana sylvatica*), typically metamorphose at a smaller size than do large species, and they also are more likely to use temporary ponds that periodically dry up. In these species, selection favors a relatively short larval period, regardless of the mortality risks to terrestrial juveniles and adults (Werner 1986).

In contrast to ranids, North American bufonids show little or no correlation between adult body size and size at metamorphosis. All species transform at a small size (fig. 13.2), and juveniles of a large species, such as *Bufo alvarius,* are similar in size to those of a smaller species, such as *Bufo americanus.* Most toads breed in temporary water, so a short larval period is favored regardless of conditions in the terrestrial environment. Even those that breed in permanent water typically metamorphose at a relatively small size, so pond hydroperiod is not the only determinant of the length of the larval period.

North American spadefoot toads (*Scaphiopus* and *Spea*), which often breed in even more ephemeral pools than do toads, have extremely rapid rates of development (R. Newman 1987, 1988a, b, 1989, 1994; Pfennig, Mabry, and Orange 1991). In contrast, Old World spadefoot toads (*Pelobates*) have more prolonged breeding seasons and breed in more permanent ponds. They have longer larval periods and metamorphose at larger sizes than do tadpoles of *Spea* or *Scaphiopus.* There also are phylogenetic differences between the two North American genera that do not correspond precisely to differences in permanence of breeding habitats. The two species of *Scaphiopus, S. couchii* and *S. holbrookii,* have shorter larval periods and smaller size at metamorphosis than do species of *Spea,* even though some of the latter breed in desert rainpools (Buchholz and Hayes 2000, 2002).

There are costs associated with small transformation size that probably limit how small a metamorphosing anuran can be. Juvenile toads (*Bufo*) have poorly developed lungs and low aerobic capacities compared to adults, but this is not true of ranids that metamorphose at a larger size (Taigen and Pough 1981; Pough and Kamel 1984; see also chapter 5). Short larval periods also can be associated with incomplete morphological development at metamorphosis. For example, in both *Bufo americanus* and a hylid with relatively rapid development, *Pseudacris crucifer,* the middle ear is poorly developed at metamorphosis, whereas in ranids, the ear of metamorphosing juveniles is very similar to that of the adult (Hetherington 1988b). Small metamorphic size also can be disadvantageous in dry environments, such as deserts, because of the more rapid rate of evaporative water loss in small individuals (R. Newman and Dunham 1994).

Werner's model also is consistent with the life histories of various salamanders, although he did not discuss these in detail. For example, the plethodontid salamander *Gyrinophilus porphyriticus* inhabits a variety of permanent aquatic habitats, including springs, seepage areas, and headwater streams in moist forests (Bruce 1979). This species has a remarkably long larval period, lasting up to four years in some locations, and larvae are larger in relation to adult body size than those of most other plethodontid salamanders (Bruce 1972b, 1978b, 1979, 1980). Most larvae metamorphose at about the same size (Bruce 1980). Although both larvae and adults utilize the same aquatic habitats, adult salamanders take some of their food on land and exhibit a marked shift in diet at metamorphosis. Larvae are dietary generalists, feeding mainly on invertebrates and smaller salamander larvae; adults feed heavily on adults of other salamander species. Bruce (1979, 1980) suggested that selection has favored a prolonged larval period because this allows the salamanders to reach a size at which they are effective predators on other salamanders. This fits very well with Werner's view that metamorphosis should occur at an optimum size for shifting from an aquatic to a terrestrial niche, but is hard to explain solely as a function of larval growth. Many salamanders, including one species of *Gyrinophilus,* have gone a step further and have abandoned metamorphosis altogether. These salamanders exhibit a life history known as paedomorphosis, in which larval characters are retained in a reproductive adult. This type of life history has evolved frequently enough in the urodeles (there are no paedomorphic anurans) to suggest a major cost to maintaining a dual life cycle under certain ecological conditions. This topic is discussed in more detail at the end of the chapter.

Werner's ontogenetic niche shift model and those derived from it are essentially evolutionary models that are useful in understanding the selective pressures that have led to major differences in larval life history traits among species or populations. For example, these models allow us to make at least qualitative predictions about the range of sizes at metamorphosis and lengths of larval periods that can be expected in amphibians that breed in permanent ponds, semipermanent ponds, or ephemeral rain pools, and in habitats with different densities of predators. These models are less useful for predicting how individual larvae will respond to different environmental conditions. Aquatic larvae have no way of anticipating rates of growth and mortality on land and comparing these with growth and mortality in the water. They can only respond to conditions as they encounter them in the aquatic environment (R. N. Harris 1999). In some circumstances, deteriorating conditions in the water probably are accompanied by unfavorable conditions on land as well. For example, a rapidly drying pond is likely to be surrounded by relatively hot and increasingly dry terrestrial habitat. Nevertheless, larvae have no chance of surviving if a pond dries up completely, so they often will be forced to move into an unfavorable environment, and not necessarily one in which the growth to mortality ratio improves dramatically.

Although Werner's model postulates relatively fixed ages and sizes at metamorphosis within populations, he readily acknowledged that life-history traits such as timing of metamorphosis and size at metamorphosis often are not fixed for a given species, but show considerable plasticity. Much of the research on amphibian life cycles has been devoted to understanding the proximate determinants of rates of growth and development of larvae, the timing of metamorphosis, and the size of individuals at metamorphosis within populations.

Divergent Approaches to the Study of Amphibian Metamorphosis

The process of metamorphosis has been studied both by developmental biologists and ecologists, but these two disciplines traditionally have approached the problem from very different perspectives, with minimal interaction between these fields. Developmental biologists have been concerned mainly with processes of morphogenesis, the regulation of gene expression, and the hormonal control of development (Etkin 1968; Dodd and Dodd 1976; B. White and Nicoll 1981; H. Fox 1984; Kikuyama et al. 1993; Denver 1996; Kaltenbach 1996; Tata 1996, 2005; C. Rose 1999; Shi 2000). A few representative species, such as *Rana catesbeiana, R. pipiens, Xenopus laevis,* and *Ambystoma tigrinum,* have been used as model systems for understanding development in all amphibians. This work has led to a very detailed understanding of metamorphosis at the level of genes, cells, and tissues. Generally the process is viewed as an orderly sequence of steps culminating in the transformation of an aquatic larva into a terrestrial adult, with little attention to environmentally induced variation in larval growth and development. Several methods have been devised to describe the stages of larval development (see Just, Kraus-Just, and Check 1981 for a review). The staging table for *Bufo valliceps,* shown in fig. 13.3, was developed by Gosner (1960) and is derived from the embryonic staging table of Shumway (1940) and the widely used staging table for *Rana pipiens* tadpoles published by A. Taylor and Kollros (1946). Staging procedures for salamander larvae are less standardized, and different authors have characterized development in different ways (Just, Kraus-Just, and Check 1981).

While developmental biologists have become increasingly reductionist in their approaches to amphibian metamorphosis (e.g., Shi 2000), ecologists have been more concerned with the way in which the environment impinges upon and modifies the basic program of larval development (Wilbur and Collins 1973). Staging tables such as those in fig. 13.3 are based on groups of tadpoles raised at constant temperatures with unlimited food. These tables often include estimates of larval size and age at each stage, giving the impression of highly predictable rates of development. However, amphibian larvae in nature are exposed to variable conditions that can affect growth rates, length of the larval period, and size at metamorphosis. Laboratory workers have long recognized that rearing conditions, including temperature, larval density, and food abundance, can have major effects on rates of growth and differentiation (see Salthe and Mecham 1974 for an early review). Amphibian larvae often respond to environmental cues such as larval density, food abundance, and pond drying by altering their developmental trajectories, either speeding up or slowing down progression toward metamorphosis in ways that presumably enhance their fitness. Ideally, one should attempt to combine the perspectives of developmental biologists and ecologists to provide new insights into the evolution of amphibian life history strategies and the proximate determinants of plastic developmental responses, but such connections have been made only recently (e.g., Denver 1995, 1997a, b; C. Rose 2005).

Hormonal Control of Metamorphosis

A detailed discussion of the physiology of metamorphosis is beyond the scope of this book, but a brief overview of hormonal control will be useful for understanding ecological aspects of metamorphosis. This summary is based on several general reviews that can be consulted for additional details (Etkin 1964, 1968, 1970; Frieden and Just 1970; M. Dodd and Dodd 1976; B. White and Nicoll 1981; Hourdry and Beaumont 1985; Kikuyama et al. 1993; Denver 1996; Kaltenbach 1996; Tata 1996; C. Rose 1999; Shi 2000; Denver, Glennemeier, and Boorse 2002; Tata 2005).

The Role of Thyroid Hormones

The timing of critical events in amphibian development ultimately is under genetic control, but gene expression is mediated by hormone action. Larval development involves both growth (an increase in mass) and differentiation (structural changes in tissues and organs leading to metamorphosis), and different hormones control the two processes. It has been known since early in this century that metamorphosis is initiated by thyroid hormones. Thyroid-mediated metamorphosis probably is an ancestral trait for all amphibians, but we do not have complete data to test this hypothesis. Both anurans and urodeles have thyroid-mediated metamorphosis, but very little is known about metamorphosis in caecilians (C. Rose 1999). Thyroid-mediated metamorphosis also is found in teleost fishes that undergo pronounced metamorphosis (de Jesus, Toledo, and Simpas 1998; Schreiber and Specker 1998; Yamano and Miwa 1998; Solbakken et al. 1999). On the other hand, in lampreys, metamorphosis is not triggered by a rise in thyroid hormones (Youson 1997). The closest living relatives of amphibians, the lungfishes and coelacanths, are not much help. Very little is known about coelacanth reproduction, but they are thought to be live bearers. Hormonal control of lungfish development is not well understood, but these animals do not undergo a dramatic metamorphosis and appear to be neotenic (Joss et al. 1997; Joss 1998).

A simplified diagram of the production pathways and regulatory interactions of thyroid hormones and other

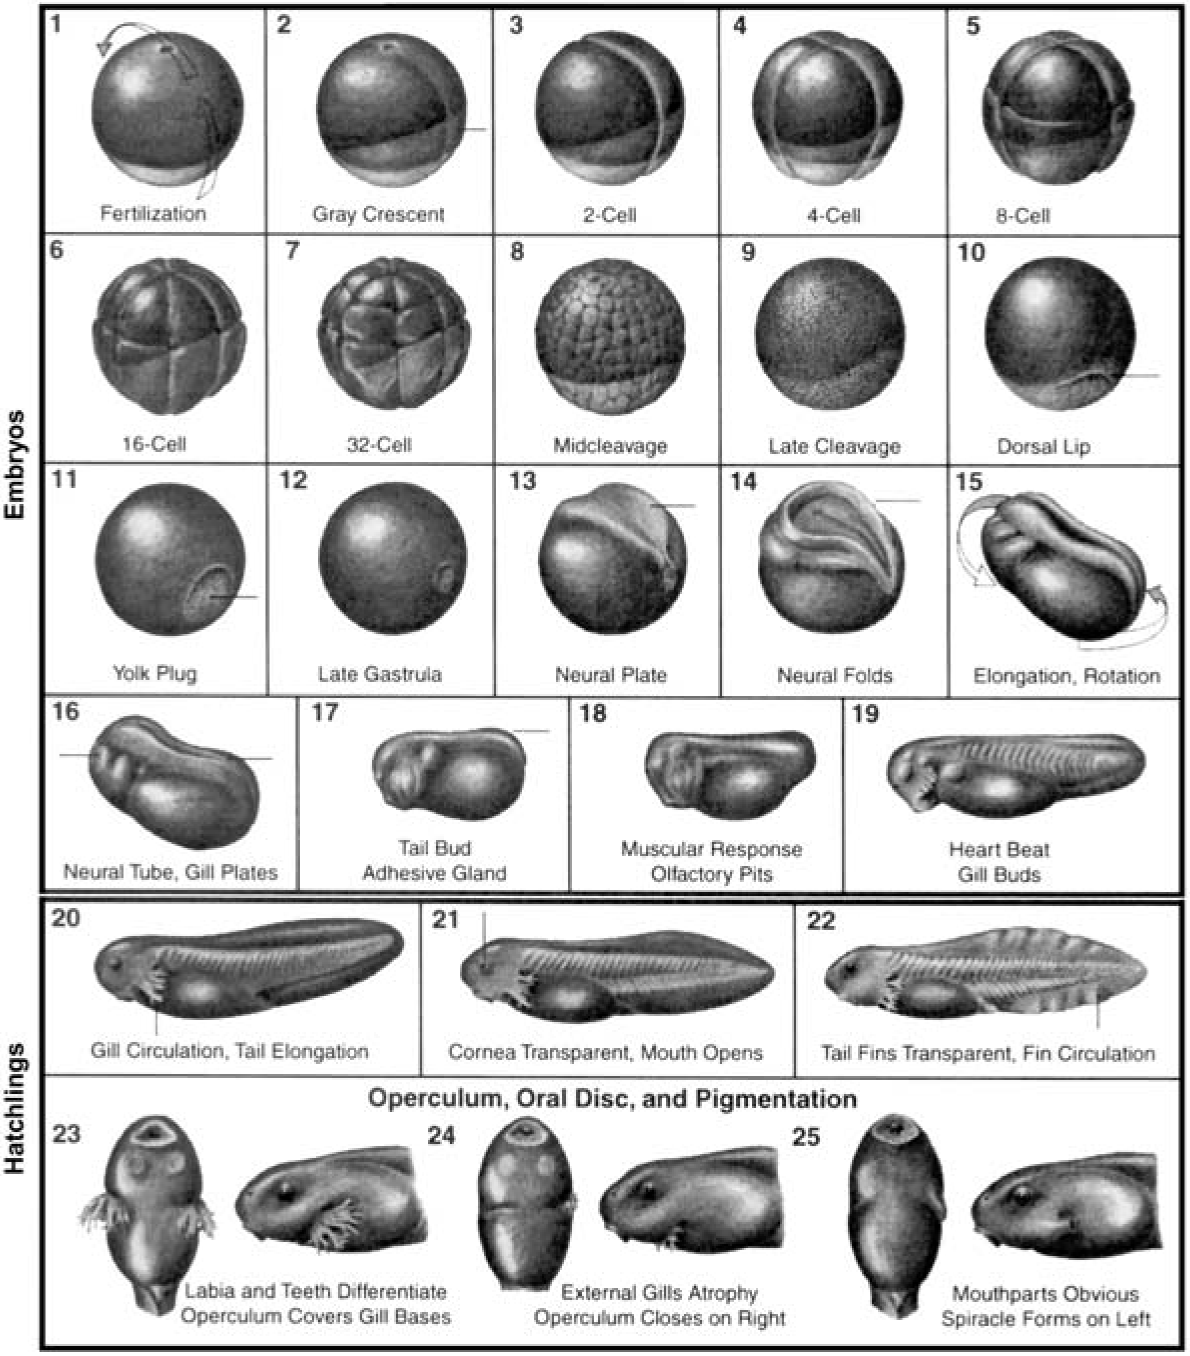

Fig. 13.3. Gosner (1960) staging system for anuran tadpoles. These stages are based on Bufo valliceps raised at 25° C. Stages 1–19 are embryonic stages, although hatching can occur as early as stage 16 in some anurans. Hatchling stages (20–25) represent the transition to an active, feeding tadpole. External gills disappear by the end of the hatchling period, and the spiracle (opening from internal gill chamber) appears. Mouthparts used in feeding also appear. Stages 26–41 are tadpoles, which undergo extensive growth and develop limbs. Metamorphs (stages 41–46) have fully developed legs, and eventually reabsorb the tail. After McDiarmid and Altig (1999).

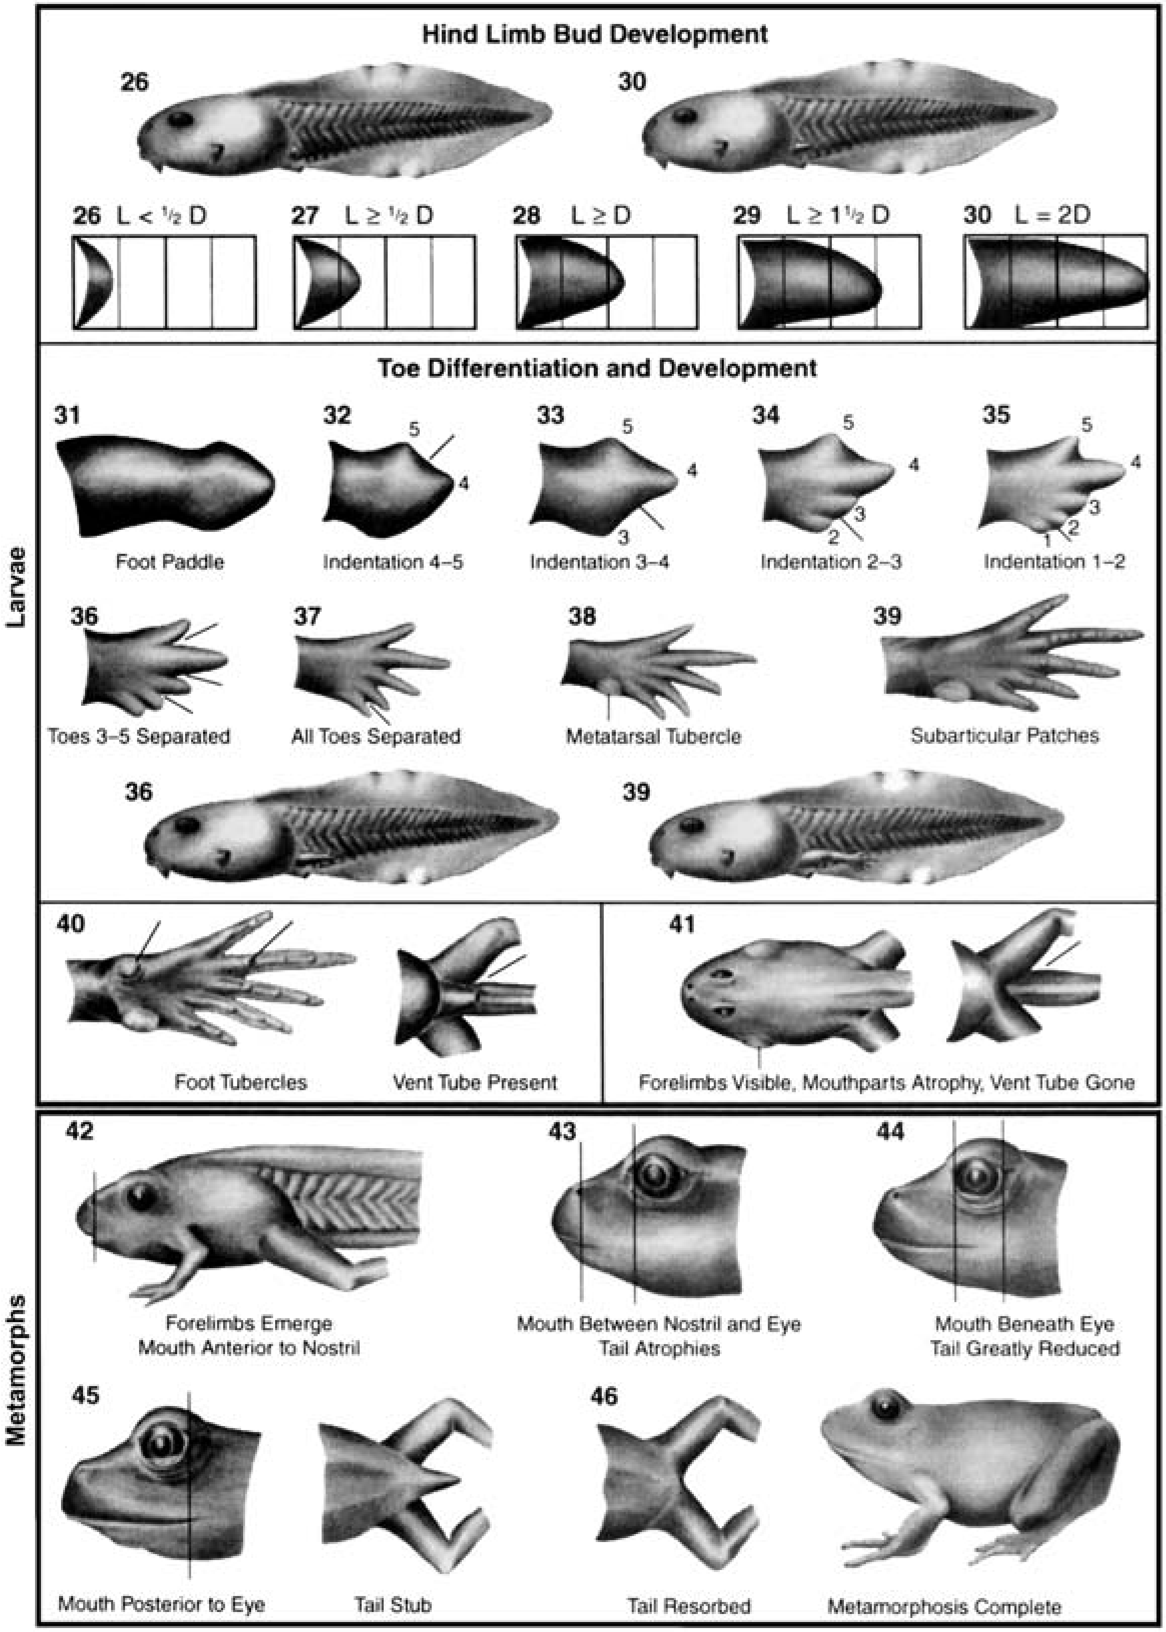

Fig. 13.3. (continued)

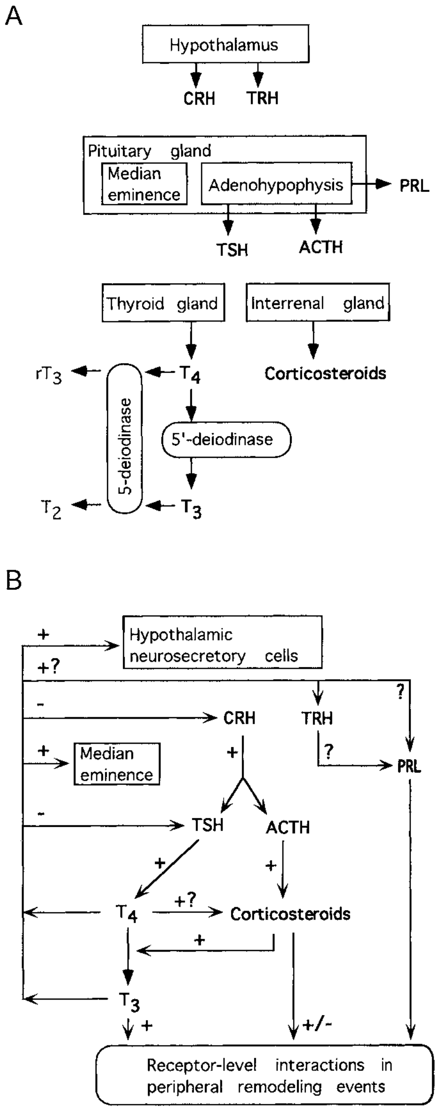

Fig. 13.4. Production pathways and regulatory interactions of thyroid hormones, corticosteroid hormones, and prolactin in tadpoles. (A) Endocrine glands involved in hormone production and their products. (B) Stimulatory (+) and inhibitory (–) effects of these hormones on gland maturation, hormone production and processing pathways, and tissue responses. Abbreviations: ACTH = adrenocorticotropin; CRH = corticotropin-releasing hormone; PRL = prolactin; TRH = thyrotropin-releasing hormone; TSH = thyroid-stimulating hormone; T_2 = diiodothyronine; T_3 = triiodothyronine; T_4 = thyroxine. After C. S. Rose (1999).

hormones that affect amphibian metamorphosis is shown in fig. 13.4. Early in development, the thyroid gland is small and relatively inactive. The production of thyroid hormones is regulated by thyroid-stimulating hormone (TSH) produced in the pituitary, which in turn is regulated by production of corticotropin-releasing hormone (CRH) in the hypothalamus (Denver 1996; Denver, Glennemeier, and Boorse 2002). Initially, the part of the hypothalamus that releases CRH is relatively small. It increases in size and activity in response to low levels of thyroid hormones in the blood, and levels of CRH begin to rise. Circulating levels of thyroid hormones are very low in the earliest stages of tadpole development, but they increase during prometamorphosis and peak at metamorphic climax (Kaltenbach 1996). At the same time, the sensitivity of target tissues to thyroid hormones increases and also peaks at metamorphosis, but the timing of sensitivity peaks varies in different tissues. The action of thyroid hormones is mediated by interactions with several other hormones, including prolactin, which is produced by the pituitary gland, and corticosterone, produced by the adrenal glands (T. Hayes 1997).

The Role of Prolactin

Growth is stimulated by prolactin and possibly other hormones secreted by the pituitary. Apparently this occurs because prolactin increases intestinal absorption of amino acids and glucose from digested food (Frye, Brown, and Snyder 1972). The action of prolactin and thyroid hormones is antagonistic at the level of the target tissues, and treatment of tadpoles with mammalian prolactin can have inhibitory effects on metamorphosis. These results lead Etkin (1968) to propose a model of metamorphosis that predicted that circulating levels of prolactin would be high early in development and decrease as tadpoles progressed toward metamorphosis, resulting in low levels of this hormone at the time when thyroid hormones are high. This model was widely adopted as the standard model of amphibian metamorphosis (e.g., Bentley 1982; Duellman and Trueb 1986; Beachy, Surges, and Reyes 1999). Subsequent work has shown this model to be incorrect, because circulating levels of prolactin increase during development and peak in late metamorphic climax (Kikuyama et al. 1993; Kaltenbach 1996), as does expression of the gene that encodes prolactin (Buckbinder and Brown 1993). Rather than inhibiting production of prolactin, thyroid hormones have been shown to increase circulating levels of prolactin late in development (K. Kawamura, Yamamoto, and Kikuyama 1986; Denver 1996). Prolactin does not appear to affect the timing of metamorphosis, but it does mediate the effects of thyroid hormones on particular target tissues (Denver 1996). For example, prolactin can inhibit some, but not all, of the programs of tail resorption in *Xenopus* tadpoles (Huang and Brown 2000; Tata 2005).

Interaction between Hormones and Environmental Cues

While this overview is simplified, it indicates how growth and differentiation are regulated by interactions among different endocrine glands and the target tissues. What is less well understood is how environmental factors impinge on this regulatory process. Changes in temperature, food availability, or larval density could affect the production of hormones by the endocrine glands, the regulating function of the hypothalamus, the sensitivity of the target tissues to different hormones, or a combination of all three. For example, low temperature is known to inhibit production of thyroxin and reduce the sensitivity of target tissues to this hormone (Kollros 1961; Etkin 1964, 1968; Smith-Gill and Berven 1979). Starvation can inhibit both growth and differentiation, although not necessarily to the same degree (Pandian and Marian 1985a). Hence, there is ample opportunity for environmental variables to influence both duration of the larval period and body size at metamorphosis.

As discussed in more detail in the next section, many anuran tadpoles exhibit considerable plasticity in the timing of development and size at which individuals metamorphose. A number of species exhibit accelerated metamorphosis under deteriorating environmental conditions, such as pond drying (R. Newman 1992). Ecological models of metamorphosis are based on the assumption that larvae can alter their rates of development in response to environmental conditions such as pond drying, increased competitor density, or decreasing food supplies (Wilbur and Collins 1973). Most ecologists, however, have paid little attention to the link between environmental cues and the hormonal control of metamorphosis, and most development biologists have not considered environmental factors at all.

Corticotropin-releasing hormone (CRH) provides a possible link between certain types of environmental stress, such as pond drying, and the hormonal control of metamorphosis (fig. 13.5). In all vertebrates, CRH functions as a general stress hormone that stimulates production of corticosterone in the adrenal glands. This hormone in turn stimulates escape reactions and other behavioral and physiological responses to stressful conditions. In tadpoles, CRH has been shown to activate both adrenal and thyroid hormone secretion (Denver 1995, 1997a, b; Boorse and Denver 2004; C. Rose 2005). One effect on tadpoles that are close to metamorphosis is an increase in foraging behavior and increased mobilization of energy reserves, which in turn can accelerate growth and development (Crespi and Denver 2004, 2005). In addition, CRH stimulates increased production of thyroid hormones and facilitates conversion of thyroxine to a more potent thyroid hormone, triiodothyronine (T. Hayes and Wu 1995). Circulating levels of CRH and corticosterone have been shown to increase dramatically in tadpoles in response to pond drying (Denver 1998; Boorse and Denver 2004), increased density of competitors (T. Hayes 1997; Glennemeier and Denver 2002), and restricted food availability (Boorse and Denver 2004; Crespi and Denver 2005). When tadpoles of *Bufo, Spea,* and *Rana* were treated with CRH, metamorphosis was significantly accelerated compared to untreated controls (Denver 1993, 1997a, b; Miranda, Affani, and Paz 2000). Similar results were obtained in experiments with *Ambystoma tigrinum,* indicating a common mechanism for anurans and urodeles (Boorse and Denver 2002). Taken together, these studies provide a plausible mechanistic explanation for the ability of tadpoles to assess environmental conditions and alter their development in ways that increase their chances of survival.

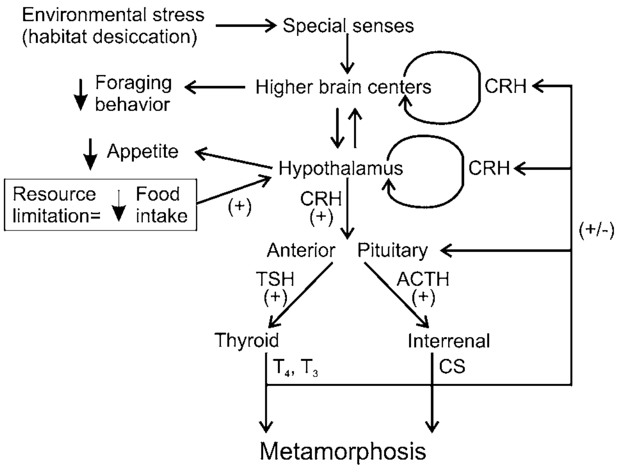

Fig. 13.5. A model for the interaction of environmental stress factors, especially pond drying, with the hormonal control of metamorphosis in tadpoles. The stress of pond drying is sensed through special senses, which have yet to be determined. This stress activates extrahypothalamic corticotropin-releasing hormone (CRH) neurons, which then reduce foraging behavior. Activation of CRH neurons in the hypothalamus reduces appetite. Hypothalamic CRH stimulates pituitary thryoid-stimulating hormone (TSH) and adrenocorticotropic hormone (ACTH) secretion, which in turn stimulates the production of thyroid hormones (TH) and corticosteroid (CS) hormones that promote metamorphosis. After Denver (1997a).

Another way in which the environment could affect the hormonal control of metamorphosis is through variation in larval diet (Kupferberg 1997c). When tadpoles are fed on a high protein diet, they grow faster than those fed on low protein diets, and they metamorphose earlier as well. Much of this difference is no doubt due to the direct effect of improved nutrition on growth and development, but it is possible that diet quality has an indirect effect on metamorphosis through its effect on hormone function. In other vertebrates, the activity of an enzyme that converts thyroxine to triiodothyronine is mediated by the availability of dietary protein. Diet quality in natural populations of *Pseudacris regilla* tadpoles in California has been shown to affect larval growth and development. Tadpoles with access to filamentous green algae covered with epiphytic diatoms had shorter larval periods and metamorphosed at a larger size than did tadpoles that did not have access to diatoms (Kupferberg, Marks, and Power 1994). Diet also can affect other aspects of development, such as the development of specialized carnivorous or cannibalistic morphs in spadefoot toad (*Spea*) tadpoles and tiger salamander (*Ambystoma tigrinum*) larvae (see chapter 12). Unfortunately, there has not yet been a study of thyroid hormone levels in relation to variation in tadpole diets that would establish the link between diet and hormone function (C. Rose 2005).

The Ecology of Amphibian Development and Metamorphosis

Ecologists have long been interested in the way in which environmental factors influence the growth and development of amphibian larvae (e.g., R. Savage 1952, 1961; Salthe and Mecham 1974). It was not until the 1970s, however, that a conceptual framework for understanding larval development and metamorphosis was developed. The starting point for modern discussions of the ecology of amphibian metamorphosis is a model developed by Wilbur and Collins (1973; see R. N. Harris 1999, for a detailed review). Wilbur and Collins were mainly concerned with explaining why individual larvae in the same population and even the same age cohort often differ dramatically in growth rate, the length of the larval period, and size at metamorphosis. They proposed that the timing of metamorphosis is related to larval growth rates and physical condition, these being proximate physiological cues that allow an individual larva to assess the relative costs and benefits of remaining in the larval stage or emerging onto land. Larval growth, in turn, is influenced both by physical factors such as temperature and by larval density and food availability. This model has been very influential in studies of amphibian metamorphosis, but it has been applied to the development of other organisms as well, including insects (Bradshaw and Johnson 1995; Peckarsky et al. 2001), copepods (Twombly 1996), barnacles (Hentschel and Emlet 2000), and fishes (Reznick 1990).

Elements of the Wilbur-Collins Model

The essential features of the Wilbur-Collins model are as follows. Amphibian larvae raised in isolation exhibit an initial period of nearly exponential growth, followed by a decrease in growth rate and eventually a reduction in mass at metamorphosis. In a natural population, individuals vary in growth rate. Faster-growing individuals will enjoy a head start over their companions, and this translates into competitive superiority throughout the larval period. This produces a skewed distribution of body sizes in the population, with many individuals remaining small while a few reach larger sizes.

Wilbur and Collins postulated that each species has a characteristic minimum size that must be reached before metamorphosis can occur, as well as a maximum size that cannot be exceeded in the larval stage because of increasing inefficiencies in feeding (fig. 13.6). They predicted that when resources are abundant, larvae grow quickly, and most reach the maximum size before transforming. Consequently, variation in the length of the larval period and size at metamorphosis will be minimal. When resources are scarce, both the average size at metamorphosis and the range of variation will change with larval density. Competitively superior individuals will be the first to reach the minimum metamorphic size. Because conditions are unfavorable for growth, these larvae are expected to transform at or near the minimum size. Others, having been released from competition with larger conspecifics, eventually reach metamorphic size, but only after a longer larval period. If the breeding pond lasts long enough, some late-transforming larvae reach a larger size at metamorphosis because of reduced competition. However, in temporary ponds, many larvae cannot reach metamorphic size before the water disappears.

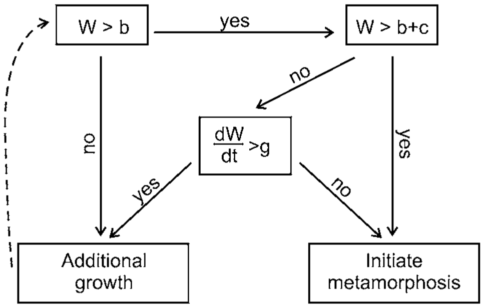

Fig. 13.6. Graphical representation of the Wilbur-Collins model of amphibian metamorphosis. The model postulates that larvae must reach a minimum threshold size (b) before they can undergo metamorphosis. Metamorphosis must occur before the larvae reach a maximum size (b + c), at which it is no longer possible to remain in the larval stage. The probability of undergoing metamorphosis depends upon larval body size (W) and size-specific growth rate (dW/dt). If larvae have reached a body size that exceeds the minimum size for metamorphosis (W > b), but have not yet reached the maximum larval size (b + c), then they are expected to continue growing if recent growth rates are high (dW/dt > g). If recent growth rates are low (dW/dt < g), where g is some function of current body mass, then they are expected to metamorphose. After Wilbur and Collins (1973).

Day and Rowe (2002) developed a more formal mathematical model with many of the same elements as the Wilbur-Collins verbal model. Specifically, they examined the effect of developmental thresholds on the response of larvae to changes in environmental conditions. Their results were largely consistent with the Wilbur-Collins model. They pointed out that a developmental threshold, such as the minimum size required for metamorphosis postulated by Wilbur and Collins, has the effect of reversing the growth response to poor resource availability. Below the threshold for metamorphosis, larvae are expected to respond to low food levels by slowing rates of growth and development, thereby lengthening the larval period. Above the size threshold, larvae are expected to respond to slow growth rates brought about by low food availability by accelerating development and metamorphosing as quickly as possible. This model is consistent with the findings of Crespi and Denver (2004) that stress hormones, which increase when food levels are reduced, stimulate foraging and accelerate growth and development in tadpoles nearing metamorphosis, but do not affect foraging by tadpoles in earlier stages of development.

Empirical Evidence for Variation in Larval Growth Rates

Many studies have established that individual larvae grow at different rates, even when raised under identical conditions (Wilbur 1984). In some species, individuals that initially have slow growth rates never catch up with faster-growing larvae (Travis and Trexler 1986), but in other species, they do (Semlitsch and Caldwell 1982). Life-history traits such as larval growth rate, length of the larval period, and size at metamorphosis all are affected by genetic differences among individuals, leading to consistent differences in performance among sibships (Travis 1980a, 1981, 1983a; Berven and Gill 1983; Płytycz et al. 1984; Travis, Emerson, and Blouin 1987; Blouin 1992; Semlitsch 1993; Girish and Saidapur 1999b; G. R. Smith 1999; Laurila, Karttunen, and Merilä 2002). These phenotypic differences translate into competitive differences among individuals or different capacities to escape predation (Travis 1980b, 1983b; Travis, Keen, and Juilianna 1985a, b; Travis and Trexler 1986). Experiments in which half-sibs were raised under identical conditions have shown that both paternal and maternal genotypes influence phenotypic characters related to larval fitness (Woodward 1986; Travis, Emerson, and Blouin 1987; R. Newman 1988a; Semlitsch 1993). In some studies, maternal effects were of relatively minor importance (Travis 1983b; Travis and Trexler 1986; Travis, Emerson, and Blouin 1987; Laurila, Karttunen, and Merilä 2002) or diminished as the larvae grew (R. Newman, 1988a).

Nongenetic maternal effects can be important as well. Variation in egg size and energy content within and among females has been documented in a number of species (Kuramoto 1978; R. Kaplan 1980, 1985; Crump 1981b, 1984a; Travis 1983a), but the importance of such variation for larval fitness is poorly understood. The effect of variation in egg size is discussed in more detail in chapter 10, and only a brief summary will be given here. Kaplan (1980, 1985) found that *Ambystoma* and *Taricha torosa* larvae that hatched from large eggs grew more rapidly and transformed at a larger size than did those from smaller eggs. In most studies, however, egg size had relatively little effect on the length of the larval period (see examples in table 10.7 in chapter 10). It is more common for egg size to influence the size of larvae at hatching and at first feeding, but differences often disappear by metamorphosis (e.g., Semlitsch and Gibbons 1990). In one study of natterjack toads (*Bufo calamita*) in Spain, egg size was positively correlated with the size of hatchlings when they began to feed, but this variation did not have any effect on survivorship or size at metamorphosis (Tejedo and Reques 1992). Berven and Chadra (1988) examined the effects of egg size, density, and food level on larval development in wood frog tadpoles (*Rana sylvatica*). Tadpoles that hatched from large eggs had shorter larval periods, but only at relatively low densities. There was no direct effect of egg size on size at metamorphosis, but there were complex interactions between egg size and both density and food abundance. At low density, tadpoles that hatched from small eggs metamorphosed at a larger size than did those from large eggs, but the pattern was reversed at high density. Overall, tadpoles derived from large eggs were less sensitive to the effects of density than were those derived from small eggs. In a study of *Salamandra salamandra,* which gives birth to larvae rather than laying eggs, larger size at birth translated into faster development and larger size at metamorphosis, although the effect was mediated by environmental factors such as temperature and food availability (Alcobendas, Buckley, and Tejedo 2004). Taken together, these studies suggest that genetic and nongenetic variation among individuals in a larval cohort is sufficient to produce the asymmetries in body size and competitive ability required by the Wilbur-Collins model, but the sources of such phenotypic variation vary considerably among species.

Intraspecific Competition and Density-Dependent Growth

Studies of Anuran Tadpoles

The effects of intraspecific competition on larval growth and metamorphosis have been investigated in both the laboratory and field for many species of anurans. Many laboratory studies have shown that tadpoles raised under crowded conditions have slower growth rates, longer larval periods, and smaller sizes at metamorphosis than those raised at lower densities (Adolph 1931; Lynn and Edelmann 1936; Richards 1958; S. Rose 1960; Licht 1967; Pourbagher 1969; Heusser 1972a, b; Gromko, Mason, and Smith-Gill 1973; Wilbur 1977a, b; Smith-Gill and Gill 1978; Crump 1981a; Semlitsch and Caldwell, 1982; Berven and Gill 1983; Petranka 1984d; A. Sokol 1984; Travis 1984; Pandian and Marian 1985a, b; Berven and Chadra 1988; Cummins 1989; G. R. Smith 1999; Buchholz and Hayes 2000; Tejedo, Semlitsch, and Hotz 2000; Morey and Reznick 2001; Saidapur and Girish 2001; Girish and Saidapur 2003; Gramapurohit, Veeranacoudar, Shanbhag, and Saidapur 2004). Manipulation of food levels while density is held constant produces similar results, with tadpoles having longer larval periods and smaller size at metamorphosis when provided with small amounts of food (Travis 1984; Berven and Chadra 1988; Semlitsch 1993; Hotz et al. 1999; Laugen, Laurila, and Merilä 2002) or low quality food (Álvarez and Nicieza

2002a). Some of these studies have used densities of tadpoles that seem unrealistically high for natural populations of the species being studied (e.g., G. R. Smith 1999), but others have used more natural densities (e.g., Wilbur 1977a, b). Nevertheless, laboratory studies are somewhat biased toward discovering competitive effects because of the highly simplified environment in which the tadpoles are raised (see Skelly and Keisecker 2001).

Several workers have raised tadpoles at different densities in field enclosures, cattle tanks, or natural pools, with similar results (Brockelman 1969; Wilbur 1971, 1972, 1976; Wilbur and Collins 1973; D. C. Smith 1983; Travis 1983b; Travis, Keen, and Juilianna 1985a; Travis and Trexler 1986; R. Newman 1987, 1989; Warner, Dunson, and Travis 1991; Goater 1994; Tejedo and Reques 1994b; Altwegg 2002). Typically, as initial density increases, larval growth rates decrease (fig. 13.7). Not only does size at metamorphosis decrease with increasing density, but the variance in size at metamorphosis changes as well. At high densities, most larvae remain very small, while a few continue to grow and reach metamorphic size (fig.13.8; Wilbur and Collins 1973; Wilbur 1976). At lower densities, most of the tadpoles reach a relatively large size, and variation is reduced. In some cases, survivorship of tadpoles is reduced at high densities as well (Warner, Dunson, and Travis 1991). Similar density effects have been found in experiments designed to examine interspecific competition among two or more species of tadpoles; these experiments are discussed in chapter 15.

Semlitsch and Caldwell (1982) found that *Scaphiopus holbrookii* tadpoles raised at high densities in the laboratory actually transformed at a larger mean size than those raised at intermediate densities. They attributed this to lower survivorship at high densities, with the survivors being released from competition and resuming growth. In experiments with *Hyla gratiosa* tadpoles raised individually in separate containers, Travis (1984) showed that low food levels had the same effect on larval growth, length of the larval period, and mean size at metamorphosis as high-density treatments. However, absolute food level did not affect variation in length of the larval period. Travis simulated competitive release by adding increments of food to each tadpole's container in proportion to the number of larvae in the other containers that transformed each day. Under these conditions, tadpoles responded to the food supplement by increasing growth and reaching a larger size at metamorphosis. R. Newman (1987) provided supplemental food to tadpoles of *Scaphiopus couchii* in natural ponds with high and low densities of tadpoles. Many of these ponds dried up before the tadpoles reached metamorphosis. Nevertheless, one high- and one low-density pond with supplemental food produced larger metamorphs than ponds without extra food (fig. 13.7 B).

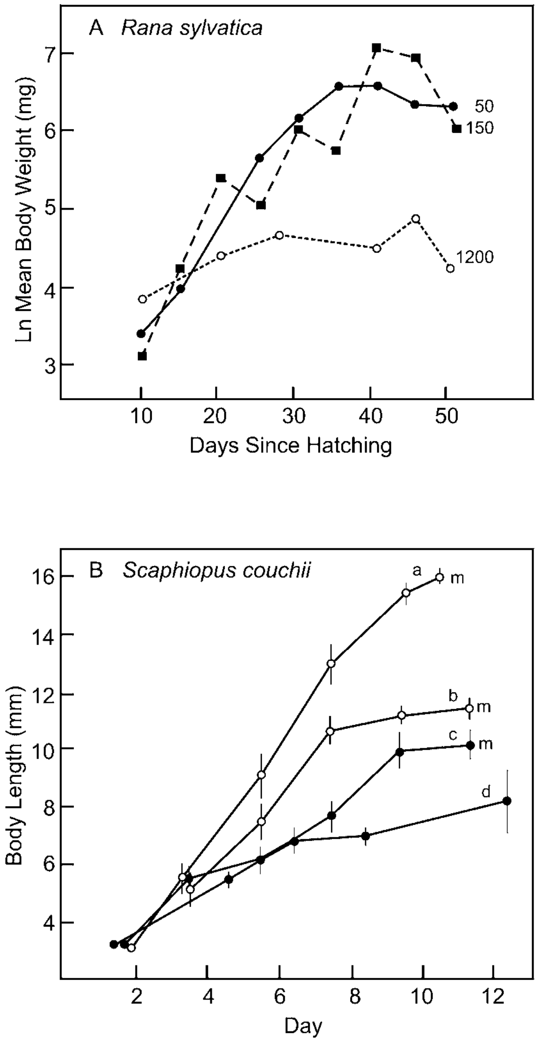

Fig. 13.7. Representative growth curves for tadpoles raised at different densities. (A) Growth curves for *Rana sylvatica* tadpoles at initial densities of 50, 150, and 1,200 individuals reared in pens in a natural pond. After Wilbur and Collins (1973). (B) Growth curves for *Scaphiopus couchii* tadpoles in high- and low-density natural ponds. Curve (a) is for a low-density pond to which food was added. Curve (b) is for a low-density pond to which food was not added. Curve (c) is a high-density pond to which food was added that produced metamorphs. Curve (d) is for a high-density pond to which food was not added that failed to produce metamorphs before the pond dried up. After Newman (1987).

In most of the experiments designed to test for density effects on larval growth, environmental conditions have been held relatively constant. However, in natural ponds, density per se has little direct effect on larval survival, but can affect survival through the action of other selective agents, such as predators and a failure of larvae to reach metamorphosis before ponds dry up (e.g., R. Newman 1987; Loman 2002c). The responses of larvae to differences in density and other environmental variables interact in complex ways. For example, predators reduce larval densities, thereby freeing surviving larvae from competition and allowing them to grow at faster rates (D. C. Smith 1983; Wilbur, Morin, and Har-

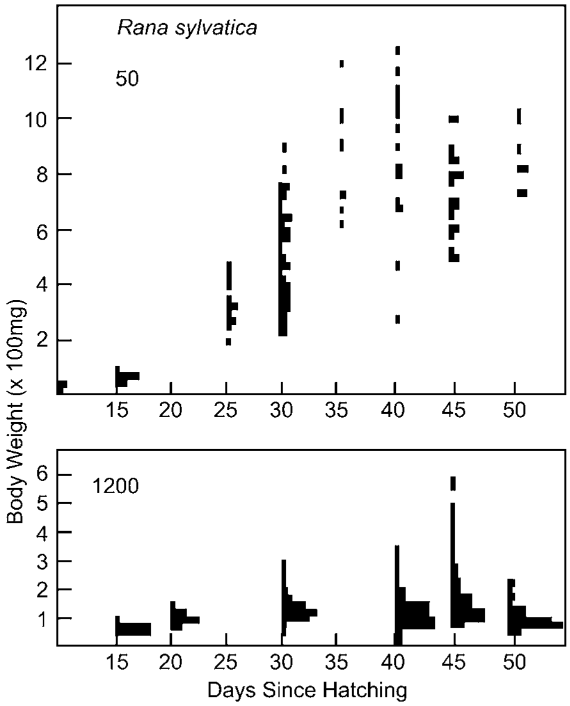

Fig. 13.8. Frequency histograms of body mass of *Rana sylvatica* tadpoles at different ages. Tadpoles were raised at low (50) and high density (1,200). Tadpoles in low-density pens grew rapidly and metamorphosed at relatively large sizes. Tadpoles in high-density pens mostly remained very small, with only a few individuals reaching metamorphic size. After Wilbur and Collins (1973).

ris 1983; Travis, Keen, and Juilianna 1985a). On the other hand, the effectiveness of predators in removing larvae from the population is influenced by initial larval density (Travis, Keen, and Juilianna 1985a) and larval size (Caldwell et al. 1980; Woodward 1983; Travis, Keen, and Juilianna 1985b; Cronin and Travis 1986; see chapter 14).

Studies of Salamander Larvae

Density effects and intraspecific competition for food have not been studied as extensively in salamander larvae as in tadpoles, and most of the work that has been done has been on pond-dwelling *Ambystoma* larvae. In an early study using pens in natural ponds, Wilbur (1972) found that the presence of a predator, *Ambystoma tigrinum,* reduced the survivorship of larvae of other species of *Ambystoma,* but body size of the survivors was larger than when predators were not present. This suggested that predation reduced densities of larvae and enabled the survivors to find more food. In another set of experiments in the same pens, Wilbur (1976) raised larvae of *A. maculatum* and *A. laterale* at different densities. High-density treatments resulted in higher mortality, slower growth, smaller size at metamorphosis, and longer larval periods in both species. Similar results were reported by Wilbur and Collins (1973), and they also found that body sizes of larvae were skewed toward small sizes in high-density pens. Later, Van Buskirk and Smith (1991) manipulated densities of *A. laterale* larvae in natural rock pools along the shore of Lake Michigan, all of which were free of predators. As in earlier pen experiments, high densities decreased both growth rate and survival, and body sizes of larvae in high-density pools were skewed toward small sizes. Studies of larval *A. talpoideum* in artificial ponds (Semlitsch 1987a) and *A. tigrinum nebulosum* in pens placed in a natural lake (Brunkow and Collins 1996) showed similar density-dependent effects on larval growth.

Studies of the marbled salamander (*Ambystoma opacum*) are particularly useful in evaluating the effects of density on larval growth and development because of the variety of techniques that have been used. Experiments have been conducted in laboratory containers (Stenhouse, Hairston, and Cobey 1983), small pens placed in natural ponds (C. K. Smith 1990), artificial ponds (C. K. Smith 1990), large enclosures in natural ponds (D. Scott 1990, 1994; Chazal, Krenz, and Scott 1996), and natural ponds divided in half (Petranka 1989b). The results of these studies have been synthesized into a general demographic model for *Ambystoma opacum* (B. Taylor and Scott 1997). Experiments conducted in small pens or laboratory containers can bias results toward finding density effects (Travis, Keen, and Juilianna 1985a), and often result in considerable variation among replicates of the same treatment (e.g., Wilbur 1976). The same is true for small artificial ponds or cattle tanks, but to a lesser degree (Skelly and Kiesecker 2001). Laboratory experiments and those conducted in small field enclosures sometimes yield unusually high estimates of survivorship, because predators are excluded from the experiments (see D. Scott, 1990, for a comparison of survivorship estimates for *A. opacum*).

Stenhouse, Hairston, and Cobey (1983) raised larvae of both *Ambystoma maculatum* and *A. opacum* at different densities in small laboratory containers and reported that both species exhibited slower growth at high densities than at low densities. Densities in these experiments ranged from those similar to field densities to densities that probably were higher than those commonly observed in the field. Petranka (1989b) attempted to deal with the problems of laboratory and small enclosure experiments by dividing eleven natural ponds in half and stocking larvae of *A. opacum* in each half at natural densities or at one fourth natural densities. Overall, there were few differences in larval growth rates in high- and low-density treatments for the first seven weeks of development, but size differences began to appear by the eleventh week and persisted until metamorphosis, when larvae from low-density treatments emerged at significantly larger sizes. There was considerable variation among ponds, however, with larvae from ponds with low absolute densities generally showing little or no difference between treatments. Nevertheless, density-dependent growth was evident in one low-density pond and was not detected in one high-density pond. Probably these differences were due to variation in characteristics of the ponds, including predator density and food supply. Density dependence was most pronounced in ponds with relatively low populations of cladocerans, the principal food of *Ambystoma* larvae. In most ponds, survival of larvae was higher in the low-density half of the pond.

D. Scott (1990, 1994) conducted a similar set of experiments with the same species, but in large enclosures that allowed for replicated treatments within ponds. These were open-topped enclosures of either 41 m^2 or 23 m^2, placed in two different natural ponds. Each enclosure contained natural populations of invertebrate prey and predators. Initial density of larvae was varied to mimic high and low densities in natural ponds. As in Petranka's study, larvae at high densities had lower survivorship, slower growth rates (fig. 13.9), and smaller size at metamorphosis than those at low density. Survival rates were not significantly different from those in natural ponds, however. Mortality was especially high, up to 98%, in high-density enclosures in years when the ponds dried early, because most larvae had not yet reached metamorphic size. The effect of density on length of the larval period in these experiments and others conducted in one of the same ponds (Chazal, Krenz, and Scott 1996) were inconsistent, with high densities resulting in longer larval periods in some years, but not in others. Variation among years accounted for much more of the variance in larval period than did density treatment (D. Scott 1990). Experiments conducted in replicated artificial ponds with the same species also showed density-dependent growth and development (C. K. Smith 1990). Variation in larval performance can have significant effects on adult demographic traits (D. Scott 1994) and population dynamics (B. Taylor and Scott 1997). The specific effects on adult fitness are discussed in more detail in a later section.

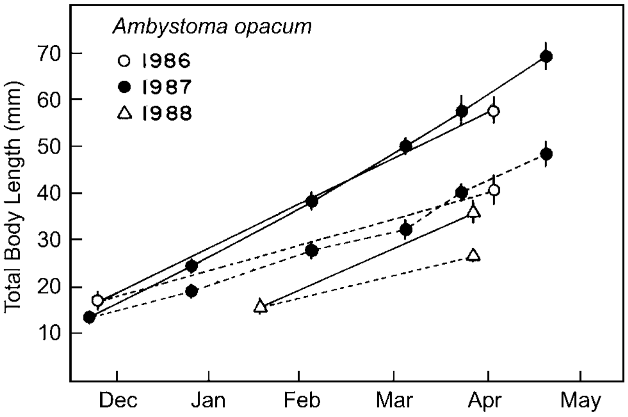

Fig. 13.9. Growth curves for *Ambystoma opacum* larvae grown at high densities (dashed lines) and low densities (solid lines) in field enclosures in a temporary pond in three different years. In all three years, growth rates and size at metamorphosis were higher for larvae in low-density enclosures, but all larvae grew slowly in 1988, regardless of density. After D. Scott (1990).

Information on salamanders other than *Ambystoma* is limited, but density-dependent effects on growth and survival have been reported for both *Notophthalmus viridescens* and *Siren intermedia* larvae raised with different densities of conspecifics in cattle tanks (R. N. Harris 1987b; Fauth, Resetarits, and Wilbur 1990). Larval growth and size at metamorphosis also were lower in a natural pond with high larval densities than in the same pond in another year with low densities (R. N. Harris, Alford, and Wilbur 1988). In contrast, larvae of *Hemidactylium scutatum* raised under different food regimes showed little difference in length of the larval period, although slow-growing larvae did metamorphose at a smaller size (O'Laughlin and Harris 2000). These results suggest that this species has a relatively fixed rate of larval development, but growth rate is influenced by food availability.

Evidence for Food Limitation in Nature

An implicit assumption of all of the studies described in the previous section is that levels of competition detected under experimental conditions reflect those normally encountered in nature. However, this assumption has seldom been explicitly tested (Skelly and Kiesecker 2001; Skelly 2002). In some studies, larval densities have been considerably higher than estimates for field populations, but evidence for competition has been found even at relatively low densities (Travis et al. 1985b; Travis and Trexler 1986). Several field studies of natural ponds have demonstrated a negative correlation between tadpole density and size at metamorphosis, or increased mortality at high densities (R. Savage 1952, 1961; R. Newman 1987; Reques and Tejedo 1995; Reading and Clarke 1999). These studies suggest that intraspecific competition is occurring, although factors such as food abundance and quality, water volume, and temperature variation cannot be controlled in natural ponds, and all of these factors could influence the growth and survivorship of tadpoles, either independently or in conjunction with tadpole density.

Many anuran tadpoles eat periphyton and other plant material that is seasonally superabundant (see chapter 12), and they are subject to predation that can rapidly decrease tadpole numbers (see chapter 14). This has led some authors to conclude that tadpole populations often are below carrying capacity and not food-limited (Herreid and Kinney 1966; Calef 1973a; Heyer 1973, 1974, 1976; Licht 1974; Heyer, McDiarmid, and Weigmann 1975; Cecil and Just 1979). Nevertheless, there is evidence of food limitation in some natural habitats. Food quality for tadpoles can vary annually in the same habitat (Kupferberg, Marks, and Power 1994) or in adjacent habitats (Peterson and Boulton 1999), or as a result of natural succession and changes in leaf litter composition in ponds (Rubbo and Kiesecker 2004). Variation in food quality is reflected by differences in growth rate. For example, both wood frog (*Rana sylvatica*) and spring peeper (*Pseudacris crucifer*) tadpoles grew more slowly in closed-canopy, light-limited ponds with low productivity than in open-canopy ponds with higher productivity (Skelly, Friedenburg, and Kiesecker 2002). Experimental supplementation of food in pond enclosures increased growth rates in both open- and closed-canopy ponds, but the effect was greatest in open-canopy ponds. Tadpoles of two European frogs, *Rana temporaria* and *R. arvalis,* also had slower development and smaller size at metamorphosis in closed-canopy ponds than in open-canopy ponds (Loman 2002b), and tadpoles of the Australian frog *Litoria ewingii* had slower development and decreased growth rates in shaded ponds (Lauck, Swain, and Barmuta 2005). Tadpoles of the stream-breeding frog *Ascaphus truei* had much slower growth rates in a shaded, cool stream than in a nearby less-shaded, warmer stream (Mallory and Richardson 2005).

Dense populations of tadpoles can substantially reduce the standing crop of algae in ponds and streams and alter the composition of the algal community (Dickman 1968; Seale et al. 1975; Seale, Rodgers, and Boraas 1980; Lamberti et al. 1992; Kupferberg 1997b; Graham and Vinebrooke 1998; Holomuzki 1998), whereas lower densities of tadpoles sometimes have little measureable effect on algal biomass (Kiffney and Richardson 2001). In some circumstances, grazing by tadpoles can actually facilitate growth of some algae (Osborne and McLachlan 1985; Kupferberg 1997a). Measurements of organic nitrogen in one pond ecosystem indicated limited availability of food for tadpoles (Seale 1980). Similarly, addition of nutrients to stream channels in British Columbia increased the biomass of both periphyton and grazing *Ascaphus* tadpoles, with tadpoles growing at much faster rates in nutrient-enriched streams (Kiffney and Richardson 2001). In a study of *Pseudacris triseriata* tadpoles in isolated pools, D. C. Smith (1983) found that addition of food to pools partially reversed the negative effects of density on tadpole growth and development. The positive effect of food supplementation on growth of *Scaphiopus couchii* tadpoles (R. Newman 1987) in natural ponds has already been discussed. All of these data indicate that anuran larvae can be food-limited in natural habitats.

There is less direct evidence for food limitation in pond-dwelling salamander larvae, but it seems likely that salamander larvae often are food-limited because of their high trophic position in the community. Kusano (1981) reported that larvae of *Hynobius nebulosus* grew more slowly in a pond than larvae raised in the laboratory at the same temperature, and he found a negative correlation between number of larvae emerging from the pond each year and mean larval size. Stenhouse, Hairston, and Cobey (1983) reported that *A. opacum* larvae appeared to be hungrier in the field than in the laboratory. In some studies, *Ambystoma* larvae have been shown to eliminate preferred arthropod prey from ponds (Dodson and Dodson 1971; Sprules 1972), and these results provide indirect evidence of food limitation. On the other hand, Van Buskirk and Smith (1991) did not find any relationship between abundance of prey and larval growth rate in *A. laterale,* even though both growth and survival were negatively correlated with larval density. They also reported that high densities of larvae did not significantly reduce prey abundance. G. Bell and Lawton (1975) found that larvae of *Triturus vulgaris* were always well fed and grew at near maximum rates in the field, although this could have been related to some peculiarity of their study area, such as unusually high productivity.

Food is likely to be limiting for many stream-dwelling salamander larvae because of the low productivity of most stream environments (Beachy 1995). Stream-dwelling larvae often grow very slowly compared to pond-dwelling larvae, sometimes taking several years to reach metamorphosis. This could be due to low food availability, low temperature, or both, but there have been very few experimental studies designed to separate the effects of temperature and food availability on growth (Bernardo and Reagan-Wallin 2002). Petranka (1984d) reported that *Ambystoma barbouri* larvae in a stream had substantially higher growth rates when provided with supplemental food. Furthermore, size of metamorphosing larvae was inversely related to larval density (Petranka and Sih 1986). After catastrophic flooding of one stream, there was a dramatic decline in larval density, but the few surviving larvae experienced reduced competition and had faster growth rates and larger sizes at metamorphosis than larvae produced in years without floods. Studies of clinal variation in larval life histories of stream-dwelling plethodontids have shown that larvae from cold, high-elevation sites generally grow more slowly and metamorphose at smaller sizes than do those at warmer low-elevation sites (Bernardo and Reagan-Wallin 2002). In one study of *Desmognathus ocoee* from high and low elevations, the abundance of invertebrate prey and the length of the feeding season appeared to be more important that average environmental temperature in determining differences in growth rate (Bernardo and Agosta 2003).

Mechanisms of Intraspecific Competition

Another assumption of the Wilbur-Collins model is that larger individuals are competitively superior to smaller ones, a prediction supported by some experiments (e.g., Steinwascher 1978b, 1979a; Woodward 1987), but not others. Both exploitative and interference competition could be involved, but the relative importance of the two mechanisms probably differs among species. Exploitative competition operates through individual differences in the ability of larvae to obtain and process food resources. Interference competition involves behavioral or chemical interactions among individuals that prevent some individuals from gaining access to resources, or directly inhibit growth.

Exploitative Competition in Anuran Tadpoles

Exploitative competition probably is the most important form of competition in anuran tadpoles, but predicting the outcome of such competition is complicated. Larger tadpoles can pump water at a faster rate because buccal volume is a direct function of body size. Therefore, the quantity of suspended particles ingested should be greater for larger tadpoles, and they can monopolize a disproportionate share of the available food. On the other hand, efficiency of food capture is related to the surface area of the food capturing structures (Wassersug 1975). These structures exhibit negative allometric growth, which means that the surface area of the food-capturing structures does not increase in direct proportion to overall body size (Wassersug and Hoff 1979). Consequently, relative feeding efficiency should decrease as tadpoles grow. Wassersug (1975) found that twelve small *Rana pipiens* tadpoles could clear suspended particles from water faster than three large tadpoles of equivalent total mass. He suggested that this is important in setting an upper limit on tadpole size. One of the largest known tadpoles is that of *Pseudis paradoxa* (Emerson 1988b), which has branchial baskets no larger than those of the smaller tadpoles of *Rana catesbeiana*. Perhaps *P. paradoxa* tadpoles get by with a less efficient feeding apparatus by living in habitats with very high productivity.

The outcome of competitive interactions between tadpoles of different sizes also is hard to predict because of plasticity in their feeding behavior. Tadpoles can alter rates of ingestion in response to change in food concentration (Seale and Wassersug 1979). Generalized pond tadpoles also can change their feeding behavior, depending on the availability of different types of food. For example, Steinwascher (1979a) found that *Rana clamitans* tadpoles concentrated on solid food (rabbit chow) when food was abundant, but shifted to feeding on suspended particles when food was scarce. The efficiency of feeding on each type of food was a function of body size. Tadpoles also respond to reduced food levels by increasing the residence time of food in the gut, thereby increasing digestive efficiency (Wassersug 1975), and by increasing the proportion of time spent feeding (Horat and Semlitsch 1994).

Interference Competition in Anuran Tadpoles

In some species, large tadpoles physically displace smaller ones from food patches (R. Savage 1952; Gromko, Mason, and Smith-Gill 1973; John and Fenster 1975; Wilbur 1977a; Faragher and Jaeger 1998), a form of interference competition. Cannibalism of small tadpoles by larger conspecifics also occurs in some species (see chapter 12). However, the possibility of chemical interference has received more attention in the literature. Early laboratory studies showed that large tadpoles often inhibit the growth of smaller individuals under crowded conditions, even when food is superabundant (Bilski 1921; Goetsch 1924; Adolph 1931; Rugh 1934; Lynn and Edelman 1936). This suggested that large tadpoles release a growth-inhibiting chemical into the water, and considerable effort has gone into identifying such a substance.

Several investigators have shown that the growth of tadpoles can be inhibited by water conditioned by tadpoles, even when other tadpoles are not present (C. Richards 1958; S. Rose 1960; S. Rose and Rose 1961; Akin 1966; Licht 1967; Gromko, Mason, and Smith-Gill 1973). C. Richards (1958, 1962) hypothesized that growth inhibition was associated with "algal-like" cells found in tadpole feces, an explanation supported by other workers (S. Rose and Rose 1961, 1965; Licht 1967). However, L. West (1960) believed growth inhibitors were found in the "slime" growing on the walls of the rearing containers, not cells in the feces. Akin (1966) reported that conditioned water inhibited tadpole growth even when feces and associated material were filtered out. She proposed that an inhibitory chemical produced by the tadpoles became associated with algal cells and was subsequently released into the water, but the nature of the chemical was unknown. Various proteinaceous compounds have been found in the excreta of tadpoles (Runkova, Stepanova, and Koval'chuck 1974; Stepanova 1974). These metabolites inhibit the growth of other tadpoles, but the precise nature of the inhibitory substances remains unknown. A further complication is that kinship alters the effect of growth inhibitors, although how it does so is unclear. Some tests have shown that tadpoles reared with siblings grow more slowly than did those grown with nonsiblings (Shvarts and Pyastolova 1970a; Waldman 1986b), but in other cases, the opposite was true (Waldman 1986b).

Gromko, Mason, and Smith-Gill (1973) found no evidence that any sort of cells was necessary to produce a growth-inhibiting effect, and they questioned whether diffusable substances are responsible for crowding effect in tadpoles. They suggested that the cells observed by Richards and others are parasitic, with the reduction in tadpole growth being a result of increases in the parasite population. A similar suggestion was made by Steinwascher (1978b, 1979b), who found cells in the guts of *Rana clamitans* tadpoles that were identified as a parasitic yeast, *Candida humicola*. At low concentrations, these yeast cells actually enhanced the growth of tadpoles, but at higher concentrations, growth was inhibited. Inhibition was size-specific, with small tadpoles being inhibited more than large ones. Furthermore, the effect of the yeast on tadpole growth depended on the amount of food available and the density of tadpoles (Steinwascher 1979a). The result is a complex interaction in which small tadpoles are consistently at a competitive disadvantage relative to larger individuals.

Several conclusions can be drawn from this brief review of interference competition. First, many authors have assumed that tadpoles produce chemical substances that evolved specifically as growth inhibitors, but at present there is only circumstantial evidence to support this view. Second, crowding effects observed in laboratory experiments can involve several different processes that produce superficially similar results. These include responses to specific growth inhibitors, responses to metabolic waste products (see the following), interactions with parasite populations, or a complex interaction between exploitative and interference competition. Finally, the significance of crowding effects and growth inhibitors for tadpoles in natural populations is unclear. In most studies, tadpoles reared in the laboratory were exposed to densities far greater than those normally encountered in the field. Furthermore, the choice of subjects for such studies was unfortunate, because most have involved ranid tadpoles, particularly *Rana pipiens,* which are not noted for having exceptionally high population densities in nature. Much of the evidence for interspecific growth inhibition comes from laboratory studies in which tadpoles were raised in crowded conditions (e.g., Beebee 1991).

Neither Morin and Johnson (1988) nor Petranka (1989a) found any evidence of such inhibition in artificial or natural ponds. In contrast, workers studying interspecific competition between tadpoles in England reported significant inhibition of growth in relatively small artificial ponds (Griffiths, Edgar, and Wong 1991; Griffiths, Denton, and Wong 1993). They identified an unpigmented unicellular alga (*Prototheca richardsi*) in the tadpole feces that affected tadpole growth. Subsequent genetic work has shown that this organism apparently does not belong in the genus *Prototheca,* but should be placed in a new genus, *Anurofeca* (G. Baker, Beebee, and Ragan 1999). The alga apparently is not toxic to tadpoles (Wong and Beebee 1994). Nevertheless, when algal cells were abundant in the water, tadpoles fed on them, but derived relatively little nutritional benefit. Growth inhibition would then occur because of tadpoles being diverted away from more profitable food (Beebee and Wong 1992). The significance of this mechanism for intraspecific competition is unclear. It has been implicated in interspecific competition (see chapter 15), but there is considerable controversy over the interpretation of experimental results (Beebee 1995b; Griffiths 1995; Petranka 1995; R. N. Harris 1999).

One difficulty with the argument that chemical interference is an important form of intraspecific competition is that it is not clear why individuals that are the source of chemicals would be immune to their negative effects. Some observations and experiments that have suggested a role for chemical interference could be related to general deterioration of the aquatic environment, especially in very shallow ponds in hot climates, where ponds tend to dry up quickly. For example, Schmuck, Geise, and Linsenmair (1994) found that concentrations of nitrogenous waste products, especially ammonia, reached high levels in natural ponds inhabited by dense populations of *Hyperolius* tadpoles in Africa. High tadpole densities in these ponds resulted in longer larval periods and smaller size at metamorphosis, but whether these effects were related to ammonia concentrations or to other density effects is not clear. One species, *H. viridiflavus ommatostictus,* responded to high ammonia concentrations physiologically by increasing the activity of the enzyme cycle that converts ammonia to nontoxic urea. Another species, *H. marmoratus nitidulus,* exhibited an unusually high tolerance for ammonia. Physiological adjustments that enable tadpoles to tolerate high ammonia concentrations also have been reported in leptodactylid frogs in which tadpoles develop inside a foam nest (Shoemaker and McClanahan 1973; see also chapter 2). These physiological adjustments that allow tadpoles to survive in crowded conditions carry costs in reduced growth rates, however.

Competition in Salamander Larvae

Many studies have shown that growth rates of salamander larvae decrease with increasing density. This could be due either to exploitative or interference competition. Large individuals might enjoy an advantage over smaller individuals in exploitative competition. Because a larva's gape increases with age, larger individuals are expected to exploit a wider range of prey sizes than small individuals (see chapter 12). For the most part, however, experimental studies have failed to support this prediction. For example, Brunkow and Collins (1996) found that larvae of *Ambystoma tigrinum nebulosum* were negatively affected by high densities, but those with similar-sized individuals actually grew more slowly than did those with variable-sized individuals, perhaps because of increased aggression among similar-sized larvae. Large individuals do not necessarily have an advantage over small individuals when all size classes feed on the same small prey items, such as zooplankton.

C. K. Smith (1990) explicitly tested for effects of variation in body size on competition among *A. opacum* larvae in laboratory and field experiments. In laboratory experiments, he found that high densities of larvae resulted in slower growth, but the size of competitors was important only when larvae could physically interact with one another

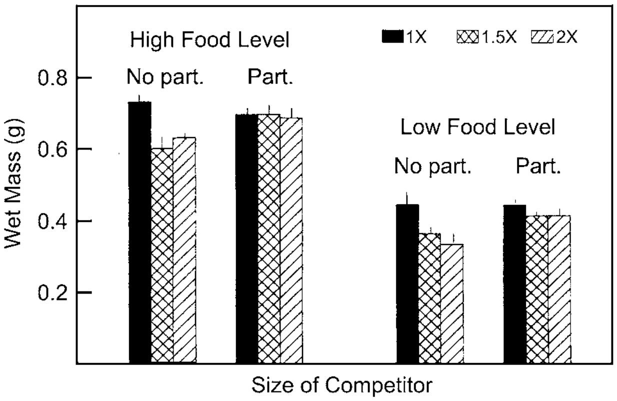

Fig. 13.10. Effects of relative size of competitors (1X, 1.5X, 2X) on body mass of *Ambystoma opacum* larvae raised in the laboratory in containers with and without partitions to separate the larvae. The containers without partitions allowed larvae to interact aggressively and resulted in reduced growth of small larvae when competitors of 1.5 or 2 times their body mass were present. This effect was seen at both high and low food levels. Relative body size of competitors did not affect larval growth when the larvae could not interact. After D. C. Smith (1990).

(fig. 13.10). He interpreted this as evidence that behavioral interference is more important than exploitative competition, at least with regard to differences in body size. He did not find the same effect of body size differences in experiments conducted in artificial ponds, where larval densities were much lower. This could have been due to limited opportunities for larvae to interact with one another. Van Buskirk and Smith (1991) did find evidence of competition among *A. laterale* larvae in natural rock pools. High densities of larvae did not significantly reduce prey abundance, but did result in much higher frequencies of tail damage. These results suggested that aggressive attacks on conspecifics constituted the most important type of competition. Evidence of aggressive interactions among larvae and extensive injuries at high densities have been reported for several species of salamanders (R. N. Harris 1987a; Walls and Jaeger 1987; Petranka 1989b; Semlitsch and Reichling 1989; D. Scott 1990; Walls and Roudebush 1991; Hokit, Walls, and Blaustein 1996; Reques and Tejedo 1996). In some extreme cases, large salamander larvae become cannibalistic and eat smaller conspecifics (see "Cannibalism and Cannibalistic Morphs" in chapter 12).

Phenotypic Plasticity in Larval Growth, Development, and Metamorphosis

The studies of intraspecific competition discussed in the previous sections have clearly shown that high larval densities and a shortage of food can have detrimental effects on growth, survival, and the length of the larval period. The results of many of these studies are consistent with the basic assumptions of the Wilbur-Collins model and other models of amphibian metamorphosis. Nevertheless, a demonstration of density-dependent growth and mortality does not, in itself, test a key prediction of these models. The effects of density observed in studies of intraspecific competition can be attributed to the direct effect of resource depletion or interference competition, and larvae that emerge from the water at small sizes can simply be viewed as losers in competitive interactions.

All of these models predict that amphibian larvae should exhibit adaptive phenotypic plasticity in response to environmental conditions. In other words, larvae are expected to adjust the timing of metamorphosis and size at metamorphosis in ways that enhance their overall fitness. To examine this prediction, we need to know what environmental variables can trigger plastic responses in larvae and the limits of phenotypic plasticity in these animals.

As originally formulated, the Wilbur-Collins model of metamorphosis assumed that tadpoles can respond to environmental conditions at virtually any point in development by altering the timing of metamorphosis and size at transformation. In fact, there are constraints on plasticity related to temporal differences in the sensitivity of growth and development to environmental conditions. For example, the Wilbur-Collins model predicts that declining food supplies late in development will cause tadpoles to speed up development and metamorphose at a size close to the minimum viable size for terrestrial juveniles, or initiate metamorphosis immediately if the minimum size has already been reached. Conversely, if the availability of food actually increases late in development, perhaps because competing larvae have already left the pond or have been eaten by predators, then tadpoles are expected to delay development and continue growing to a larger size. If, on the other hand, rates of differentiation become relatively fixed late in development, then tadpoles might not be able to respond to altered food supplies in this way, because the timing of metamorphosis has already been determined.

Travis (1984) proposed an alternative view of amphibian metamorphosis that postulated that development rate is fixed relatively early in the larval period, but growth remains plastic, continuing throughout development, resulting in variation in size at metamorphosis. Several other authors have proposed modifications of the Wilbur-Collins model that provide for plastic responses in both growth and development rates for part of the larval period, but with development rate becoming fixed at a particular developmental stage (Alford and Harris 1988; Hensley 1993; Leips and Travis 1994; Hentschel 1999). Hentschel's model went further than did the others in attempting to predict the point at which phenotypic plasticity in timing of metamorphosis is lost. Day and Rowe (2002) argued that what appears to be a fixed rate of development after a critical point in the larval period actually may result from developmental thresholds that reverse the effects of changing food resources.

R. N. Harris (1999) proposed a graphical model that is consistent with the other models, but focuses on the relative allocation of energy to growth and development at different stages in the larval period. He argued that when larvae experience low food levels, they will allocate relatively more resources to development than to growth and will metamorphose at the minimum viable size, as proposed by Wilbur and Collins. Those with more food available will allocate relatively more resources to growth and reach a larger size at metamorphosis. The absolute level of resources for both growth and development obviously is higher for well-fed tadpoles, and they not only will tend to be larger at metamorphosis, but will have shorter larval periods than poorly fed individuals.

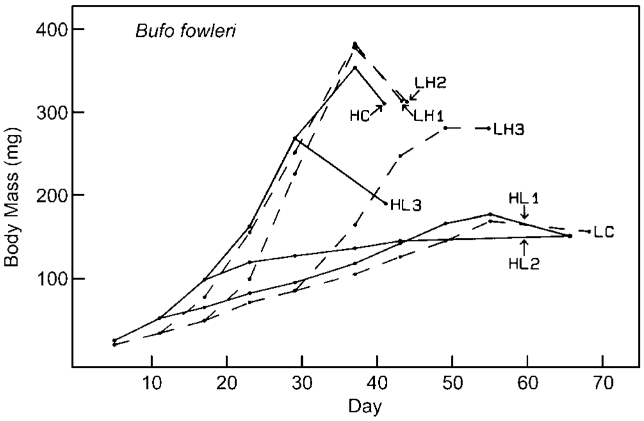

Fig. 13.11. Growth curves for *Bufo fowleri* tadpoles raised in small containers at different food levels. Tadpoles raised at constant high food levels (HC) grew rapidly and metamorphosed at a large size, whereas those raised at constant low food levels (LC) grew slowly and metamorphosed at a small size. Tadpoles switched from high to low food rations early (HL1) or in the middle (HL2) of development grew slowly and reached a size similar to those raised at constant low food. Tadpoles switched to low food late in development (HL3) grew rapidly until the food change and then metamorphosed at the same time as those in constant high food, but at a much smaller size. Tadpoles switched to high food early (LH1) or midway through development (LH2) caught up to those raised on constant high food. Tadpoles raised for most of development on low food and switched late to high food (LH3) took longer to reach metamorphosis, but metamorphosed at a size only slightly below that of tadpoles on constant high food. After Alford and Harris (1988).

Phenotypic Plasticity and Variation in Food Resources

The empirical evidence to support these modified versions of the Wilbur-Collins model comes from experiments in which food rations for tadpoles were changed at different points in development. For example, Alford and Harris (1988) raised tadpoles of *Bufo fowleri* with either high or low food rations and then switched some tadpoles to either lower or higher food rations at different ages. As expected, individuals on high food rations grew faster and reached a larger size at metamorphosis than did those on low food, and they had shorter larval periods as well. When slowly growing tadpoles were switched to high food rations, they had longer larval periods than did those with constant high food, but they all reached about the same size at metamorphosis (fig. 13.11). Conversely, when rapidly growing tadpoles were switched to low food rations relatively early in development, larval periods were similar to those of tadpoles on a constant low food ration, and they metamorphosed at the minimum size. Tadpoles switched to a low food ration late in development metamorphosed at about the same time as those on a constant high food ration, but they were smaller at metamorphosis. These results generally supported the Wilbur-Collins model, but with some limitation on phenotypic plasticity in timing of metamorphosis. Experiments with another species of toad, *Bufo calamita,* showed that tadpoles switched from low to high resources tended to speed up metamorphosis relative to those on constant low food. Those switched from high to low resources did not alter timing of metamorphosis relative to tadpoles on constant high food, but they were smaller at metamorphosis (Tejedo and Reques 1994a). Resources were switched at only one time (17 days) in this study, so the effect of timing of resource change was not investigated.

Hensley (1993) performed a similar experiment with *Pseudacris crucifer* tadpoles. He found that changes in food rations before about Gosner stage 38 affected both the length of the larval period and size at metamorphosis, but changes at later stages did not affect the timing of metamorphosis. Switching tadpoles to low food rations late in development had little effect on size at metamorphosis, but switching them to high food late in development produced larger metamorphs. Leips and Travis (1994) obtained comparable results with tadpoles of *Hyla cinerea,* which breeds in relatively permanent ponds, and *H. gratiosa,* which breeds in temporary ponds. In both species, the length of the larval period was affected by changes in food rations through about 60% of the larval period, but not in the last 40%. *Hyla gratiosa,* the temporary pond species, exhibited greater plasticity in the timing of metamorphosis than did *H. cinerea,* but the period of sensitivity to changes in food level was similar in the two species. The effect of food rations on size at metamorphosis was more complex, but in general, additional food resulted in larger metamorphs, and decreased food resulted in smaller ones. Food ration late in development had the greatest effect on size at metamorphosis. There also were differences in response of tadpoles, depending on which way the food rations were changed. Those that started with high food rations and were switched to low food all were smaller at metamorphosis than were those on constant high food rations. In contrast, those that were switched from low to high rations generally reached a size at metamorphosis similar to tadpoles on constant high food rations, regardless of when the switch occurred (fig. 13.12).

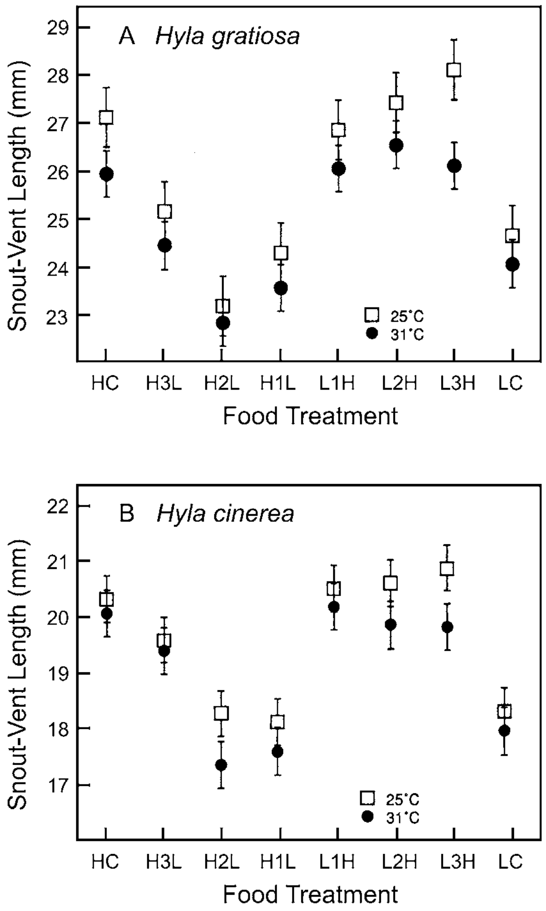

Fig. 13.12. Size at metamorphosis for *Hyla gratiosa* and *Hyla cinerea* tadpoles raised at two different temperatures on different food rations. In general, switching from low to high food rations (LH1, LH2, LH3) increased size at metamorphosis relative to tadpoles on constant low food, regardless of when the switch occurred. Switching tadpoles from high to low food rations decreased size at metamorphosis, especially if the switch occurred early in development (LH1, LH2). Tadpoles raised at the lower temperature reached larger body sizes at metamorphosis than those raised at the warmer temperature, but took longer to reach metamorphosis. After Leips and Travis (1994).

A study by Audo et al. (1995) used a different experimental design to investigate the effects of short-term starvation on larval growth and development in *Hyla chrysoscelis.* In their experiments, tadpoles were fed unlimited food, except for a period of ten days in which they were deprived of food. The starvation period occurred in the early, middle, or late stages of development. Tadpoles that were starved early and then given plenty of food were able to catch up with those that were given constant high food. They metamorphosed at a similar size, but had longer larval periods than did those on high food rations. This treatment might mimic a situation in which high tadpole densities early in development result in strong competition for food, but some individuals are later released from such competition by high predation on competing tadpoles (e.g., Semlitsch and Caldwell 1982). Tadpoles that were starved late in development metamorphosed at the same time as those on constant high food, but they were smaller and suffered much higher mortality.

Beck (1997) examined the effect of food resources on metamorphosis in yet another hylid treefrog, *Hyla squirella.* The experimental design was similar to the other studies, except that food rations were adjusted to the changing mass of the tadpoles. This was considered a better test of the Wilbur-Collins model, because it predicts that tadpoles will adjust the timing of metamorphosis in response to changes in mass-specific growth rate. As in the other studies, switching the tadpoles from high to low rations or from low to high late in development (after late limb bud development) did not affect timing of metamorphosis. Tadpoles switched from high to low rations all were smaller at metamorphosis than those maintained on constant high rations. The trend was for the difference to be greatest in tadpoles that were switched early, although results for individual treatments did not differ from one another statistically, probably because of relatively small sample sizes. The opposite pattern was seen in tadpoles switched from low to high rations.

In all of the previous studies, tadpoles that were switched to low resource levels continued to receive some food. Morey and Reznick (2000) used a different approach in a study of three species of spadefoot toads, *Scaphiopus couchii, Spea intermontana,* and *Spea hammondii. Scaphiopus couchii* breeds in highly ephemeral ponds and has perhaps the shortest larval period of any North American anuran, about seven days (Buchholz and Hayes 2000). The other two species breed in longer-lasting ponds and have larval periods of up to a month. Morey and Reznick raised tadpoles initially at high, medium, or low food levels, and then abruptly cut off all food at different stages of development. At constant food levels, tadpoles of all three species reached larger sizes at metamorphosis on high food rations than on low rations. Length of the larval period was not much affected by food ration in *Scaphiopus couchii,* but in *Spea intermontana,* tadpoles on low food took twice as long to reach metamorphosis as those on high food (fig. 13.13). In all three species, tadpoles deprived of food early in development usually failed to reach metamorphosis, whereas those switched at later stages usually did complete metamorphosis (fig. 13.14). Each species had a characteristic developmental threshold after which metamorphosis was possible when tadpoles were deprived of food. In *Scaphiopus couchii,* tadpoles that had their food removed at Gosner stage 34 could still achieve metamorphosis, whereas in the other two species, the developmental threshold was slightly later. When tadpoles initially were maintained on a high food ration before food was removed, the developmental threshold for successful metamorphosis was slightly earlier than for tadpoles on a low food ration. Presumably this was because they had greater energy reserves available when food was removed.

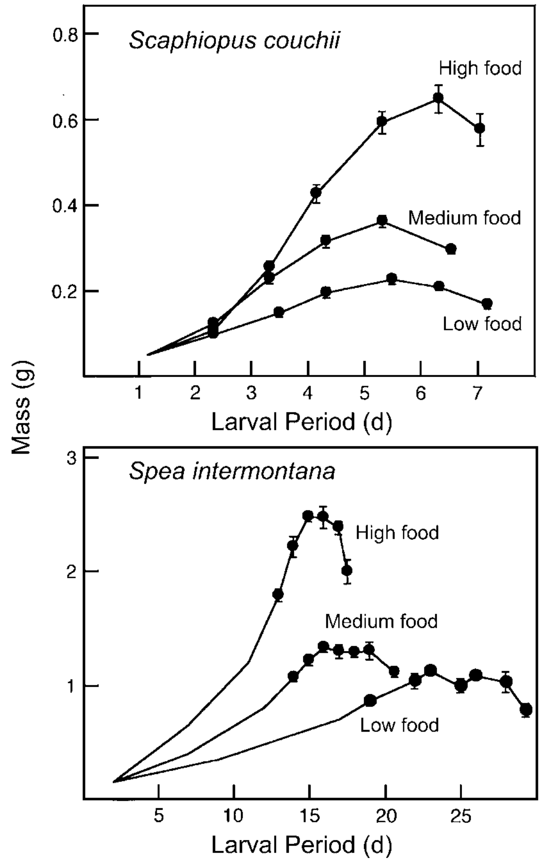

Fig. 13.13. Growth of tadpoles of *Scaphiopus couchii* and *Spea intermontana* at three different food rations. Food ration had a large effect on size at metamorphosis in *Scaphiopus couchii,* but a relatively small effect on length of the larval period, which is normally very short. Food ration affected both size at metamorphosis and length of the larval period in *Spea intermontana,* which has a much longer larval period. After Morey and Reznick (2000).

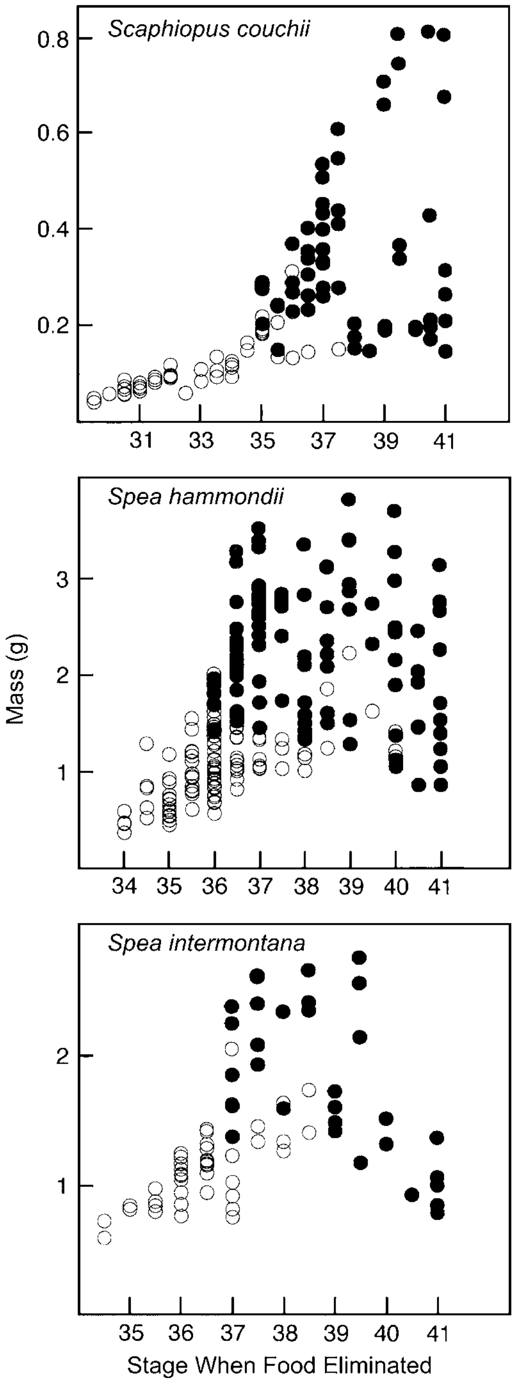

Fig. 13.14. Growth of tadpoles of three species of spadefoot toads when food was completely eliminated at different stages of development. Closed circles show tadpoles that reached metamorphosis. Open circles are those that failed to metamorphose. Tadpoles of *Scaphiopus couchii* could reach metamorphosis if food was removed as early as Gosner stage 35. The threshold for successful metamorphosis was later for *Spea hammondii* (stage 36) and *Spea intermontana* (stage 37). After Morey and Reznick (2000).

Nevertheless, all tadpoles that metamorphosed early after being deprived of food did so at much smaller body sizes than those maintained on constant food (see also Boorse and Denver 2004).

Overall, the experiments of Morey and Reznick were consistent with predictions of the Wilbur-Collins model and the developmental threshold model of Day and Rowe (2002). Both timing of metamorphosis and size at metamorphosis were plastic traits that were influenced by food availability and growth rate. In general, *Scaphiopus couchii,* the species that breeds in the most ephemeral habitats, showed the most plastic responses. The methods used Morey and Reznick's experiment do not precisely mimic situations that tadpoles normally encounter in the field. Indeed, in some spadefoot toads, tadpoles have access to increased resources late in development because they either feed on dead or dying conspecifics or actively cannibalize other tadpoles (see chapter 12). Nevertheless, the results of these experiments were consistent with those of R. Newman (1994), who found that decreasing food rations resulted in an acceleration of metamorphosis, whereas a constant low food ration delayed metamorphosis. The sudden deprivation of food in Morey and Reznick's experiments probably induced a stress response in the tadpoles, and such responses have been shown to induce early metamorphosis in these tadpoles (Denver 1997a). In nature, however, the principal environmental stress favoring early metamorphosis in spadefoot toads probably is not a lack of food, but drying up of breeding ponds.

Phenotypic Plasticity and Pond Drying

For amphibians that breed in temporary ponds, direct mortality of larvae due to starvation or poor-quality food probably is relatively rare. The major threat to survival in these habitats is drying of the ponds before larvae are able to metamorphose. Thus, while competitive effects do not necessarily result in direct mortality, slower growth rates and longer larval periods in competitive environments will decrease the chances that tadpoles will reach metamorphosis before the pond disappears. In such species, selection should favor plastic developmental responses that enable individuals to speed up development in response to pond drying. Indeed, a number of observational and experimental studies have shown that some species do exhibit this type of plasticity, although interpretation of experimental results is not always straightforward.

The best-studied examples are spadefoot toads. Reproductive failure due to pond desiccation is common in these species (R. Newman 1987), so there is strong selection on tadpoles to increase rates of development and minimize the length of the larval period. Tadpole densities often are extremely high in these species, and food availability can be low. In addition, breeding pools often reach high temperatures, especially as they begin to dry out. Selection pressures in this very harsh environment have resulted in spadefoot toads having the fastest rates of development and the shortest larval periods of any North American anurans, as well as the greatest tolerance of high temperatures (Zweifel 1977). Some species of spadefoot toads can accelerate metamorphosis by becoming carnivorous and even cannibalistic, which provides higher-quality food and allows for more rapid development. This type of phenotypic plasticity is discussed in more detail in chapter 12.

In addition, several species of spadefoot toads exhibit considerable plasticity in timing of metamorphosis in response to pond drying (R. Newman 1992). In an experiment with *Scaphiopus couchii*, R. Newman (1988b) reared sibling groups of tadpoles in pens placed in artificial ponds that differed in initial depth and therefore in pond duration. Each sibling group was replicated four times in long- and short-duration ponds. Tadpoles had shorter larval periods in short-duration ponds than in long-duration ponds, and size at metamorphosis was positively correlated with larval period (fig. 13.15). There also were significant differences among sibling groups in development rate, and the sibship with the slowest development suffered high mortality in the short-duration ponds. The different sibling groups did not benefit uniformly from being in long-duration ponds, because tadpoles from some groups reached larger metamorphic sizes than did others in the same ponds.

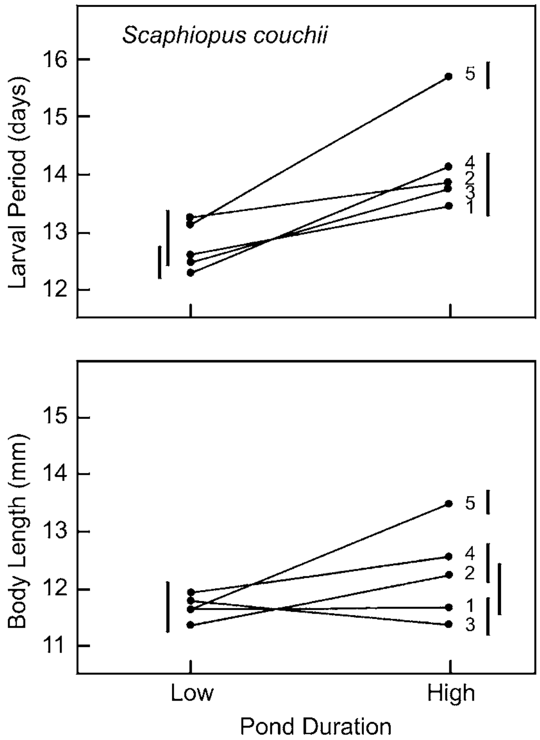

Fig. 13.15. Effect of pond duration on length of the larval period and size at metamorphosis for spadefoot toad (*Scaphiopus couchii*) tadpoles. In general, early drying of ponds resulted in shorter larval periods and smaller size at metamorphosis. Different sibships (1–5) differed in timing and size at metamorphosis in ponds of long duration, but mostly were similar in short-duration ponds. Vertical lines indicate values that are not significantly different from one another. After Newman (1988b).

In another experiment, pond duration, tadpole density, and food rations all were varied in both long- and short-duration ponds. Tadpoles at high density with low food never reached metamorphosis before ponds dried, even in long duration ponds (pond duration varied between 11 and 17 days). In other food and density treatments, tadpoles were more likely to reach metamorphosis in long duration ponds. As in the previous experiments, tadpoles metamorphosed earlier in short-duration ponds than in long-uration ponds. In general, tadpoles with longer larval periods emerged at larger sizes, but food level had the greatest effect on metamorphic size. The patterns seen in the experimental ponds mirrored those seen in nearby natural ponds, where tadpoles metamorphosed earlier from short-duration ponds.

Natural ponds with very high tadpole densities typically did not produce any metamorphs. These results suggest that adult spadefoot toads are not very good at predicting conditions in ponds when they lay eggs, because the very ponds that were most heavily used by breeding adults often resulted in no reproductive success.

These experiments did not directly address the proximate causes of abbreviated larval periods in short-duration ponds. Many features of the ponds changed as the ponds dried, including water depth, pond surface area, resource levels, tadpole density, and temperature. Drying ponds almost certainly change in water chemistry as well, partly as a result of the buildup of nitrogenous waste products of tightly packed tadpoles (e.g., Schmuck, Geise, and Linsenmair 1994). Temperature alone could have accounted for some or all of the accelerated metamorphosis in rapidly drying ponds, because temperature increased substantially in these ponds. A set of laboratory experiments in which both food and tadpole density were varied showed that tadpoles that experience declining growth rates respond by metamorphosing early, and at a relatively small size, as predicted by the Wilbur-Collins model and other models derived from it (R. Newman 1994). Metamorphic size and age were positively correlated when food was abundant, but there was no such correlation when food was scarce. In other words, most tadpoles exposed to low food levels metamorphosed at similar small sizes.

Laboratory experiments with both *Scaphiopus couchii* and *Spea hammondii* directly addressed the effect of decreasing water volume on initiation of metamorphosis (Denver, Mirhadi, and Phillips 1998; Boorse and Denver 2004). The main result of these experiments was that decreasing water volume alone led to shorter larval periods, in the absence of any change in temperature. Furthermore, the response was continuous. Larval periods were shortest and body size smallest in response to the most extreme volume reductions (fig. 13.16). When water volumes were increased before tadpoles reached metamorphosis, they resumed rapid growth and delayed metamorphosis until they had reached a larger size. These responses were not due solely to increases in tadpole density as water volume decreased, because tadpoles raised alone showed a similar response. As discussed in the section on hormonal control of metamorphosis, experimental reductions in water volume resulted in dramatic increases

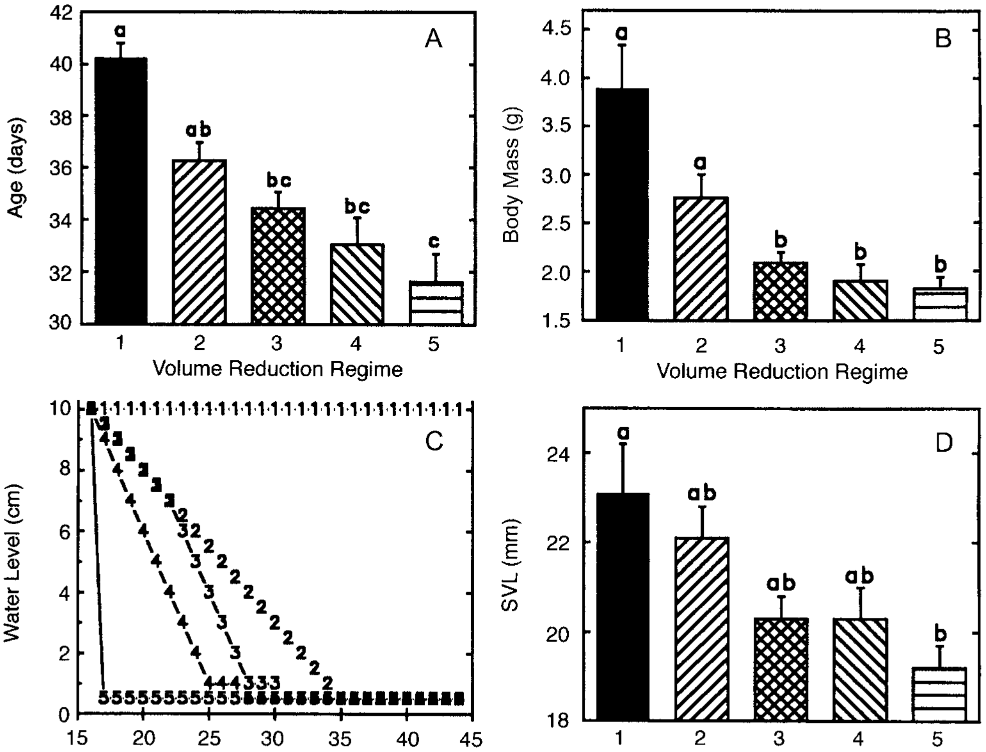

Fig. 13.16. Effect of drying regime on age and size at metamorphosis for spadefoot toad (*Spea hammondii*) tadpoles raised in laboratory aquaria. (A) Age at metamorphosis as a function of drying regime. (B) Body mass at metamorphosis as a function of drying regime. (C) Water levels in containers with different drying regimes (1–5). (D) Snout-vent length as a function of drying regime. Bars show means ± 1 SE. Lowercase letters indicate values that are not significantly different from one another. After Denver, Mirhadi, and Phillips (1998).

in levels of corticosterone and thyroid hormones in the body (Denver 1997a, b, 1998). This hormonal response was very rapid, occurring within 24 hours in tadpoles that were exposed to a sudden drop in water volume (Boorse and Denver 2004).

While plasticity in the timing of metamorphosis is particularly dramatic in spadefoot toads, which breed in some of the harshest environments of any amphibian, these are not the only species that show such responses. For example, M. Crump (1989a) reported that tadpoles of a Neotropical treefrog, *Hyla pseudopuma,* which breeds in ephemeral rain pools and other temporary ponds, exhibits accelerated metamorphosis in response to reduction in water volume. A tropical toad (*Bufo maculatus*) from the Ivory Coast also had shorter larval periods and smaller size at metamorphosis, but a ranid frog (*Hoplobatrachus occipitalis*) that also breeds in temporary water did not (Spieler 2000). The natterjack toad (*Bufo calamita*), another temporary pond breeder, also changed the timing of metamorphosis in response to variation in pond duration, density, and food level, but the interaction among these factors was complex (Tejedo and Reques 1994b). Tadpoles in some short-duration ponds metamorphosed early, but only when raised by low density. At high density, size at metamorphosis was greatly reduced, larval periods were long, and the number of tadpoles reaching metamorphosis was reduced, probably because of inadequate nutrition resulting from increased density. Another study of *Bufo calamita, B. bufo,* and *Rana temporaria* in England found no effect of pond drying on timing of metamorphosis, although tadpoles from drying ponds metamorphosed at smaller sizes (Brady and Griffiths 2000). In an experiment designed mainly to look at intra- and interspecific competition, Wilbur (1987) found that tadpoles of *Bufo americanus* at low density metamorphosed several days earlier in ponds that dried after 50 or 100 days than in those that never dried. In *Rana lessonae* and the hybridogenetic species *R. esculenta,* drying regime did not have a significant effect on timing of metamorphosis, but tadpoles emerged at a smaller size in drying ponds (Semlitsch and Reyer 1992b). Experiments with *Rana blairi* and *R. sphenocephala* using a similar experimental design showed a significant reduction in length of the larval period and metamorphic size for both species in drying ponds (M. Parris 2000; T. Ryan and Winne 2001).

In contrast to the results obtained by Brady and Griffiths (2000), several experiments with European common frogs (*Rana temporaria*) exposed to gradual (Laurila and Kujasalo 1999) or rapid (Loman 1999) reduction in water volume showed some acceleration in timing of metamorphosis. A comparison of populations in southern Sweden, where ponds frequently dry up, and northern Sweden, where ponds seldom dry, revealed greater plasticity in timing of metamorphosis in the southern population (Merilä et al. 2000; Laurila, Karttunen, and Merilä 2002). Another study compared tadpoles from ponds in a relatively small geographic area in southern Sweden that differed in hydroperiod. Tadpoles from temporary and permanent ponds showed no difference in degree of plasticity in timing of metamorphosis under controlled conditions (Loman and Claesson 2003), even though tadpoles in natural ponds accelerated metamorphosis if ponds were in danger of drying up (Loman 2002b). There are limits to plasticity that can prevent tadpoles from escaping from drying ponds. Loman (2002c) found that *R. temporaria* tadpoles exposed to a rapid reduction in water volume at an early stage of development mostly failed to accelerate metamorphosis, but instead grew and developed more slowly than those exposed to constant water depth. He attributed this mostly to the effects of crowding, but it also may be that the tadpoles were subjected to the drying regime before reaching the developmental threshold (Day and Rowe 2002) that would enable them to accelerate development.

In all of these species, differences in timing of metamorphosis were considerably less impressive than in spadefoot toads. For example, in *Bufo calamita,* the difference in length of the larval period for tadpoles at low density in long- and short-duration ponds was only one day, or about 3% of a 32-day larval period in constant water. Differences were similar in *Bufo americanus,* with a 4% difference between ponds that dried after 50 days and those that never dried. *Bufo maculatus,* which breeds at the edges of rivers, reduced the larval period by about 10–20%. In *Rana temporaria,* differences ranged from about 1 day to 2.5 days, about 3–6% of the larval period in constant water. Differences in development time for *R. blairi* averaged about 8% of the expected larval period in constant water, while the difference for *R. sphenocephala* was only about 4%. Development times for *Hyla pseudopuma* in decreasing water volume were highly variable, but averaged about 3–5% less than those of tadpoles in constant volumes. This compares with differences in length of the larval period of up to 50% for spadefoot toad tadpoles in natural long- and short-duration ponds (R. Newman 1989), and up to 20% in laboratory drying experiments (Denver, Mirhadi, and Phillips 1998). These differences suggest that phenotypic plasticity in response to pond drying is much greater in species that breed in highly ephemeral desert pools than in those using other types of temporary ponds. A much larger range of species in different habitats needs to be examined to rigorously test this hypothesis. Clades that exhibit considerable interspecific variation in choice of breeding sites would be particularly useful for comparative studies to control for phylogenetic differences that confound interpretation of the available data.

One difficulty in interpreting the results of studies in which hydroperiod is varied is that drying treatments produce several effects simultaneously. Experimental drying obviously reduces the volume of water and the persistence of the pond, and hence the time available for tadpoles to develop. In addition, average water temperature also tends to increase, which would tend to increase development rates. On the other hand, shallower ponds experience increased variation in temperature, reaching colder temperatures at night that partially compensate for higher temperatures during the day (Brady and Griffiths 2000). Perhaps most important, tadpole densities are greatly increased in drying ponds. This can result in increased competition for food, as well as possible chemical interactions that inhibit growth and development. For example, in experiments with *Hyla gratiosa* and *H. cinerea,* Leips, McManus, and Travis (2000) found that drying regime did not have a direct effect on length of the larval period, but increased density of tadpoles in drying ponds actually resulted in longer larval periods and smaller sizes at metamorphosis. Hence, neither species exhibited the predicted adaptive shortening of development time in drying ponds. Even though *H. gratiosa* typically breeds in temporary ponds, it actually had a considerably longer larval period than did *H. cinerea,* which tends to breed in more permanent water.

Much less work has been done on responses of salamander larvae to pond drying, in part because most salamanders do not breed in highly ephemeral habitats. S. Freeman and Bruce (2001) studied variation in length of the larval period in *Eurycea guttolineata,* a pond-breeding species. At low elevations, larval periods were several months shorter than at high elevations, where most larvae overwintered before metamorphosing. There was little difference in temperature at the different elevations, but breeding sites at low elevations tended to dry up by late summer. Freeman and Bruce interpreted their results as evidence of adaptive change in length of the larval period in response to increased likelihood of pond drying. The study did not involve experimental manipulation of drying regimes, however, so it is not clear whether this represents a plastic developmental response or genetic differences in life-history traits that have been favored by different selective regimes.

The only detailed experimental studies of the effect of pond drying on larval development in salamanders are on *Ambystoma talpoideum,* which breeds in Carolina bays and other relatively shallow temporary ponds. Reproductive success varies considerably from pond to pond and from year to year within ponds, with most larval mortality resulting from early drying of ponds (Semlitsch 1987d; Pechmann et al. 1989; Semlitsch et al. 1996). In natural ponds, the timing of metamorphosis can vary by more than 100 days, with metamorphosis occurring earlier in ponds that dry early (fig. 13.17 A). Larvae cannot reach metamorphosis in ponds that persist for less than 145 days. Those in ponds of long duration typically reach larger sizes at metamorphosis.

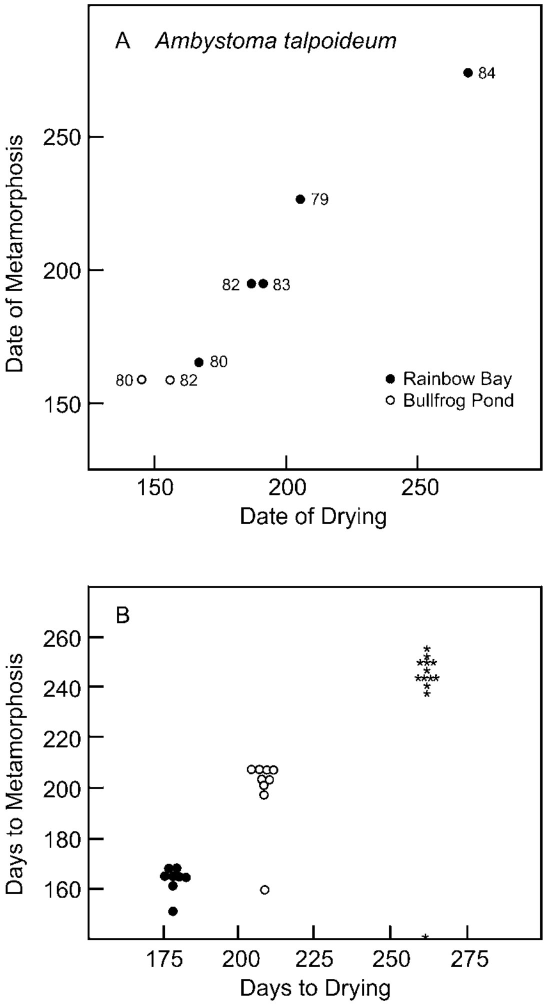

Fig. 13.17. Relationship of pond duration to date of metamorphosis in *Ambystoma talpoideum.* (A) Natural variation in date of metamorphosis in two temporary ponds (Rainbow Bay and Bullfrog Pond) between 1979 and 1984. After Semlitsch (1987c). (B) Number of days to metamorphosis as a function of three different drying regimes in artificial ponds. Data points represent individuals at three drying dates: July 20 (solid circles), August 21 (open circles), and October 14 (asterisks). After Semlitsch and Wilbur (1988).

Semlitsch and Wilbur (1988) conducted an experiment in which *A. talpoideum* larvae were housed in artificial ponds that either had constant water levels, or one of three different drying regimes. They found that timing of metamorphosis was strongly correlated with time to pond drying, and the pattern closely mirrored that seen in natural ponds (fig. 13.17 B). The first metamorphs emerged from all ponds at about the same time, however, indicating significant individual variation in timing of metamorphosis within ponds. Individuals that emerged from drying ponds did so at a smaller size than those that emerged from ponds with constant water. Many of the larvae in constant ponds reached very large sizes and became paedomorphic; these responses are discussed in more detail in a later section.

Fitness Consequences of Variation in Size and Age at Metamorphosis

A general assumption of all models of amphibian metamorphosis is that larvae that metamorphose at a large size will do better on land than those that metamorphose at a small size. Interspecific comparisons suggest that species that metamorphose at small sizes, relative to adult body size, often are morphologically or physiologically underdeveloped. For example, in some species with relatively short larval periods, such as *Bufo americanus,* juveniles emerge from the water with poorly developed lungs and aerobic capacities that are much lower than those of adults. This is not true for some species with long larval periods, such as *Rana clamitans* (Taigen and Pough 1981, 1985; Pough and Kamel 1984; Burggren and Just 1992). Sensory systems sometimes are incompletely developed in species with short larval periods. For example, the development of structures in the ear that enable frogs to detect airborne sounds are less developed in species with short larval periods than those with long larval periods (Hetherington 1988b). Another important physiological consequence of small metamorphic size is greater susceptibility to evaporative water loss, a problem that can be particularly acute for species such as spadefoot toads that emerge into very dry environments (R. Newman and Dunham 1994).

Interspecific comparisons suggest that patterns of larval development can affect juvenile performance, but they do not directly address the question of whether developmental differences among individuals of the same species affect juvenile performance and lifetime fitness. Several laboratory studies have examined the behavioral and physiological performance of conspecific juveniles that experienced different densities as larvae. John-Alder and Morin (1990) reported that juvenile Fowler's toads (*Bufo fowleri*) emerging from high-density larval populations were smaller and achieved shorter jump distances than those emerging from low-density populations. Differences in performance were due entirely to differences in metamorphic body size, not independent effects of larval crowding. Toads from high-density populations also had lower locomotor stamina than did those from low-density populations. Lower jumping performance in small individuals emerging from high-density larval populations also has been reported in another toad, *Bufo bufo* (Goater, Semlitsch, and Baernasconi 1993). Two ranids with longer larval periods, *Rana blairi* and *R. sphenocephala,* showed similar differences between high- and low-density metamorphs, and again, most of the variation in jumping performance was due to differences in body size (Semlitsch et al. 1999). Differences in body size also affected jumping performance in metamorphs of *Discoglossus galganoi,* but in this case, the differences were due to manipulation of food quality and temperature during larval development, rather than larval density (Álvarez and Nicieza 2002b).

In European water frogs (*Rana esculenta* complex), the effect of larval growth history on morphology and jumping performance was not consistent (Tejedo, Semlitsch, and Hotz 2000). In general, frogs derived from low-density ponds were larger and jumped farther than were those from high-density ponds. In one hemiclone of the hybrid *Rana esculenta* genotype, frogs raised at low density had relatively longer hind legs than those raised at high density, and this translated into increased jumping performance. This pattern was not seen in one of the parental species, *R. lessonae,* or two other hemiclones of *R. esculenta.* Surprisingly, larval density did not affect relative hind limb length in the other parental species, *R. ridibunda,* but these frogs did show an effect of larval density on juvenile jumping performance. This suggests that larval growth history affected muscle morphology or physiological traits that are related to jumping performance.

Beck and Congdon (2000) examined the effect of both age and size at metamorphosis on metabolic rate, sprint speed, and endurance in juvenile *Bufo terrestris.* Differences in age and size at metamorphosis were induced by varying food rations and temperature, but not tadpole density (tadpoles were reared alone). Metabolic rate, sprint speed, and locomotor endurance all were negatively correlated with length of the larval period and positively correlated with size at metamorphosis (fig. 13.18). Metabolic rate also was affected by temperature and food rations, after accounting for differences in age and size. The negative effect of age at metamorphosis on performance variables such as sprint speed is related to a negative correlation between age at metamorphosis and relative hind-limb length (Emerson 1986). Variation in metabolic rate is hard to interpret in terms of organismal performance, because the effects of activity on metabolic rate were specifically excluded from the experiment.

In a related study, Beck and Congdon (1999) measured metabolic rates of juveniles that varied in age and size at metamorphosis and then released them into small (0.5 m^2) enclosures in a forest. They then counted the number of survivors after one month and determined the mass of each animal. This experiment failed to show any relationship between either body size or metabolic rate and survival of the toads, but unfortunately, sample sizes were too low to detect such an effect. Initial body size was positively correlated with body size at the final census. In a second experiment, newly metamorphosed toads were placed in small field enclosures that were designed to allow some small terrestrial arthropods to move into the enclosures as prey for the toads. After 11 days, the toads were placed in a second set of

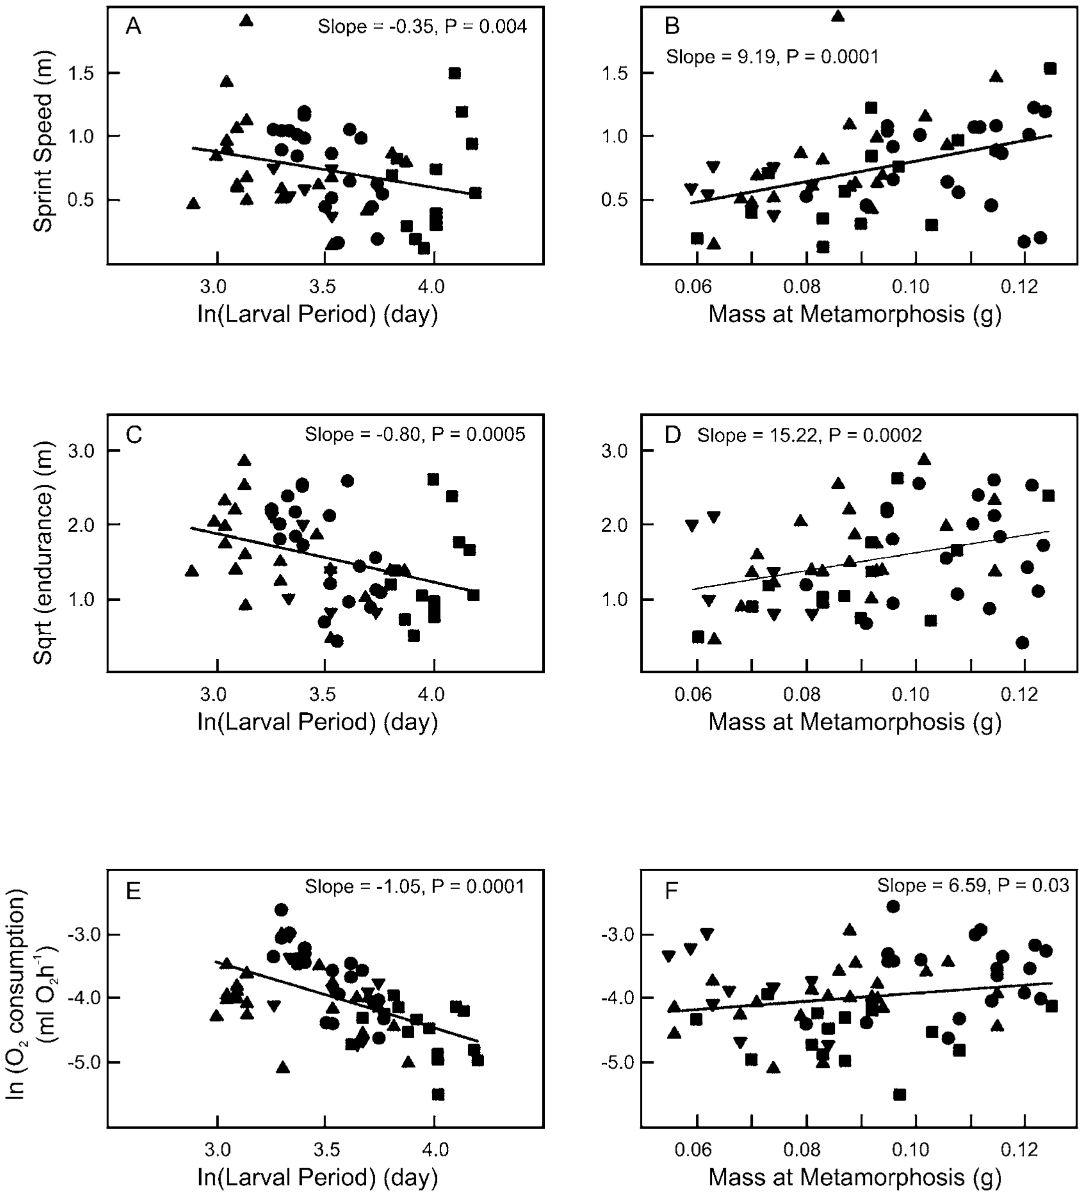

Fig. 13.18. Relationship of physiological performance of juvenile toads (*Bufo terrestris*) to length of the larval period and size at metamorphosis. Top: Sprint speed as a function of length of the larval period (A) and mass at metamorphosis. Middle: Endurance as a function of length of the larval period (C) and mass at metamorphosis (D). Bottom: Metabolic rate as a function of length of the larval period (E) and mass at metamorphosis (F). After Beck and Congdon (2000).

enclosures at lower densities to simulate dispersal away from a pond. In this experiment, size at metamorphosis was positively related to survival to day 11, but age at metamorphosis was not. Small individuals grew more rapidly than large ones, but mass at metamorphosis was not related to growth in mass or length. Relatively few toads (24%) were recaptured after about two months in the second, lower-density enclosures. There was a weak positive relationship between age at metamorphosis and survival after two months.

Overall, the results of these experiments suggested that age- and size-related differences in behavioral performance of newly emerged toads had relatively little effect on short-term survival. Juvenile toads undergo enormous increases in body size after metamorphosis, so it seems likely that the effects of small differences in initial body size will disappear as the toads grow. Unfortunately, the sources of mortality in these experiments were not known, although it is unlikely that major predators were present in the enclosures. Initial differences in performance variables such as sprint speed and endurance still could have significant effects on early survival if the animals were confronted with predators such as garter snakes soon after emerging from a pond (e.g., Wassersug and Sperry 1977).

Another experiment that used experimental enclosures to examine the effects of larval density on juvenile survivorship was conducted by Morey and Reznick (2001) on spadefoot toads (*Spea hammondii*). Tadpoles raised at low density metamorphosed at a larger size than did those raised at high density, and larger juveniles were more likely to survive their first year on land. Initial differences in body size were maintained or increased during the first year of terrestrial life. These size differences disappeared when juveniles were provided with extra food, either in the laboratory or in field enclosures. Hence, while the larval environment can influence fitness of juveniles and adults, such effects are mediated by conditions in the terrestrial environment. Altwegg and Reyer (2003) also used enclosures to follow survivorship of juveniles of *Rana esculenta* and *R. lessonae* raised in different larval environments. They found that large metamorphs had higher survivorship, faster growth rates, and larger size at maturity than did small metamorphs, regardless of what experimental manipulation produced the differences in body size. In contrast to the work with spadefoot toads, they did not find any tendency for small metamorphs to compensate for small initial size by increasing rates of postmetamorphic growth. Manipulations of juvenile density in enclosures had some effect on juvenile growth rate, but the effect was less than that of larval density. Juvenile density did not affect survivorship (Altwegg 2003b).

Several studies have examined the effect of size at metamorphosis on fitness in adults by following cohorts of individuals emerging from natural ponds and then returning one or more years later to breed. D. C. Smith (1987) followed marked juveniles of *Pseudacris triseriata* emerging from natural rock pools and measured survival and both age and size at sexual maturity. Frogs that metamorphosed early and at a large size had higher survival to maturity than did those that metamorphosed late and at a small size. The larger frogs also tended to reach sexual maturity after one year, whereas smaller frogs often did not reach maturity until the second year. Overall survival to the second year was not affected by size at metamorphosis, however. Given the relatively short life span of these frogs, early sexual maturity probably has a large effect on total lifetime reproductive success.

Berven and Gill (1983) reported a positive correlation between size at metamorphosis and both juvenile survival and size at first reproduction in populations of wood frogs (*Rana sylvatica*). Sample sizes were very small (< 12 individuals) because of high mortality. In another population, cohorts of juveniles emerged from two nearby ponds at different times and at different sizes. On average, the later-emerging cohort was larger at metamorphosis and at sexual maturity. The difference in average size of the two cohorts at metamorphosis was about 2 mm, as was the difference in size at maturity. The latter was about 4.7% of the average size of the larger cohort. Other work on this species suggests that a size difference of this magnitude would translate into a fecundity difference of about 50 eggs in first-year females, or about 10% of average clutch size (Berven 1988). The impact of this difference on overall fitness is unknown, as is the effect of differences in size at maturity for males.

Two studies of salamanders suggest that age and size at metamorphosis can affect adult fitness traits. Semlitsch, Scott, and Pechmann (1988) conducted an eight-year study of *Ambystoma talpoideum* in Rainbow Bay, a temporary Carolina bay that was completed encircled by a drift fence that allowed all immigrating and emigrating salamanders to be captured, marked, and measured. Sample sizes were relatively robust (about 20–111 individuals measured at sexual maturity each year). Survival to maturity was not affected by either age or size at metamorphosis, but both of these variables affected size at maturity. In general, individuals that metamorphosed early were larger at maturity than were those that metamorphosed late. Independent of age at metamorphosis, those that emerged at larger sizes were larger at maturity, and they remained larger in their second year of reproduction. Early metamorphosis and large metamorphic size also resulted in earlier reproduction by females, but this was not true for males.

In contrast to many anurans, *A. talpoideum* metamorphoses at a very large size, up to 95% of size at maturity. This compares with about 37% in wood frogs (Berven and Gill 1983). The limited growth of these salamanders after metamorphosis means that size at metamorphosis is likely to have a greater impact on adult fitness than in many anurans, some of which complete up to 95% of their growth after metamorphosis. Presumably the greater opportunities for postmetamorphic growth in anurans means that at least some individuals that emerge at a small size eventually will catch up to those that emerged at a larger size. This probably is more likely in species with long life spans than in those with relatively short life spans, such as *Pseudacris triseriata* (D. C. Smith 1987).

The second study of salamanders was a nine-year study of *Ambystoma opacum* (D. Scott 1994). Larvae were raised in large enclosures in natural ponds, as described in a previous section. At metamorphosis, the animals were released into the surrounding habitat. Various fitness-related traits, such as body size and clutch size, were then measured in individuals that returned to the ponds to breed over six or

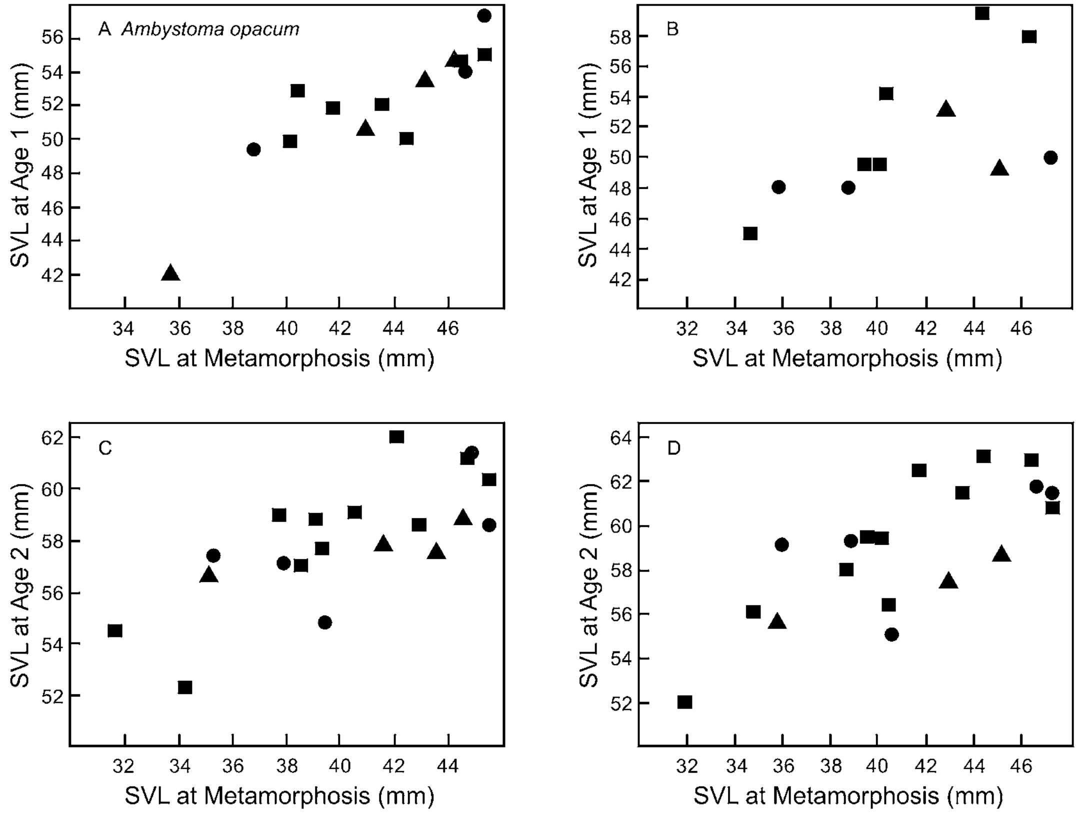

Fig. 13.19. Effect of size at metamorphosis on adult size of males (A, C) and females (B, D) at one and two years after metamorphosis in *Ambystoma opacum*. Each point represents a cohort of individuals from different experimental and natural ponds: Ginger's Bay experimental populations (squares), Ginger's Bay natural populations (circles), and Rainbow Bay natural populations (triangles). After D. Scott (1994).

seven breeding seasons. Scott found that metamorphs that emerged from low-density enclosures were larger and had larger lipid stores at metamorphosis than those from high-density enclosures. The former group returned to breed as larger adults than did those raised in high-density enclosures, and this size difference persisted in the second year (fig. 13.19). This species grows more between metamorphosis and sexual maturity than does *A. talpoideum;* metamorphs were about 75–88% of size at maturity. Individuals from low-density enclosures also had higher survivorship and reproduced at a younger age than those from high-density enclosures. Egg clutches of females were up to 70% larger in low-density individuals in one year, but not in another. The effect of body size on foraging success in a natural habitat is unknown, but any size-related difference in the ability of terrestrial adults to obtain food is likely to translate into a significant difference in reproductive performance, especially for females (D. Scott and Fore 1995). Overall, the results of this study provide the most convincing evidence for any amphibian that larval growth and development can have a significant impact on adult fitness and therefore on the dynamics of populations (B. Taylor and Scott 1997).

Temperature Effects on Larval Life-History Traits

Most field and laboratory studies of larval growth and development have focused on density effects and competition for food, and most have been consistent with the major features of the Wilbur-Collins model and later modifications of that model. In general, larvae reared under conditions that are unfavorable for growth transform at a small size and leave the water as soon as possible; under more favorable conditions, they continue to grow to a larger size. However, some embryologists criticized the model on the grounds that differentiation rate, not growth rate, is the most accurate predictor of the timing of metamorphosis (Smith-Gill and Berven 1979; Just, Kraus-Just, and Check 1981). As discussed in more detail later, this argument is somewhat circular, because differentiation rate is, by definition, the rate at which a tadpole progresses toward metamorphosis. Nevertheless, there is no doubt that temperature can have a major impact on rates of growth, timing of metamorphosis, and size at metamorphosis. For example, *Rana pipiens* tadpoles reared at low temperatures grow more slowly and take longer to reach metamorphosis than those reared at

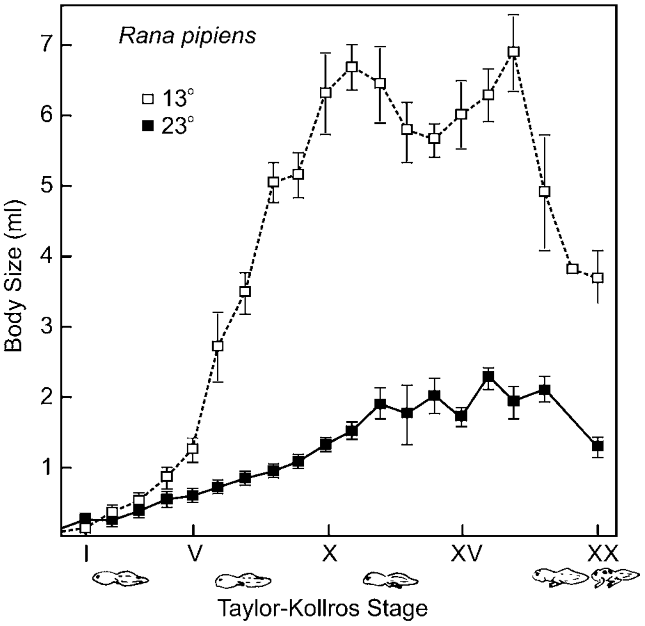

Fig. 13.20. Effect of temperature on development and body size in *Rana pipiens* tadpoles. Tadpoles raised at 13° C were larger at any given developmental stage than those raised at 23° C, but took longer to reach those sizes. Data are shown as means ± 2 SE. After Smith-Gill and Berven (1979).

warm temperatures, but they are larger at every stage (fig. 13.20). Hence, slow-growing tadpoles actually transform at a larger size than fast-growing ones, a result that appears to contradict the predictions of the Wilbur-Collins model. The explanation is that low temperatures inhibit differentiation more than growth (Smith-Gill and Berven 1979).

An analogous situation occurs in tadpoles that spend one or more winters in the larval stage. Differentiation virtually ceases during the winter, but growth continues, albeit at a reduced rate. In the spring, growth increases more rapidly than differentiation, so overwintering tadpoles typically transform at larger sizes than individuals that metamorphose in the same year that they hatch (Viparina and Just 1975; Collins 1979a; Berven, Gill, and Smith-Gill 1979; Smith-Gill and Berven 1979). Cold temperatures also reduce growth rates in pond-dwelling salamander larvae, but larvae from cold habitats often transform at a larger size (Bizer 1978; Sexton and Bizer 1978; Petranka 1984d). Similar effects can be produced by experimental manipulation of water temperature (Harkey and Semlitsch 1988 [corrected data for their table 2 supplied by R. Semlitsch]; Beachy 1995).

Temperature and Geographic Variation in Larval Life Histories

Differences in environmental temperature and the length of the growing season probably account for much of the geographic variation in larval life-history traits reported for many amphibians. Interpreting patterns of geographic variation can be difficult (Berven and Gill 1983). Some differences among populations are genetic responses to selective pressures in different environments, but others represent plastic responses to local environmental variables. Often these variables are confounded with one another in ways that makes analysis of life-history traits even more difficult. For example, habitats of pond-dwelling tadpoles vary in pond permanence, water depth, pond surface area, temperature, dissolved oxygen concentration, pH, habitat productivity, and abundance and types of predators. Closed-canopy ponds have lower light levels, lower temperatures, lower productivity, and often lower numbers of predators than do open-canopy ponds (Loman 2002b; Skelly, Friedenburg, and Kiesecker 2002). All of these variables could affect larval growth and development, either independently or in concert. Latitudinal gradients differ in average temperature, the length of the growing season, and the number of hours of daylight during the summer growing season, all of which can affect pond productivity.

Despite this confounding of variables, there is a clear tendency for many pond-dwelling amphibians to have slower growth and longer larval periods in cold environments than in warm ones. In some cases, however, larvae from cold environments actually metamorphose at a larger size because of the greater effect of cold temperatures on differentiation than on growth. These patterns are particularly evident along altitudinal or latitudinal gradients in similar breeding sites. For example, North American bullfrogs (*Rana catesbeiana*) have much faster growth rates and shorter larval periods in southern populations than in northern ones, but size at metamorphosis often is smaller in southern populations (Viperina and Just 1975; Collins 1979a). Tailed frogs (*Ascaphus*) of western North America have larval periods of up to four years in cold mountain streams (Metter 1967; H. Brown 1990), but only one or two years in coastal and southern populations (Wallace and Diller 1998; Bury and Adams 1999).

Berven, Gill, and Smith-Gill (1979) studied the genetic and environmental components of such variation in high- and low-elevation populations of *Rana clamitans*. High-elevation tadpoles experience colder temperatures and have shorter growing seasons than lowland populations. Consequently, high-elevation tadpoles grow more slowly and have much longer larval periods than lowland tadpoles, but they transform at a larger size because of the greater effect of low temperature on differentiation than on growth. When tadpoles from high and low elevations were raised at low temperatures, those from high elevations actually grew faster than those from low elevations, while the reverse effect was observed at high temperatures. Hence, while differences in growth rate and length of the larval period are largely developmental responses to environmental temperature, natural selection appears to have acted against the selection gradient, so that the negative effect of temperature on growth is reduced. In other words, while high-elevation tadpoles grow more slowly than low-elevation tadpoles in natural environments, they would grow even more slowly if they had the same sensitivity to temperature as low-elevation tadpoles. Although Berven, Gill, and Smith-Gill (1979) did not perform genetic crosses, it is clear that differences in life histories among populations result from interactions of genetic and environmental effects.

A more detailed analysis of altitudinal variation in life history strategies of wood frogs (*Rana sylvatica*) was performed by Berven (1982b). He combined measurements of growth and development under natural conditions with reciprocal transplants of larvae and genetic crosses between high- and low-elevation males and females to unravel genetic and environmental contributions to life-history variation. As in most previous studies, tadpoles from high-elevation natural environments had slower growth rates, longer larval periods, and larger sizes at metamorphosis than those from low-elevation sites (fig. 13.21). Transplant experiments revealed that nearly all the variation in length of the larval period was due to environmental effects, whereas genetic differences between populations accounted for some of the differences in larval growth rates and size at metamorphosis. High-elevation tadpoles had faster growth rates than low-elevation tadpoles in both types of ponds. However, environmental effects still accounted for nearly three-quarters of the variation in size at metamorphosis. Nongenetic maternal effects, such as differences in egg size (Berven 1982a), also had small, but significant, effects on size at metamorphosis. Subsequent crossing experiments showed high heritabilities and considerable additive genetic variance for development time in montane and lowland populations, and for body size at metamorphosis in montane populations (Berven 1987).

Berven and Gill (1983) extended the work on *R. sylvatica* to broader geographic comparisons. Despite the fact that pond temperatures generally decrease with increasing latitude, the length of the larval period of wood frogs actually decreases from south to north, as does size at metamorphosis. In part this is due to genetic differences in temperature sensitivity. Wood frog tadpoles from the Canadian tundra are less sensitive to temperature changes and therefore have shorter larval periods at low temperatures than tadpoles from the mountains of Virginia or low-elevation ponds in Maryland. These populations also differed in their responses to changes in tadpole density. In the Canadian population, the length of the larval period was relatively insensitive to changes in density, whereas size at metamorphosis decreased rapidly with increasing density. In contrast, the size of Maryland tadpoles was less affected by density, whereas the length of the larval period was more sensitive. Montane tadpoles from Virginia were somewhat intermediate (fig. 13.22).

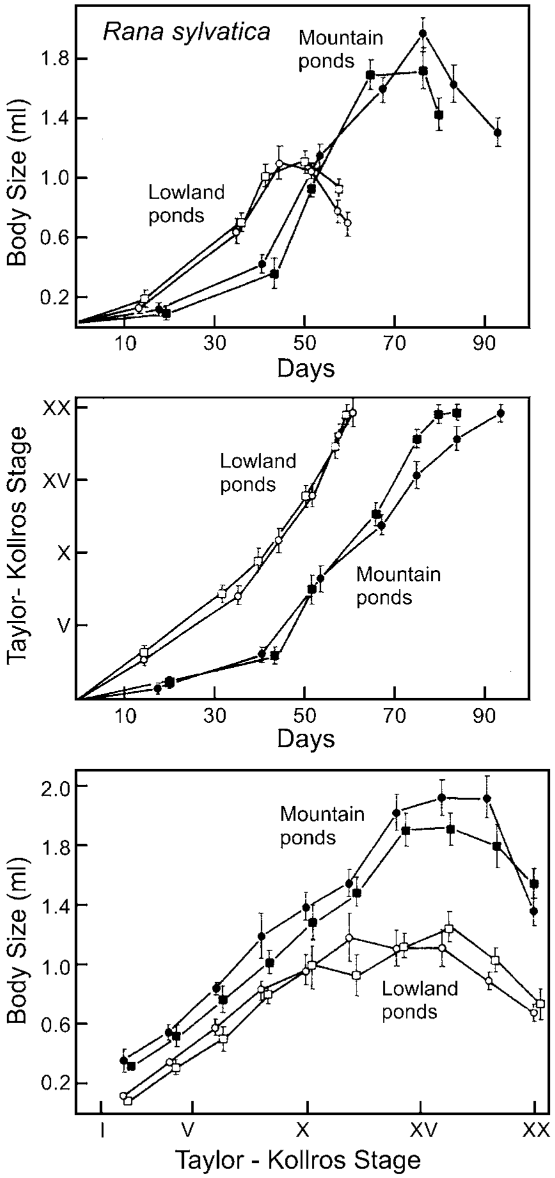

Fig. 13.21. Growth and development curves for wood frog (*Rana sylvatica*) tadpoles in natural ponds at high and low elevations. Tadpoles in mountain ponds grew more slowly and had longer larval periods than did those in low-elevation ponds, but reached larger sizes at metamorphosis. Data are shown as means ± 2 SE. After Berven (1982b).

Berven and Gill (1983) interpreted their results as evidence that the strength of natural selection operating on life-history traits differs among the populations. In the lowland population, both juvenile survivorship and size at first reproduction were positively correlated with size at metamorphosis. Selection seems to have favored large size at metamorphosis and has acted to minimize the sensitivity of this trait to environmental variables, particularly density. Be-

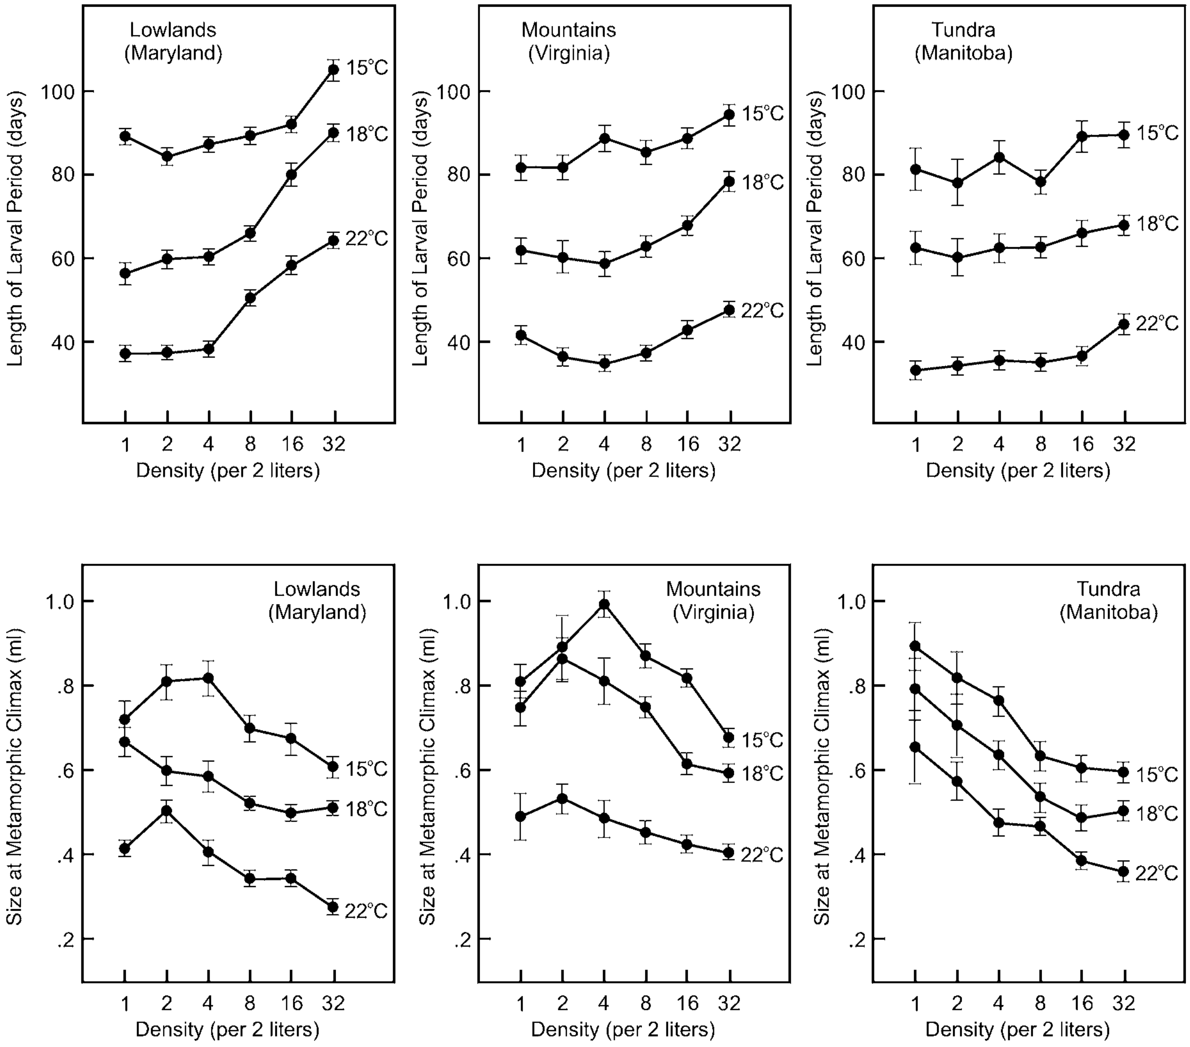

Fig. 13.22. Effect of temperature and larval density on length of the larval period and size at metamorphosis in wood frog (*Rana sylvatica*) tadpoles from three geographic locations. Size at metamorphosis was strongly affected by density in tundra tadpoles, but length of the larval period was not. In lowland tadpoles from Maryland, both length of the larval period and size at metamorphosis were affected by density. Tadpoles from the mountains of Virginia were somewhat intermediate, but more similar to those from Maryland than to those from the tundra. Data are shown as means ± 1 SE. After Berven and Gill (1983).

cause the growing season is relatively long, the disadvantage of a long larval period is reduced; selection has favored tadpoles that remain in the pond long enough to reach maximum body sizes. The more intense selection on body size was reflected in low heritability of that trait. In contrast, the very short growing season in the tundra appears to favor rapid larval development, even at the expense of a small size at metamorphosis. Consequently, length of the larval period was relatively insensitive to environmental effects in the Canadian population and exhibited low heritability, suggesting strong selection on that trait. Size at metamorphosis, on the other hand, was strongly influenced by density, and exhibited a much higher level of additive genetic variance. One mechanism that may allow for faster growth rates at high latitudes, or in other environments with short growing seasons, is a higher physiological efficiency in converting food into body tissue (Lindgren and Laurila 2005).

Studies of wood frogs in Michigan revealed a suite of life-history traits that were somewhat different from those in Maryland and Virginia and those in Canada (Riha and Berven 1991). In Michigan, tadpoles in the field grew faster, had shorter larval periods, and were larger at all stages of development than were low-elevation populations in Maryland or high-elevation populations in Virginia. When raised in the laboratory, most of the variation in development rate in populations from all three areas was due to variation in temperature, but development was slower in Michigan and Maryland than in Virginia. In contrast, Maryland and Virginia populations had similar growth rates at the same temperature, but growth rates of Michigan larvae were higher, especially at low temperatures. Some of the differences in larval life histories in these populations were due to differences in breeding time. Wood frogs in Michigan breed later in the spring than do those in Maryland and Virginia, and breeding ponds actually warm up faster than in the more southern populations. Pond productivity appears to be higher in Michigan as well, so more food is available to tadpoles. This could be due to longer days during the growing season, to local differences in nutrient input, or both.

In some amphibians, larvae do not metamorphose at larger sizes in cooler environments, as previously described. For example, some stream-breeding plethodontids exhibit the opposite pattern, with larvae reaching larger sizes at metamorphosis in warm, low-elevation habitats than in cool, high-elevation habitats (Bruce 1988b; Juterbock 1990; Voss 1993; Benardo and Reagan-Wallin 2002; Bernardo and Agosta 2003). Habitats of stream-dwelling salamander larvae vary along altitudinal gradients in a number of respects, including stream order, current velocity, temperature, habitat productivity, abundance of invertebrate prey, and density of predators. For these larvae, the low productivity of cool, high-elevation streams, and particularly the low abundance of suitable invertebrate prey, appear to limit feeding opportunities for salamander larvae and retard rates of growth and development. While prey abundance can be affected by environmental temperature, the effect of prey abundance on larval growth and development appears to be greater than the direct effect of temperature.

Taken together, these studies demonstrate that both environmental effects and genetic differences among populations can be important determinants of variation in life history strategies. In some cases, differences in patterns of larval growth and development that appear to be adaptive responses to natural selection actually are phenotypically plastic responses to the environment. In other instances, there are genetic differences among populations, but these can be identified only through carefully controlled experimental studies. Investigators should resist the temptation to invoke adaptive explanations for differences in life-history traits without adequate data on the genetic basis of such variation. In some cases, natural selection can favor increased phenotypic plasticity as an adaptation to highly variable environments.

The work of Smith-Gill and Berven (1979) and subsequent studies have been useful in demonstrating the importance of temperature as an environmental variable that can profoundly influence growth rate, the timing of metamorphosis, and size at transformation. However, the conclusions of these studies are not inconsistent with the Wilbur-Collins model and other models of amphibian metamorphosis that focus on relative growth rates. These models were designed primarily to explain variation in larval life histories among cohorts of larvae in the same population, where individuals are exposed to similar temperature regimes. They were not designed to account for differences among populations that differ substantially in environmental temperature.

The argument that differentiation rate is more useful than growth rate in predicting amphibian metamorphosis is ecologically uninformative. The stages used by developmental biologists to describe larval differentiation (e.g., the Gosner stages in fig. 13.3) culminate in metamorphosis, so by definition, differentiation rate is the rate at which a larva progresses toward metamorphosis. Therefore, it is a tautology to state that differentiation rate predicts the timing of metamorphosis (Sokol 1984; Wilbur 1984). Furthermore, their model assumes that all larvae metamorphose at exactly the same stage of development. However, Sokol (1984) found that tadpoles of *Litoria ewingi* differed in body proportions, and therefore degree of development, depending on rearing conditions, even though they all metamorphosed at the same Taylor-Kollros stage. Tadpoles reared under crowded conditions were anatomically underdeveloped compared to those reared at low densities, and this could affect their subsequent survival. Interspecific differences in degree of development can be even greater. Indeed, as the discussion in the next section makes clear, the degree of differentiation of larvae at metamorphosis can be just as plastic as are traits such as length of the larval period and size at metamorphosis, especially in urodeles.

Paedomorphosis as a Life-History Strategy

When the Spanish invaded Mexico in the sixteenth century, they found among the food items of the Aztecs a peculiar creature resembling the salamanders of Europe, but having conspicuous gills on each side of the head (fig. 13.23). The Aztecs called these creatures axolotls, after the exceptionally ugly god Xolotl, who once assumed this amphibian form and retreated into a deep lake to escape the wrath of other deities (H. M. Smith and Smith 1971). Over the next 300 years, various Spanish travelers mentioned axolotls in accounts of Aztec life, and a few preserved specimens found their way to Europe. Naturalists puzzled over the taxonomic status of the animal. Most considered it to be a primitive salamander, allied to the sirens, but others, including the great French naturalist Cuvier, thought it must be the larval form of an undiscovered species. A few, including Henri Milne-Edwards, considered it to be a functionally adult salamander, but one that had remained in an arrested stage of development (Gould 1977).

Scientific interest in the axolotl increased in the mid-nineteenth century, when live specimens were imported to

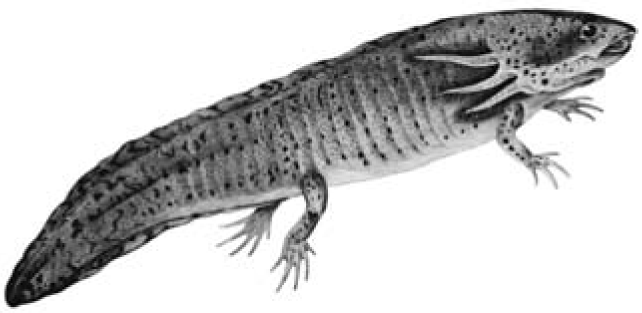

Fig. 13.23. An early engraving of the axolotl (*Ambystoma mexicanum*), a permanently paedomorphic salamander that retains gills throughout life. From Duméril, Bibron, and Duméril (1854).

France from Mexico. The specimens were collected in Lake Xochimilco, near Mexico City, during a short-lived attempt to add Mexico to a resurgent French empire. They were sent by an army officer to the French herpetologist, Auguste-Henri-André Duméril, who soon established a thriving colony in Paris. Several individuals attained sexual maturity and reproduced, but retained their larval morphology. However, to Duméril's astonishment, some of the offspring subsequently lost their gills and transformed into terrestrial adults that were nearly indistinguishable from salamanders of the genus *Ambystoma* (or *Amblystoma,* as the genus was called at the time). This created a considerable stir, since most naturalists had placed the axolotl in the genus *Siredon.* Either Duméril had witnessed the transformation of one genus of salamander into another, or the classification was in error. Eventually the axolotl was recognized as an example of arrested development, an adult form that retained the morphological features of a larva. August Weismann (1878) and others realized that this type of life history was a major blow to the idea that ontogenetic development recapitulates phylogenetic history; the axolotl clearly was derived from a terrestrial ancestor, yet it did not pass through a terrestrial stage during ontogeny (Gould 1977).

The Mexican axolotl, now called *Ambystoma mexicanum,* has become a famous animal, and descendents of Duméril's original stock continue to be used for all manner of experimental laboratory studies (H. M. Smith and Smith [1971] recorded more than 3,300 publications on the axolotl). However, its peculiar life history is far from unique. We now know that similar life histories are widespread among urodeles. All members of four families, the Cryptobranchidae, Sirenidae, Amphiumidae, and Proteidae retain some larval traits as adults and do not undergo further metamorphosis, even when treated with thyroid hormones. They differ, however, in which larval characters are retained in the adult stage (Noble 1924; Dent 1968; Rosenkilde 1979). Cryptobranchids, for example, lack external gills as adults, whereas these are retained in the other families. Retention of larval traits in mature adults occurs in some species in most other urodele families (Ambystomatidae, Dicamptodontidae, Hynobiidae, Plethodontidae, and Salamandridae). In some cases, such life histories have become genetically fixed, but in others they are facultative (Whiteman 1994).

A confusing variety of terms has been used to describe the retention of larval characters in sexually mature salamanders, and different authors often use these terms in contradictory ways. For example, Wilbur and Collins (1973) used the term *paedogenesis* to refer to genetic fixation of larval characters in adults, while the term *neoteny* was used to describe facultative metamorphosis. Salthe and Mecham (1974) used these terms in exactly the opposite way. Other authors have designated as neotenic any individuals exhibiting delayed metamorphosis, whereas those that become sexually mature while retaining larval characters are referred to as paedogenetic (Bizer 1978; Sexton and Bizer 1978). This confusion has led to extensive debate among herpetologists over the proper use of these and other terms (B. Pierce and Smith 1979, 1980; R. Sullivan 1980; D. Wake 1980). One problem is that the term *paedomorphosis* has been used both to describe the specific case of retention of larval characters, such as external gills, in sexually mature salamanders, and a more general evolutionary phenomenon of the retention in adults of any sort of traits in derived species that occur only in earlier developmental stages in ancestral species (see chapter 1). D. Wake (1992) argued that the term should be restricted to the latter situation, but most recent authors have referred to retention of larval characters in adult salamanders as paedomorphosis, and I have adopted that terminology here.

Gould (1977) argued that retention of larval characters in adults can come about either by retardation of somatic development (neoteny) or acceleration of sexual maturation (progenesis). He considered all paedomorphic salamanders to be neotenic, but other authors have disagreed (e.g., Denoël and Joly 2000). More recent workers have identified three processes that can operate alone or together to produce paedomorphic individuals: (1) *neoteny,* defined as a decelerated rate of somatic development, (2) *postdisplacement,* defined as the delayed onset of metamorphic change, and (3) *hypomorphosis,* defined as an early cessation of somatic differentiation that results in early onset of reproduction (Reilly, Wiley, and Meinhardt 1997; T. Ryan and Semlitsch 1998).

Gould's definitions say nothing about genetic fixation of the trait; salamanders can be genetically fixed for paedomorphosis, or facultatively paedomorphic (Whiteman 1994; Denoël, Joly, and Whiteman 2005). Even here there has been confusion. The Mexican axolotl and several other ambystomatids seldom, if ever, metamorphose in nature (see the following), and some authors have categorized them as "obligate neotenes" or "obligate paedomorphs" along with the proteids, sirenids, cryptobranchids, and amphiumids (Duellman and Trueb 1986; Werner 1986). Nevertheless, some individuals in paedomorphic populations of ambystomatids retain the capacity for metamorphosis when treated with thyroid hormones (Dent 1968; Taurog 1974; Rosenkilde 1979). As Duméril's experience showed, they sometimes metamorphose spontaneously in the laboratory (Chauvin 1876; Weismann 1878; H. M. Smith and Smith 1971; Brandon 1976; Brandon, Maruska, and Rumph 1981; Krebs and Brandon 1984). Hence, while some or all individuals are paedomorphic in nature, these species are not considered obligate paedomorphs.

Examples of Paedomorphosis in Urodeles

Ambystomatid salamanders are quite flexible in their life history characteristics, and paedomorphosis has evolved independently many times in the family. Paedomorphic life histories are particularly common in populations inhabiting the Mexican Plateau, a relatively arid region that includes a number of permanent lakes. Many of the lakes support isolated populations of *Ambystoma,* some of which are entirely paedomorphic. In addition to *Ambystoma mexicanum,* these taxa include *A. andersoni, A. dumerilii, A. taylori,* and several populations in the *A. tigrinum* complex (Brandon 1976; Brandon 1981; Krebs and Brandon 1984; Shaffer 1984a, b). Other Mexican taxa, including *A. ordinarium, A. rosaceum, A. amblycephalum, A. lermaense,* and some populations of *A. tigrinum,* have variable life histories, as does at least one species formerly placed in the genus *Ryacosiredon* (now considered part of *Ambystoma*). In some cases, paedomorphic and transforming individuals coexist in the same population, while in others, local populations vary in their metamorphic tendencies (J. Anderson and Worthington 1971; Brandon and Altig 1973; J. Anderson and Webb 1978; Collins 1979b; Shaffer 1984a, b). A similar range of variation is found in populations of *A. tigrinum, A. talpoideum,* and *A. gracile* north of Mexico (R. Snyder 1956; Gehlbach 1967, 1969; D. Larson 1968; R. Webb and Roueche 1971; Sprules 1974a, b; Eagleson 1976; F. Rose and Armentrout 1976; Patterson 1978; Collins 1981; Semlitsch and Gibbons 1985; Whiteman 1994). The four species of *Dicamptodon,* which are closely related to ambystomatids (see chapter 1), differ in their metamorphic tendencies. Individuals of *Dicamptodon copei* rarely metamorphose in the field (Nussbaum 1970). Most individuals of *Dicamptodon aterrimus, D. ensatus,* and *D. tenebrosus* metamorphose, but some individuals are paedomorphic in permanent ponds and streams (Schuierer 1958; Nussbaum 1970; Nussbaum and Clothier 1973; Petranka 1998).

The frequency of paedomorphosis in hynobiid salamanders is unclear. Most discussions (e.g., Wilbur and Collins 1973; Duellman and Trueb 1986) are based on an early report by Sasaki (1924) of paedomorphic *Hynobius retardatus* from a cold montane lake in Japan. He reported that individuals of the same species in temporary ponds always metamorphosed. The population described by Sasaki disappeared from the lake after 1932, apparently eliminated by introduced salmonid fishes, and paedomorphic individuals have never been collected from other localities (Moriya 1983). Sasaki believed that cold temperatures induced paedomorphosis in the lake population. This hypothesis was tested by Moyira (1983); he subjected larvae of transforming populations to low temperatures and found that many never metamorphosed. He did not demonstrate that the larvae ever attained sexual maturity, however, so it is not clear that they were truly paedomorphic.

In plethodontids, paedomorphosis is associated mainly with life in caves, although not all cave-dwelling plethodontids are paedomorphic. The genus *Gyrinophilus* exhibits a range of life-history strategies, from fully transforming to fully paedomorphic (Brandon 1966; Bruce 1979). *Gyrinophilus porphyriticus* is mainly a surface-dwelling species, but it sometimes lives in caves as well (Cooper and Cooper 1968; Brandon 1971). As discussed earlier, it has a very long larval period, but apparently is never paedomorphic. *Gyrinophilus subterraneus,* a species associated exclusively with caves, has larvae that reach nearly adult size that apparently transform just before sexual maturity (Besharse and Holsinger 1977). Although definitive evidence of paedomorphosis in this species has yet to be found, it appears to be evolving toward permanent larval life (fig. 13.24 A). A third species, *G. palleucus,* also is found exclusively in caves, but probably evolved independently from a *porphyriticus*-like ancestor (McCrady 1954; Lazell and Brandon 1962; Brandon 1965b, 1971). It is paedomorphic in nature, although it metamorphoses when treated with thyroid hormones (Dent and Kirby-Smith 1963), and a few spontaneously metamorphosed individuals have been found in the field (D. Simmons 1976; Brandon et al. 1986).

Most of the other paedomorphic plethodontids are in the genus *Eurycea.* Paedomorphic forms are particularly common on the Edwards Plateau of Texas, a region of extensive limestone caves and permanent springs, and the salamanders in this region form a monophyletic clade (Chippindale 2000; Chippindale et al. 2000). Again, this group exhibits a range of life histories from transforming to completely paedomorphic, with both cave- and surface-dwelling populations (Bruce 1976; Sweet 1977b, 1982; Petranka 1998). The latter are associated exclusively with permanent springs; when these fail, populations are forced underground into cave systems. In most populations, all individuals are

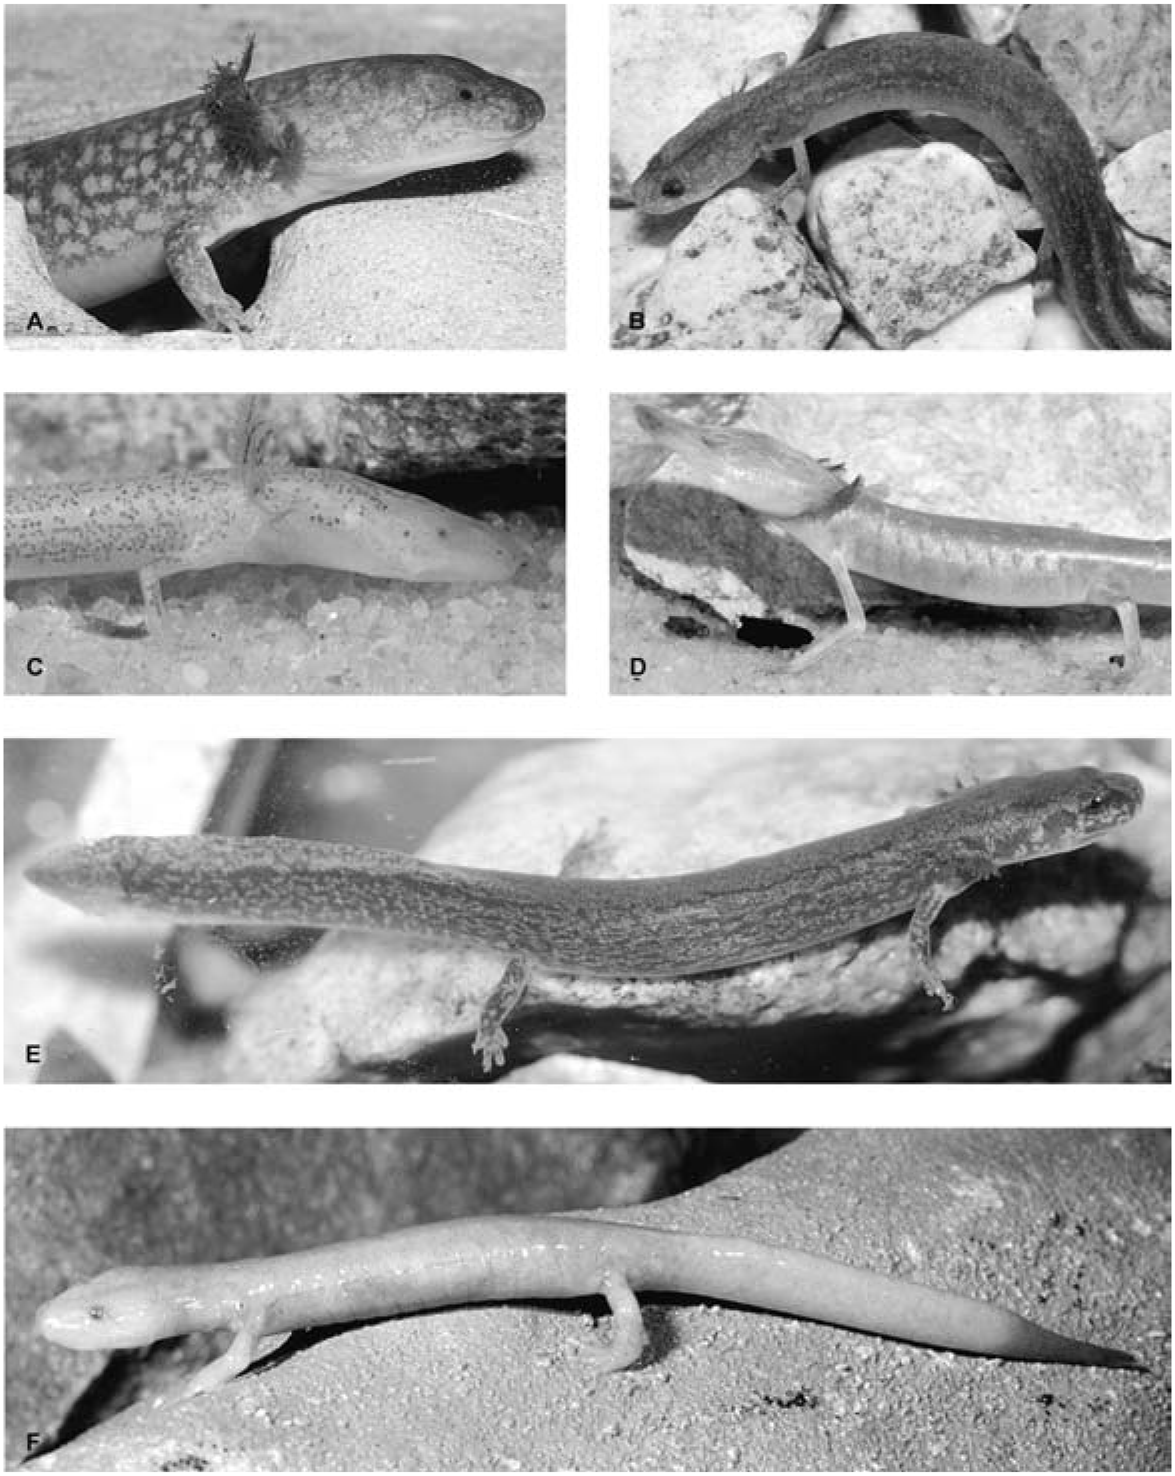

Fig. 13.24. Adaptations of plethodontid salamanders for life in caves and springs. (A) *Gyrinophilus subterraneus,* a species that sometimes lives in caves. It has a long larval period and reaches a very large size before metamorphosing. (B) *Eurycea tynerensis,* a surface-dwelling salamander from the Ozark Plateau with some paedomorphic populations. (C) *Haideotriton wallacei,* another blind paedomorphic salamander found in deep wells and caves. (D) *Eurycea rathbuni,* a species highly adapted for life in caves and springs, lacks pigment and functional eyes. (E) Pigmented, surface-dwelling larva of *Eurycea spelaea* from the Ozark Plateau. (F) Metamorphosed cave-dwelling adult of *E. spelaea,* with reduced pigment and degenerated eyes. Photos by Wayne Van Devender.

paedomorphic, but can transform when treated with thyroid hormones (Kezer 1952). However, several populations have significant numbers of transformed adults, and in some, paedomorphosis is uncommon or absent (Sweet 1977b, 1982). Metamorphosis is most common in surface-dwelling populations, but occurs occasionally in caves.

Most of the paedomorphic salamanders on the Edwards Plateau have restricted ranges, in many cases being limited to one cave system, stream drainage, or spring (J. K. Baker 1961, 1966; B. Brown 1967a, b, c; Sweet 1977a; Chippindale et al. 2000). These include *E. nana, E. neotenes, E. pterophila, E. sosorum, E. tridentifera, E. troglodytes,* and two species previously placed in a separate genus *Typhlomolge, E. rathbuni* (fig. 13.24 D), and *E. robusta* (Potter and Sweet 1981; Petranka 1998; Chippindale 2000; Chippindale et al. 2000). It is likely that many unnamed species in this complex remain to be discovered. Although these species usually are paedomorphic in nature, some retain the capacity for partial or complete metamorphosis when treated with thyroid hormones (Dundee 1957; Potter and Rabb 1960; Brandon 1971). All live in springs, but exhibit varying degrees of specialization for cave life. Most have some reduction in the size and function of the eyes, and *E. tridentifera, E. rathbuni,* and *E. robusta* are completely blind. These three species also are nearly or completely albinistic, a characteristic of most animals living in dark caves. *Eurycea rathbuni* and *E. robusta* are the most specialized cave dwellers, with spindly legs and flattened snouts that probably are used for aquatic feeding (fig. 13.24 D). These species somewhat resemble another blind paedomorphic salamander, *Haideotriton wallacei* (fig. 13.24 C), known from deep wells and caves in Georgia and Florida, but these species undoubtedly represent independent evolutionary events (Brandon 1971). This species is placed in the genus *Eurycea* by Frost et al. (2006).

Several other hemidactyline salamanders also exhibit varying degrees of paedomorphosis and adaptation to cave life. In the Ozark Plateau and Ouachita Mountains of Missouri, Arkansas, Oklahoma, and Texas, two putative subspecies of *Eurycea multiplicata* are primarily surface-dwelling and usually metamorphosing: *E. m. multiplicata* in the Ouachitas and *E. m. griseogaster* in the Ozarks (Bonett and Chippindale 2004). *Eurycea m. griseogaster* traditionally has been considered very closely related to *E. tynerensis* of the Ozark Plateau (fig. 13.24 B), which is surface-dwelling, but paedomorphic (Dundee 1965; Ireland 1976; Tumlison, Cline, and Zwank 1990). Recent phylogenetic work using mitochondrial DNA showed that *E. tynerensis* is not genetically distinct from *E. m. griseogaster,* and that a paedomorphic life history has evolved independently between three and nine times in this clade. Bonett and Chippindale (2004) recommended that all populations previously designated as *E. tynerensis* and *E. m. griseogaster* be treated as *E. tynerensis.* Another member of the *E. multiplicata* complex is *E. spelaea* (Bonett and Chippendale 2004). Larvae of this species have been found both in and out of caves. These have functional eyes, but transform into adults that have degenerate eyes and live exclusively in caves (Brandon 1970b, 1971; Besharse and Brandon 1974; fig. 13.24 E, F).

The only other urodeles in which paedomorphosis regularly occurs are the newts, particularly species of *Triturus* and *Notophthalmus.* One of the earliest accounts of paedomorphosis in any urodele was de Filippi's (1861) description of sexually mature "larvae" of *Triturus alpestris.* Paedomorphosis frequently occurs in this species (Radovanović 1951; Roček 1974; Ferracin, Lunadei, and Falcone 1980; Dolce and Stoch 1984; Džukić and Kaleszić 1984; Chacornac and Joly 1985; Giacoma 1988; Kaleszić et al. 1996; Denoël and Joly 2000; Denoël et al. 2001; Denoël 2004; Denoël, Schabetsberger, and Joly 2004). Paedomorphosis has been reported in several other European newts, including *T. helveticus, T. italicus, T. vulgaris, T. cristatus,* and *T. carnifex,* but the frequency of paedomorphosis varies among species and among populations of the same species (Kaleszić and Džukić 1985; Džukić et al. 1990; Kaleszić et al. 1994). For example, many paedomorphic individuals have been found in populations of *T. helveticus* in the Netherlands and southern France (van Gelder 1973; Gabrion, Sentein, and Gabrion 1977, 1978), but paedomorphosis is rare in British populations (Frazer 1983). In general, paedomorphosis appears to be most common in isolated mountain lakes, in regions such as the Alps and Balkans, but it sometimes occurs in permanent water at low altitudes.

There are many reports of paedomorphosis in *Triturus vulgaris* (Boettger and Schwartz 1928; Hartwig and Rotmann 1940; Gislén and Kauri 1959; Benl 1965; Dely 1967; Dolmen 1978, 1981a; Dolce and Stoch 1984; Kaleszić and Džukić 1985; Tucić et al. 1985), but usually all individuals eventually metamorphose. Hartwig and Rotmann (1940) reported that about 15% of newts in ponds near Cologne, West Germany were paedomorphic, but most eventually metamorphosed. At least one Swedish population was completely paedomorphic, but it was eliminated by introduced trout (Dolmen 1978, 1981a). There are reports of newts in some populations failing to reach sexual maturity (M. Smith 1969), perhaps as a result of incomplete development. Often such populations are albinistic (Benl 1965; M. Smith 1969; Frazer 1983). This suggests a defect in pituitary function, since both melanin production and metamorphosis are regulated by pituitary hormones.

There are scattered reports of paedomorphosis in *Triturus cristatus,* but Hartwig and Rotmann (1940) never found paedomorphic individuals of this species, even in locations where paedomorphic *T. vulgaris* were found. On the other hand, in Sweden, a permanently paedomorphic population of *T. cristatus* occurred in the same lake as paedomorphic *T. vulgaris* (Dolmen 1978, 1981a). Gabrion, Sentein, and Gabrion (1977) never found paedomorphic *T. marmoratus* in ponds where paedomorphic *T. helveticus* were common, and there appear to be no records of paedomorphosis in this species.

Paedomorphosis is uncommon in North American newts of the genus *Taricha,* many of which are largely terrestrial as adults. However, populations of the most aquatic species, *T. granulosa,* sometimes contain paedomorphic individuals (Reimer 1958), and some populations in high-altitude lakes are nearly all paedomorphic (Marangio 1978). Paedomorphosis appears to be more widespread in *Notophthalmus,* having been reported in both *N. viridescens* and *N. perstriatus* (Noble 1926a, 1929b; S. Bishop 1941a, b; Healy 1970; R. N. Harris 1987a). It is most common in coastal plain populations, but has been reported in permanent ponds in other areas as well (Brandon and Bremer 1966). Life histories of local populations shift in response to climatic variation, with larvae and even some neotenes completing metamorphosis when the aquatic environment deteriorates (Healy 1970; Reilly 1987). In many populations where paedomorphosis occurs, some transformed individuals omit the terrestrial stage and remain permanently in the water (Noble 1929b; Healy 1973, 1974). There has been confusion on this point. Some authors (e.g., Wilbur and Collins 1973) have implied that all individuals that bypass the eft stage are paedomorphic, but aquatic adults can be fully metamorphosed, or they can retain their gills (Noble 1926a, 1929b; S. Bishop 1941a; Healy 1970, 1973, 1974; Reilly 1986, 1987; R. N. Harris 1987a). Often individuals in all stages of metamorphosis occur in the same population.

One difficulty with determining the frequency of paedomorphosis in different groups is that developmental processes leading to retention of larval characters are not necessarily the same in all urodeles. For example, ambystomatids and salamandrids exhibit quite different life-history patterns. Paedomorphic ambystomatids have skulls nearly indistinguishable from those of larvae (Reilly 1986). Hence, these are individuals in which metamorphosis has been delayed beyond the onset of sexual maturity. In some species, such as *Ambystoma talpoideum,* sexually mature paedomorphic individuals can undergo rapid metamorphosis if the pond dries up (Semlitsch 1985b; Reilly 1987). In *Notophthalmus viridescens,* and probably in species of *Triturus* and *Taricha* as well, the skulls of branchiate (gilled) adults are fully metamorphosed, with the only paedomorphic characters being the retention of some or all of the gill structures. Hence, paedomorphic newts are individuals that have initiated but not completed metamorphosis. Reilly (1987) found that permanent paedomorphosis is rare in *Notophthalmus viridescens.* Eventually most branchiate adults apparently complete metamorphosis by losing the gills, even if they remain in the water.

The Mechanistic Basis of Paedomorphosis

Changes in the tendency of amphibian larvae to undergo metamorphosis must involve alterations at one or more stages of the thyroid hormone axis that affect the production of thyroid hormones, the sensitivity of tissues to these hormones, or a combination of the two. There is some evidence that alterations in the hormonal control of metamorphosis leading to a paedomorphic life history have occurred differently in different lineages of salamanders (Shaffer and Voss 1996). For example, individuals in many paedomorphic populations retain the capacity to metamorphose when they are treated with thyroid hormones, but in other populations, this capacity has been lost. In the Mexican axolotl (*Ambystoma mexicanum*), production of thyroxine appears to be normal, and there is a surge of hormone production early in the larval period, as in other larval salamanders. This surge of thyroxine does not lead to metamorphosis, however, apparently because this species lacks the enzyme that converts thyroxine to the more potent triiodothyronine, which actually initiates metamorphosis. Late in ontogeny, activity of the thyroid axis declines, and these animals never metamorphose in nature (Galton 1992; Rosenkilde and Ussing 1996). These developmental changes appear to be due to changes in a major gene, or quantitative trait locus, and not a simple single genetic locus (Voss and Shaffer 1997). In ambystomatids that are facultatively paedomorphic, the lack of metamorphosis is correlated with changes at higher levels of the thyroid axis, such as the regulation of thyroid hormones by the hypothalamus or pituitary (Shaffer and Voss 1996).

In proteids, which do not undergo metamorphosis even when treated with high doses of thyroid hormones, the loss of metamorphosis is due in part to changes in the sensitivity of target tissues to thyroid hormones. Both *Necturus* and *Proteus* have normal thyroid hormone receptor genes, but one of these genes, TRβ, is expressed at very low levels in these salamanders. This suggests that up-regulation of this gene does not occur in response to thyroid hormone secretion and metamorphosis is not initiated (Safi et al. 1997).

Ecological Correlates of Paedomorphosis

Most early students of paedomorphosis in salamanders believed that metamorphosis was directly inhibited by some environmental factor, and there were many attempts to identify the proximate causes of this condition. Because paedomorphic ambystomatids and salamandrids are frequently found in high-altitude lakes, many workers suggested that paedomorphosis is caused by low temperatures that either reduce the sensitivity of target tissues to thyroid hormones, or reduce the activity of the thyroid gland (Sasaki 1924; R. Snyder 1956). There is no doubt that environmental temperatures can affect the tendency of individual larvae to metamorphose. For example, Sprules (1974b) raised *Ambystoma gracile* larvae at 12°C and 19°C and found a greater incidence of paedomorphosis at the colder temperature. However, individuals apparently differed in their response to cold. Furthermore, there clearly are genetic differences among populations in metamorphic tendencies. For example, Eagleson (1976) raised *A. gracile* larvae from high- and low-altitude lakes at the same temperature; only 24% of the larvae from the high-altitude lake metamorphosed, compared to 88% of those from the low-altitude lake. In any case, the proximate effects of low temperature are not sufficient to account for paedomorphosis in all urodeles, since many paedomorphic salamanders do not live in cold lakes.

A variety of other direct environmental influences have been invoked to account for paedomorphic tendencies in urodele populations. These include low levels of iodine in high-altitude lakes, resulting in abnormal thyroid activity; insufficient food; an abundance of food; and steep-sided ponds that make it difficult for larvae to emerge from the water (Hartwig and Rotmann 1940; Van Gelder 1973; Salthe and Mecham 1974; Sprules 1974a). Most of these explanations lack generality, particularly for populations in which metamorphosing and paedomorphic individuals coexist. Most recent workers have assumed that paedomorphosis represents a life-history strategy that has evolved in response to natural selection. Presumably selection could operate through: (1) changes in the activity of the thyroid gland, (2) changes in the sensitivity of target tissues to thyroid hormones, (3) changes in the response of the thyroid or target tissues to environmental variables, or (4) a combination of all three. Selection also could favor plasticity in the hormonal control of metamorphosis, allowing facultative paedomorphosis when conditions are favorable, but transformation when they are not. This might occur through changes in hypothalamic activity in response to external environmental cues.

Many authors have proposed that a paedomorphic life history is favored in permanent, relatively equable aquatic habitats surrounded by unstable or inhospitable terrestrial environments (Wilbur and Collins 1973; Healy 1974; Salthe and Mecham 1974; Sprules 1974a). In fact, this was suggested more than a century ago by August Weismann (1878), who attributed the permanent larval life of the axolotl to circumstances that "made life on land more difficult than life in the water," an explanation echoed by Walter Garstang's verse at the beginning of this chapter. Often this hypothesis is stated in terms of a harsh physical environment on land resulting from cold temperatures or arid conditions (e.g., Sprules 1974a; Duellman and Trueb 1986). However, this is an oversimplification, because both physical and biological factors can affect the relative suitability of the aquatic and terrestrial environments.

Werner's niche shift model again provides a useful framework for understanding paedomorphosis. He pointed out that harsh terrestrial conditions would tend to raise the mortality/growth ratio in the terrestrial environment relative to that in the water, while equable conditions in the water would lower the mortality/growth ratio in that habitat. Environmental variables that might shift the balance between growth and mortality in the water or on land include the following: (1) differences in temperature, which could affect growth rates or the length of the growing season; (2) aridity of the terrestrial environment; (3) predation pressure; and (4) availability of food in the two habitats. In addition, the permanence of the aquatic environment will determine whether a paedomorphic life history is possible. There are many examples of paedomorphosis occurring in urodele populations that inhabit permanent ponds, lakes, or streams, whereas populations of the same species in temporary water undergo metamorphosis (Schuierer 1958; Brandon and Bremer 1966; J. Anderson and Worthington 1971; Webb and Roueche 1971; Nussbaum and Clothier 1973; Nussbaum 1976; F. Rose and Armentrout 1976; Patterson 1978; Collins 1981; Semlitsch and Gibbons 1985). Nevertheless, there also are examples of paedomorphic populations occurring in both permanent and temporary habitats, as in *Triturus alpestris* in Europe (Denoël et al. 2001).

The relative importance of these environmental variables depends on the ecology of each species. Many paedomorphic urodele populations are found in permanent lakes or ponds in relatively arid regions. The various species of paedomorphic ambystomatids on the Mexican plateau and elsewhere in western North America (Gehlbach 1967; D. Larson 1968; Webb and Roueche 1971; Collins 1979b, 1981) are obvious examples. Populations of paedomorphic *Triturus helveticus* often are associated with arid limestone tablelands (Gabrion, Sentein, and Gabrion 1977) or inland dunes (van Gelder 1973). The occurrence of paedomorphosis in some coastal plain populations of *Notophthalmus* has been attributed to the relatively arid, sandy terrestrial environment (Healy 1970; Wilbur and Collins 1973). Similarly, high-altitude environments not only have long, cold winters, but also tend to have relatively dry summers, a regime that selects against metamorphosis (Sprules 1974a; Dolmen 1978, 1981a; Marangio 1978). On the other hand, no matter how harsh the terrestrial environment, a paedomorphic life history often is impossible if aquatic predators are abundant. Consequently, paedomorphic urodeles in arid regions or at high altitudes are found mostly in lakes without predatory fish (Carr and Goin 1943; Brandon and Bremer 1967; D. Larson 1968; Sprules 1974a; Dolmen 1978, 1981a; Marangio 1978).

The relative availability of food in aquatic and terrestrial environments has not been investigated as thoroughly. Healy (1973) found that growth of young *Notophthalmus viridescens* was faster in the water than on land in coastal plain areas; this should favor paedomorphosis unless drying of the pond (Healy 1970) or high levels of predation (Werner 1986) result in excessive mortality in the water. The association of paedomorphosis with life in caves also is related to the availability of food, because much of the prey available in a cave is found in the water (Brandon 1971). Although metamorphosed salamanders often feed in the water (P. Smith 1948; Bruce 1979), they probably are less effective at doing so than aquatic larvae (Lauder and Shaffer 1986), and therefore would be at a competitive disadvantage compared to paedomorphic adults. Metamorphosed adults *of Gyrinophilus palleucus* and *G. subterraneus* tend to be emaciated, whereas larvae are robust, with extensive fat reserves (D. Simmons 1976; Besharse and Holsinger 1977; Brandon et al. 1986); this suggests a shortage of food for terrestrial animals. Even aquatic paedomorphs probably are energy-limited in many cave systems, because nearly all energy input comes from outside of the caves. At least one species, *Eurycea spelaea,* even consumes bat guano, which can be as important an energy source as invertebrate prey (Fenolio et al. 2006).

Whiteman, Wissinger, and Brown (1996) examined the foraging ecology of metamorphosed and paedomorphic tiger salamanders (*Ambystoma tigrinum nebulosum*) in Colorado, where the animals are facultatively paedomorphic. Metamorphic adults grew faster in both length and body mass than did paedomorphic adults. Metamorphosed adults also had more caloric value of food in their stomachs than paedomorphic adults. The main reason for this is that metamorphosed adults often moved to temporary ponds, where they had access to fairy shrimp, a preferred type of prey. These prey animals were not available to paedomorphic animals, which are restricted to permanent ponds where fairy shrimp do not occur. Metamorphosed adults also have access to prey in terrestrial habitats that are not accessible to paedomorphic salamanders. The results of this study suggest a strong fitness advantage for metamorphosed adults, raising the question of why paedomorphosis occurs at all in this population. The answer is not entirely clear, although Whiteman, Wissinger, and Brown (1996) suggested that paedomorphosis might be advantageous in permanent ponds with poor growing conditions, because it would allow the salamanders to reach sexual maturity and reproduce at a younger age than those that undergo metamorphosis. In this sense, paedomorphic individuals persist in the population not because they enjoy a clear advantage over metamorphs, but because that is the best option available to them ("making the best of a bad job"' see also Whiteman 1994).

Whiteman's results with *Ambystoma* contrast with studies of mixed populations of paedomorphic and metamorphosed alpine newts (*Triturus alpestris*) in Europe. As with most polymorphic populations of salamanders that have been investigated, paedomorphs and metamorphs are fully sexually compatible (Denoël, Poncin, and Ruwet 2001b) and have nearly identical courtship behavior, despite differences in morphology (Denoël 2002). The two morphs differ ecologically, however. Paedomorphs feed mainly on zooplankton and can be found throughout the water column, including deep water. Metamorphosed individuals feed mostly on terrestrial insects along the shore or in shallow water (Denoël and Joly 2001; Denoël and Schabetsberger 2003; Denoël, Schabetsberger, and Joly 2004). In a number of ponds and lakes, paedomorphs had higher food intake rates, larger fat reserves, and better body condition than did metamorphs, although this was not true for all ponds (Denoël, Hervant, Schabetsberger, and Joly 2002). When paedomorphic newts were provided with extra food in a laboratory experiment, they grew faster and were more likely to remain paedomorphic than were those on low food rations (Denoël and Poncin 2001). All of these results support the hypothesis that favorable growth conditions in the aquatic environment increase the probability that individuals will remain paedomorphic (Denoël, Džukić, and Kalezić 2005).

Genes, Environment, and Phenotypic Plasticity in Paedomorphic Urodeles

The preceding discussion has treated paedomorphosis as an adaptive life-history strategy that has evolved many times in response to a variety of selective pressures. This assumes that life-history traits such as the tendency to undergo metamorphosis are sufficiently heritable for selection to operate. I have already discussed evidence for genetic variation in larval growth rate among individuals in anuran populations, which in turn leads to differences in the length of the larval period and size at metamorphosis. This section deals with the environmental and genetic determinants of variation in life-history strategies among populations that exhibit facultative paedomorphosis.

The fact that many populations of urodeles are completely paedomorphic in nature suggests that natural selection has shaped the life histories of these animals in response to local environmental conditions. Certainly this is true for those species that have lost the genetic capacity for metamorphosis. However, the quantitative genetics of paedomorphosis have not been worked out in detail. In populations composed of both paedomorphic and metamorphosing individuals, the mixed life-history strategy could be maintained by a genetic polymorphism (Sprules 1974b; R. N. Harris 1987a), but clear evidence for such polymorphism within populations is lacking. Similarly, differences among populations in the frequency of metamorphosis could be due in part to genetic differences. However, the heritability of the tendency to undergo metamorphosis is not known for any species. There have been several studies of interspecific hybridization among species of *Ambystoma,* some of which are paedomorphic (Brandon 1972, 1977; Nelson and Humphrey 1972), but these were not designed to elucidate the genetic basis of paedomorphosis.

Several studies have examined the responses of individuals from different populations raised under the same environmental conditions. Eagleson's (1976) experimental manipulation of temperature and its effect on the frequency of metamorphosis in different populations of *Ambystoma gracile* was discussed already. R. N. Harris (1987a) reported that larval density affected the frequency of paedomorphosis in *Notophthalmus viridescens.* Larvae raised at low densities in artificial ponds were more likely to become paedomorphic than those raised at high densities. Although Harris suggested that a genetic polymorphism might be involved, he did not conduct any genetic experiments. It could be that all individuals have the capacity to retain larval characters, and paedomorphosis is a direct response to environmental cues. Harris also did not determine whether paedomorphic individuals remained permanently in this condition, or eventually metamorphosed after attaining sexual maturity (Reilly 1987).

Studies of the facultatively paedomorphic salamander *Ambystoma talpoideum* provide the most detailed information on the environmental and genetic basis for variation in life histories. In this species, environmental conditions have a strong effect on the tendency of animals to become paedomorphic. Larvae derived from a population that exhibits a high rate of paedomorphosis were raised in cattle tanks under varying conditions of larval density, food abundance, and pond-drying regime (Semlitsch 1987c). Salamanders were much more likely to become paedomorphic when raised at low density and in constant water, but tended to metamorphose in drying ponds or when larval densities were high (fig. 13.25). The presence of bluegill sunfish reduced the tendency of these salamanders to become paedomorphic, not because they increased rates of metamorphosis, but because larvae in tanks with fish tended to remain longer in the larval stage (M. Jackson and Semlitsch 1993).

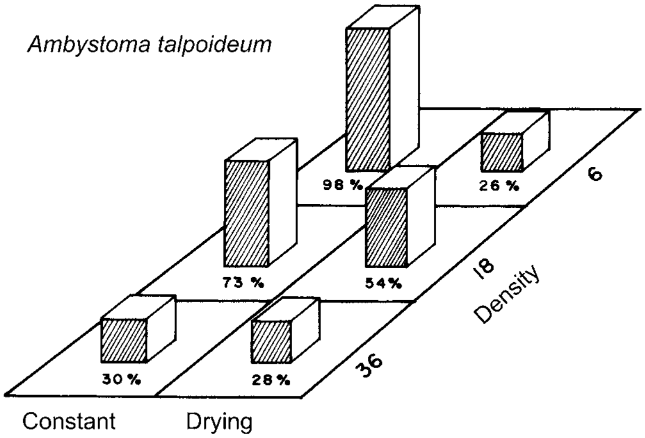

Fig. 13.25. Effect of drying regime and larval density on the percentage of *Ambystoma talpoideum* larvae becoming paedomorphic in artificial ponds. Height of each bar shows the average for eight artificial ponds. The larvae were most likely to become paedomorphic in permanent water at low larval densities. After Semlitsch (1987a).

Despite the strong effects of environmental variation on paedomorphosis, there are clear genetic differences among populations in the tendency to become paedomorphic. In an early experiment, Semlitsch and Gibbons (1985) collected females from two populations that differed in the frequency of metamorphosis. Adults from a relatively permanent pond (Ellington Bay) usually were paedomorphic, whereas those from a temporary site (Sun Bay) always transformed. Eggs from these females were raised at different densities and subjected to different rates of pond drying. There were significant differences between the populations in the frequency of paedomorphosis, with larvae from the permanent site being more likely to become paedomorphic under both constant water level and drying treatments (fig. 13.26). This could be the result of genetic differences, but maternal effects could not be ruled out, because only first-generation offspring were considered.

In a subsequent experiment, individuals from these two populations were subjected to different drying regimes over several generations to select for a paedomorphic life history (Semlitsch and Wilbur 1989). Both populations responded to selection for paedomorphosis in permanent water. However, responses of the two breeding lines differed. The line derived from a natural population with a high rate of paedomorphosis responded to selection by decreasing the number of immature larvae and increasing the number of sexually mature paedomorphs. The line derived from a population with a low rate of paedomorphosis responded by decreasing the rate of metamorphosis and prolonging the larval period. The fact that these populations could respond to selection indicated that there is some genetic basis for the tendency to become paedomorphic. This was confirmed in crossing experiments with individuals from three different populations, two from relatively permanent ponds and one from a temporary pond (R. N. Harris et al. 1990).

In another set of experiments, Semlitsch, Harris, and Wilbur (1990) reared larvae from six different populations under the same environmental conditions. Two of these populations were from ponds that seldom dry up, whereas the

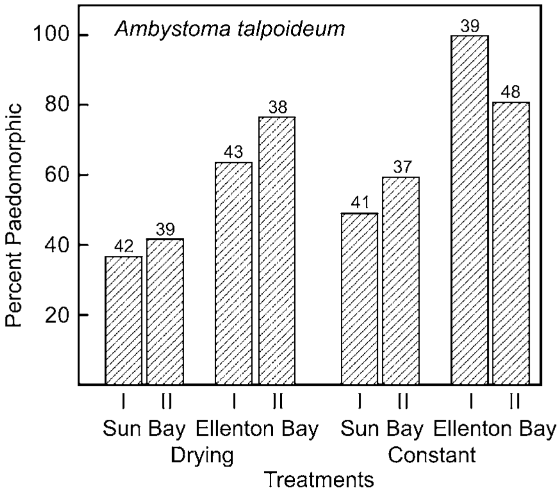

Fig. 13.26. Percentage of paedomorphic *Ambystoma talpoideum* from experimental ponds. Source populations were larvae from a relatively permanent pond (Ellenton Bay) and a temporary pond (Sun Bay). Treatments were either tanks that held constant water or those subjected to drying. Roman numerals indicate replicate tanks. Numbers at tops of bars are sample sizes of individuals. After Semlitsch and Gibbons (1985).

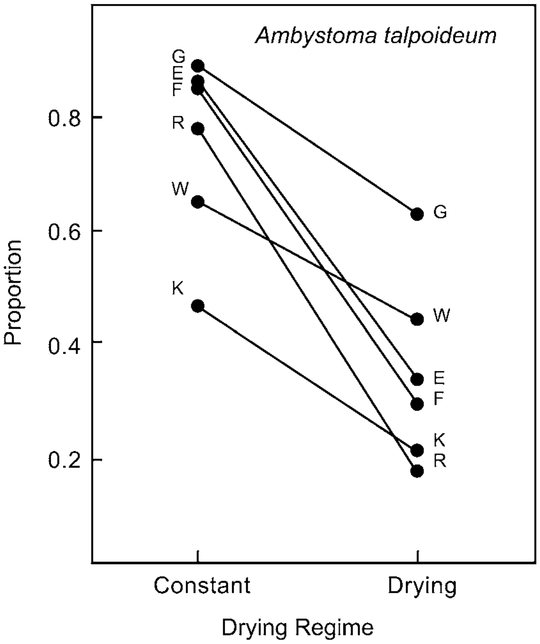

Fig. 13.27. Proportion of surviving larvae of *Ambystoma talpoideum* that became paedomorphic in experimental ponds that held constant water or were subjected to drying. Parents of the larvae used in the experiment were obtained from ponds that seldom dry up in the summer (E = Ellenton Bay; F = Flamingo Bay), those that usually dry up (W = Woodland Pond; K = Karen's Bay), and those that always dry up (G = Ginger's Bay; R = Rainbow Bay). After Semlitsch, Harris, and Wilbur (1990).

other four were from ponds that almost always become dry. All of the populations showed a stronger tendency toward paedomorphosis in constant water than in drying tanks, but there were significant differences among populations in the tendency to become paedomorphic (fig. 13.27). These differences did not perfectly reflect differences in natural drying regimes in the source populations, however. For example, one pond that always dries (Ginger's Bay) had the highest frequency of paedomorphs under both drying and constant water regimes. Larvae from another pond that usually dries (Karen's Bay) exhibited a low frequency of paedomorphosis under both drying and constant water regimes. Other populations showed highly plastic responses, with high frequencies of paedomorphosis in constant water and high frequencies of metamorphosis in drying tanks. These results suggest that selection has affected the degree of plasticity in life histories and not just the capacity to remain paedomorphic. These experiments also suggested that recent drying history of the source ponds could not account for all of the variation among populations. Other selective pressures, such as food abundance and larval density, probably are important as well.

Most studies of paedomorphic salamanders have focused on the morphological differences between paedomorphic and transformed adults as they relate to their ability to live in water or on land. However, T. Ryan and Semlitsch (1998) argued that morphological differences are a secondary effect of paedomorphic development, with the main target of natural selection actually being timing of reproduction. By forgoing metamorphosis, individuals have more energy available for growth and sexual maturation, thereby achieving an earlier age at reproduction. Paedomorphic individuals could then reproduce at an earlier age than transformed individuals, or they might reproduce at the same age, but at a larger body size, thus deriving a fecundity advantage from paedomorphosis. Earlier work on this species had shown that paedomorphic females reproduce at a younger age than do metamorphosed females, but metamorphosed females produced somewhat larger clutches for their body size than did paedomorphic individuals of the same age (Semlitsch 1985b).

In the experiments by T. Ryan and Semlitsch (1998), larvae derived from a population that normally metamorphoses were raised at high and low density. In both treatments, sexually mature paedomorphs appeared in ponds before any individuals metamorphosed, although the frequency of paedomorphosis was low at high density (fig. 13.28). None of the newly metamorphosed individuals was sexually mature. Hence a clear advantage of paedomorphosis in this salamander is the decoupling of metamorphosis and sexual maturation, allowing for earlier reproduction by paedomorphic individuals and possibly higher lifetime reproductive success. This can be especially advantageous in an environment with variable rainfall, where movement of metamorphosed individuals into breeding ponds depends on adequate rainfall.

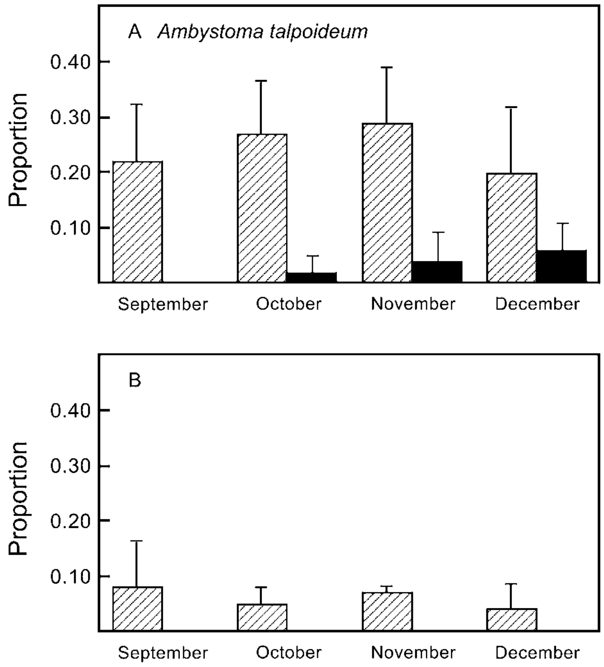

Fig. 13.28. Proportion of paedomorphic (hatched bars) and metamorphosed (black bars) adult *Ambystoma talpoideum* in experimental ponds in different months at low (A) and high (B) larval densities. In both high- and low-density ponds, paedomorphic adults appeared before sexually mature metamorphosed adults. All larvae were derived from a population in Rainbow Bay, a pond that always dries up in the summer. After T. Ryan and Semlitsch (1998).

Paedomorphic individuals are already present in permanent ponds and can initiate or even complete reproduction before metamorphosed members of the population even appear in the ponds. Early reproduction, in turn, gives the offspring of paedomorphs a head start in competition with larvae of later arriving metamorphs (T. Ryan and Plague 2004). It also would enable their offspring to complete development early, a major advantage in years when a pond dries up. Because paedomorphic adults retain the ability to metamorphose if conditions deteriorate, they can enjoy the benefits of early sexual maturation without the potential cost of becoming trapped in a drying pond and suffering an early death.

In some populations, any reproductive advantage of paedomorphosis may be greater for one sex than for the other. In a population of *A. tigrinum nebulosum*, for example, metamorphosed females reproduced at shorter intervals than did paedomorphic females, whereas the opposite was true for males. Sex ratios of paedomorphs were biased toward males, but females outnumbered males among metamorphs (Whiteman 1997). A reproductive advantage also can be affected by ecological differences among populations. In European newts, there was no reproductive advantage for paedomorphs in populations of *Triturus vulgaris* and *T. alpestris* from high-altitude lakes (Kalezić et al. 1996; Denoël and Joly 2000), but at lower elevations, paedomorphs of *T. alpestris* grew faster and reached sexual maturity earlier than did metamorphs (Denoël and Joly 2000).

Summary and Conclusions

A complex life cycle involving an aquatic larval stage and metamorphosis into a terrestrial or semiterrestrial adult is thought to be the ancestral condition for all three major groups of amphibians. Nevertheless, there has been repeated loss of this type of complex life cycle in all three groups. Most caecilians lack an aquatic larval stage, as do most urodele species (but not the majority of families). Many lineages of frogs have partially or completely lost the aquatic larval stage, including some very successful groups, such as the widespread and specious Neotropical genus *Eleutherodactylus*. Some salamanders have evolved in the opposite direction and have lost the terrestrial adult stage of the life cycle. Some salamanders, such as sirenids and proteids, are always paedomorphic, but others, including many species of *Ambystoma*, are facultatively paedomorphic.

The repeated loss of a complex life cycle has led some authors to propose that complex life cycles are inherently unstable and tend to evolve toward loss of either the aquatic or terrestrial stage. Many amphibian biologists, such as Wassersug (1975) and Wilbur (1980), have argued that a complex life cycle is maintained because of the unique ecological role of the larval stage, especially in anurans. In this view, amphibian larvae take advantage of seasonal flushes of productivity in ponds and other bodies of water to acquire abundant resources for growth that often are lacking in the terrestrial environment.

Werner (1986) argued that it is misleading to consider the larval stage of many amphibians, especially anurans, as the principal growth stage, because often more than 90% of total growth takes place in the terrestrial phase of the life cycle. He argued that the transition from an aquatic larval stage to a terrestrial juvenile and adult can be viewed as a shift in ecological niches. He further proposed that the relative costs and benefits of living in the aquatic or terrestrial environment, as measured by changes in the relationship of growth to mortality, will determine the point at which this shift is made by any given species. For many anurans that breed in temporary ponds, mortality becomes unacceptably high if they remain for very long in the aquatic environment, so early metamorphosis at a relatively small body size often is favored. The more ephemeral the breeding habitat, the shorter the larval period must be for successful metamorphosis. In contrast, anurans that breed in permanent ponds often benefit from remaining in the tadpole stage for several years before metamorphosis. Anurans all are constrained, however, by their inability to become reproductive adults while retaining the larval morphology, so eventually all anurans must metamorphose.

Urodeles are less constrained in their development, because they often are fully capable of becoming reproductive adults while retaining many features of larval morphology. The result is the widespread occurrence of either obligate or facultative paedomorphosis in this group. Even salamanders that do metamorphose often have very long larval periods; some achieve up to 90% of their total growth in the larval stage. This type of life history might be favored in species that spend much of their adult life inactive underground, as in many of the mole salamanders (*Ambystoma*), or species that live in caves and other habitats where food availability in the aquatic environment exceeds that of the terrestrial environment.

The process of metamorphosis itself generally has been viewed very differently by developmental biologists and by ecologists. Developmental biologists focus on the genetic and hormonal control of metamorphosis as a relatively orderly and predictable sequence of events, with little consideration of how the environment impinges on the process. Ecologists, on the other hand, have focused on plastic responses of larvae to variation in environmental variables such as temperature, food availability, larval density, and pond permanence, often with little idea of how environmental cues might alter hormonal pathways that ultimately control metamorphosis. Recent work has suggested possible links between the thyroid hormone axis, which regulates the timing of metamorphosis, and environmental variables such as larval density and pond drying, mediated through hormonal stress responses.

Most of the research on the ecology of metamorphosis over the last three decades has focused on proximate determinants of the timing of metamorphosis and the size of individuals at transformation. The conceptual starting point for this work was a model of metamorphosis proposed by Wilbur and Collins (1973), which related the probability of an individual undergoing metamorphosis to the quality of the aquatic environment, as indicated by its own recent growth history. Each species is thought to have a characteristic minimum size at which metamorphosis is possible, as well as a maximum size at which it is no longer efficient or possible to remain in the larval stage. Larvae that fail to reach the minimum size before a pond dries up are doomed, but those that have reached the minimum size for transformation have several options. If growth conditions are good, larvae are expected to remain in the water, acquiring additional resources and increasing body size, which almost always is beneficial once they enter the terrestrial environment. If growth conditions are poor, larvae are expected to metamorphose near the minimum body size, thereby trading an increased probability of escaping deteriorating conditions against the possible costs of being less successful in a harsh terrestrial environment. Different individuals within a population, and even within a single cohort or sibship of larvae, end up metamorphosing at different ages and at different body sizes, because the options available to each larva change as the density of larvae, the abundance of food, and the persistence of the breeding site vary over time.

A basic assumption of the Wilbur-Collins model and related models is that density-dependent competition among larvae will create asymmetries in body size and competitive ability, and these in turn will translate into differences in timing and size at metamorphosis. Many experimental studies have demonstrated such density-dependent competition in both anuran and urodele larvae in laboratory aquaria, cages placed in natural ponds, cattle tanks and other artificial ponds, and in natural bodies of water. Mechanisms of competition differ somewhat between anurans and urodeles. Exploitative competition through resource depletion appears to be most important for anuran tadpoles, with interference competition mediated by behavioral or chemical interactions playing a secondary role. Exploitative competition also occurs in larval urodeles, but interference competition in the form of aggressive interactions or even cannibalism appears to be more important in many species.

Many experiments have shown that the growth and development of amphibian larvae are very plastic and readily respond to short-term changes in resource abundance, intensity of competition, or water level. Diminishing resources or increased competition often induce larvae to speed up development at the expense of growth and metamorphose early at a small size. Drying of ponds has the same effect in some species. Increasing resources or diminished competition resulting from individuals metamorphosing and leaving the water or being eaten by predators often result in increased growth, prolongation of the larval period, and metamorphosis at a large body size. These responses are somewhat constrained by stage of development. Larvae that are deprived of resources relatively early in development often remain at a small size and early developmental stage and never reach metamorphosis. Larvae that experience increased resources late in development allocate those resources to additional growth, but with relatively little effect on the timing of metamorphosis.

The highly plastic nature of amphibian growth and development probably explains much of the success of these animals in colonizing nearly every available habitat, from wet tropical rainforests to cold mountain streams and dry deserts. Indeed, some of the most dramatic examples of developmental plasticity in amphibians can be found in species that inhabit the most unpredictable and inhospitable habitats, such as deserts. Anurans that breed in desert rain pools not only have very short larval periods compared to other anurans, but they exhibit a much greater degree of plasticity in their life histories. Some spadefoot toads, for example, can shorten the larval period by nearly 50% in response to drying of ponds. These species also exhibit extraordinary levels of phenotypic plasticity in morphology and behavior, often switching to carnivorous diets and even becoming cannibalistic, a strategy that greatly increases their rate of growth and development and improves their chances of escaping a drying pond (see chapter 12).

In contrast to anurans, some urodeles have partially decoupled developmental processes such as sexual maturation from growth and transformation. This has enabled many urodeles to become paedomorphic, essentially retaining the ecological advantages of staying in the larval habitat without the cost of delaying reproduction. Indeed, in some facultatively paedomorphic species of *Ambystoma,* individuals actually can initiate reproduction earlier by retaining the larval morphology than by metamorphosing and migrating onto land. For urodeles that live in very predictable environments, such as caves and permanent springs, lakes, and rivers, an obligate paedomorphic life history can be advantageous, especially in regions where such predictable and equable aquatic habitats are surrounded by inhospitable terrestrial habitats. In contrast, paedomorphosis often is a highly plastic trait in urodeles that inhabit unpredictable environments, such as ponds that dry up in some years but not in others. For these animals, a capacity to become paedomorphic when ponds remain full, but to metamorphose, even after reaching sexual maturity, when ponds dry up, probably gives them an advantage over species that have fixed life histories.

The evolution of paedomorphic life histories has implications that go beyond the adaptation of particular populations to local environments. One consequence of paedomorphosis is that gene flow between populations is likely to be reduced, because the terrestrial animals that normally would disperse to new breeding ponds are absent. This is especially true in species that have become obligate paedomorphs, which often become isolated in permanent ponds and lakes that are separated from other suitable aquatic habitats by inhospitable terrestrial habitats. This isolation of local populations probably accounts for the high degree of genetic diversity among permanently paedomorphic populations of *Ambystoma* in the southwestern United States and Mexico (Shaffer 1984a) and the proliferation of species of cave- and spring-dwelling *Eurycea* on the Edwards Plateau of Texas (Sweet 1977b, 1982).

One approach to studies of the ecology of metamorphosis and the evolution of phenotypic plasticity in growth and development that has been largely neglected is the inclusion of a phylogenetic perspective. Experimental work on the plastic responses of spadefoot toads and other anurans to pond drying has shown that spadefoot toads are far more plastic in their responses than other species that have been studied. However, all of these other species are in families only distantly related to pelobatids, so it is not yet possible to conclude that species using ephemeral breeding habitats have always consistently evolved more plastic responses than those using more permanent sites. Even within pelobatids, there is considerable variation in the pattern of metamorphosis that appears more closely related to phylogeny than to ecology (Buchholz and Hayes 2002). Ideally, comparisons should be made among closely related species, as Morey and Reznick (2000) have done for different species of spadefoot toads. Alternatively, multiple comparisons might be made between species in different clades that breed in highly ephemeral habitats and close relatives that use more permanent breeding sites. If species that breed in ephemeral sites are repeatedly shown to have more plastic life histories than close relatives in less ephemeral sites, then this would provide strong evidence for convergent evolution of phenotypic plasticity. A similar approach could be taken to investigate the range of variation in degree of plasticity in paedomorphic salamanders, although in this case, the range of species available for study is much more limited. European and North American newts, which exhibit a wide range of variation in frequency of paedomorphosis, might be a promising group for phylogenetic comparisons.

Chapter 14 Amphibians and Their Predators

Their common enemies are the Weasels, Poul-cats, and Ferrets, for these do gather them together, and lay of them great heaps within their dens, whereupon they feed in Winter. The Heron also and Bittern, is a common destroyer of Frogs, and so likewise some kinds of Kites. . . . The moles also are enemies to Frogs.

The Mole is also an enemy to the Toad, for as Albertus writeth, he himself saw a Toad crying above the earth very bitterly, for a mole did hold her fast by the leg within the earth, labouring to pull her in again. . . . They are also at variance with the Lizard, and all kindes of Serpents. . . . The Buzard and the Hawk are destroyers of Toads, but the Stork never destroyeth a Toad to eat it, except in extremity of famine.
—Edward Topsell, *The History of Serpents* (1658)

THE LITERATURE ON amphibian ecology often conveys an impression of animals beset by enemies on every side, leaving the reader wondering how any manage to survive. As M. Tyler (1976, p. 153) put it, "There are . . . millions of animals seeking out frogs and feeding upon them, so that frogs are the cannon fodder of the animal kingdom. Each stage of development from egg to adult faces its own particular dangers, and at no time of day or night are frogs and their offspring free from attack." Similarly, Porter (1972, p. 330) asserted that "almost anything will eat an amphibian." Certainly, many amphibians appear to be highly vulnerable to predation, being small, slow moving, and relatively defenseless against larger animals. Because amphibians are efficient at converting ingested energy into biomass (see chapter 5), they often reach high population densities, and provide a ready source of protein for animals at higher trophic levels (Burton and Likens 1975a; Pough 1980, 1983). Furthermore, the lack of indigestible materials such as hair, feathers, or chitin makes amphibians a particularly high-quality food.

Predation has been important in the evolution of many amphibian characteristics, such as toxic and distasteful skin secretions, cryptic and aposematic coloration, and a variety of defensive postures and behaviors. In addition, predation is routinely cited as a selective pressure that affects many other aspects of amphibian ecology and behavior (table 14.1). Given the central importance of predation in the lives of these animals, it is important to understand the nature of interactions between amphibians and their predators. This chapter addresses three major questions: (1) What kinds of animals eat amphibians? (2) What is the impact of predation on amphibian population dynamics? (3) How has predation acted as a selective force in shaping the evolution of amphibian ecology and behavior? The impact of predation on larval growth and development and the timing of metamorphosis are discussed in chapter 13, and the importance of predation in the dynamics of amphibian communities is discussed in chapter 15.

The Predators of Amphibians

The following section reviews what is known about the major predators of amphibians. Whenever possible, I have tried to supplement lists of potential predators with quantitative estimates of the importance of amphibians in the predators'

Table 14.1 Aspects of the ecology and behavior of amphibians that are affected by predation

Ecological or behavioral variable	Chapter	Source no.
Timing and duration of breeding season	10	2, 6, 71
Diel timing of breeding migrations	10	29, 36
Choice of breeding habitats	14	5, 19, 42, 80
Choice of calling sites	7	14, 17, 56
Patterns of calling behavior	7	13, 15, 17
Mate-searching behavior	9, 14	105, 116
Choice of oviposition sites	10, 14	2, 8, 52, 56, 86
Oviposition behavior	10, 14	63
Size and number of eggs	10	3, 11, 41
Timing of egg hatching	14	64, 74
Parental care of eggs and larvae	11	25, 27, 28
Choice of tadpole deposition sites	14	99
Tadpole morphology and coloration	14	78, 83, 91, 102, 103, 104, 108, 109, 110, 112, 114, 115
Timing of aerial breathing by aquatic larvae	4	20, 21, 26
Aggregation of larvae and juveniles	12, 14	4, 7, 18, 85
Diel activity cycles of larvae	12, 14	22, 44
Choice of foraging microhabitats	14, 15	12, 40, 43, 46, 49, 50, 54, 55, 58, 90, 95, 111
Activity and movements of larvae	14, 15	43, 47, 55, 69, 71, 75, 79, 87, 89, 92, 101, 103, 104, 108, 110, 113, 114, 115
Larval swimming speed	14	104
Larval growth rates	13, 14	10, 32, 37, 43, 55, 60, 89, 114
Timing of metamorphosis	13, 14	10, 37, 50, 101
Structure and dynamics of larval communities	15	23, 24, 35, 39, 48, 53, 57, 70, 73, 88, 92, 97, 101
Evolution of foraging behavior	5, 14, 15	16, 30, 31

Note: The first column indicates chapters in which topics are discussed in detail.

diets. These data must be evaluated cautiously, because different types of prey are digested at different rates, and analyses of stomach contents, feces, or regurgitated pellets provide only rough estimates of the number of amphibians consumed (Fitch 1960, 1963; Craighead and Craighead 1969; Calef 1973a; Kushlan 1978; Delany and Abercrombie 1986). The data are better for some groups than for others. Predation by invertebrate predators is hard to quantify, and only a few species have been investigated. Information on predation by fishes, amphibians, and most reptiles is largely anecdotal, although there is good information on predation by snakes. Many species of birds and mammals eat amphibians, but good quantitative data are available for only a few species in each group.

Predation by Invertebrates

Many species of invertebrates prey on amphibians (McCormick and Polis 1982; Toledo 2005). Among the most important predators are leeches, crabs and crayfish, amblypygids, spiders, caddisfly larvae, dragonfly naiads, aquatic bugs, the larvae and adults of aquatic beetles, and several families of flies (table 14.2). Other invertebrates, including free-living flatworms, mosquito larvae, wasps, mantids, and crickets, are less frequently reported as predators of amphibians, but can have a significant impact on amphibian populations in certain habitats. The list in table 14.2 is far from complete, because there are vast numbers of potential invertebrate predators of amphibians in various parts of the world. Regional accounts of amphibians often include invertebrates in lists of natural enemies, without detailed documentation (e.g., Kuzmin 1999), and I have not attempted to include all of these. None of the species of invertebrates that prey on amphibians is an amphibian specialist, with the exception of certain fly larvae that live in egg masses of frogs. Most species are generalist predators that feed opportunistically on amphibians when they are available, but shift to other types of food when they are not. Unfortunately, there is little information on the relative importance of amphibians in the diets of most species; invertebrates usually feed by sucking or chewing their prey, making analyses of stomach contents difficult or impossible. In one of the few studies of the ecological impact of predation on amphibians on populations of invertebrates, Hirai and Hidaka (2002) found that an endangered species of giant water bug in Japan, *Lethocerus deyrollei,* is heavily dependent upon breeding anurans and transforming juveniles during the spring and summer. Recent declines of frogs in rice paddies brought about by changes in agricultural practices therefore may threaten the survival of this insect.

Invertebrate predators undoubtedly take their greatest numerical toll on the eggs and larvae of amphibians. In many temporary ponds that lack fish, invertebrates are the most important predators of amphibian eggs and larvae. Indeed, the assemblage of invertebrate predators present in particular ponds can be one of the most important determinants of the structure and dynamics of amphibian communities (Heyer, McDiarmid, and Weigmann 1975; Van Buskirk 1988; Gascon 1992a; Hero, Gascon, and Magnusson 1998; Azevedo-Ramos, Magnusson, and Bayliss 1999; see also chapter 15).

Predation on Aquatic Eggs

In many ponds that lack fish, the larvae of caddisflies (Trichoptera) are important invertebrate predators of amphibian eggs (fig. 14.1 A). These insects feed on a broad diet of organic detritus, plant material, and occasional invertebrate prey (Winterbourn 1971a; N. Anderson 1976). Several studies have shown that a diet of animal protein enhances growth of caddisfly larvae and allows them to pupate more rapidly than when they feed entirely on plant material (N. Anderson 1976; N. Anderson and Cummins 1979; Majecki and Majecka 1996). In some species, a diet of animal protein late in development may be necessary for successful pupation (Winterbourn 1971b). Caddisfly larvae readily prey on both frog and salamander eggs, which provide a concentrated source of protein for a brief period during spring breeding seasons. They often swarm over egg masses in large numbers and easily cut through the jelly and tough capsules that surround the eggs (Stout, Stout, and Stihler 1992; C. Rowe, Sadinski, and Dunson 1994; Kwet 1996a; Majecki and Majecka 1998; Richter 2000). In one pond in West Virginia, 82% of all individuals of one caddisfly species, *Banksiola dossuaria,* were found on egg masses of spotted salamanders (*Ambystoma maculatum*), with more than 20 individuals sometimes feeding on a single egg mass (Stout, Stout, and Stihler 1992). When population densities of predatory caddisfly larvae are high, they can consume nearly all of the amphibian eggs laid in some years. Population densities often fluctuate from year to year in the same pond, enabling amphibians to breed successfully in years when caddisfly larvae are scarce (Rowe, Sadinski, and Dunson 1994; personal observations).

Leeches occur in ponds both with and without fish and sometimes prey on amphibian eggs (Cory and Manion 1953; R. D. Howard 1978b; Kwet 1996a), as well as tadpoles and adults. I have seen leeches (*Macrobdella decora*) swarming over egg masses of *Ambystoma maculatum* that also were being attacked by both caddisfly larvae and red-spotted newts (*Notophthalmus viridescens*). R. D. Howard (1978b) estimated that 43% of the eggs in one population of bullfrogs (*Rana catesbeiana*) were destroyed by leeches, with up to 80% mortality in some clutches (fig. 14.1 B). Leeches prey on the eggs of several species of Eurasian amphibians, as do free-living planarians, snails (*Lymnaea*), mites (*Gydrachna,*

Hydryphantes), and the usual assortment of aquatic insects (Kwet 1996a; Kuzmin 1999). Planarians (*Polycelis nigra*) can sometimes consume entire clutches of *Rana temporaria* eggs within a few days (Kwet 1996a).

Several species of freshwater crayfish prey on eggs of *Ambystoma* (Ward and Sexton 1981), *Taricha* (Gamradt and Kats 1996), and *Triturus, Bufo, Hyla,* and *Rana* (Axelsson et al. 1997). Crayfish that have been introduced into nonnative habitats may pose a significant threat to amphibian populations. Gamradt and Kats (1996) discovered that the introduced crayfish *Procambarus clarkii* readily preyed upon egg masses of *Taricha torosa* in California and eliminated the newts from some streams. These newts normally breed in streams that are largely free of egg predators, and they lay their eggs in submerged vegetation or under rocks, where crayfish are most likely to forage. Introduced crayfish are considered a potential threat to amphibian populations in some parts of Europe as well (Axelsson et al. 1997).

Predation on Nonaquatic Eggs

Many amphibians do not place their eggs directly in water, but lay them in foam nests floating on the water's surface,

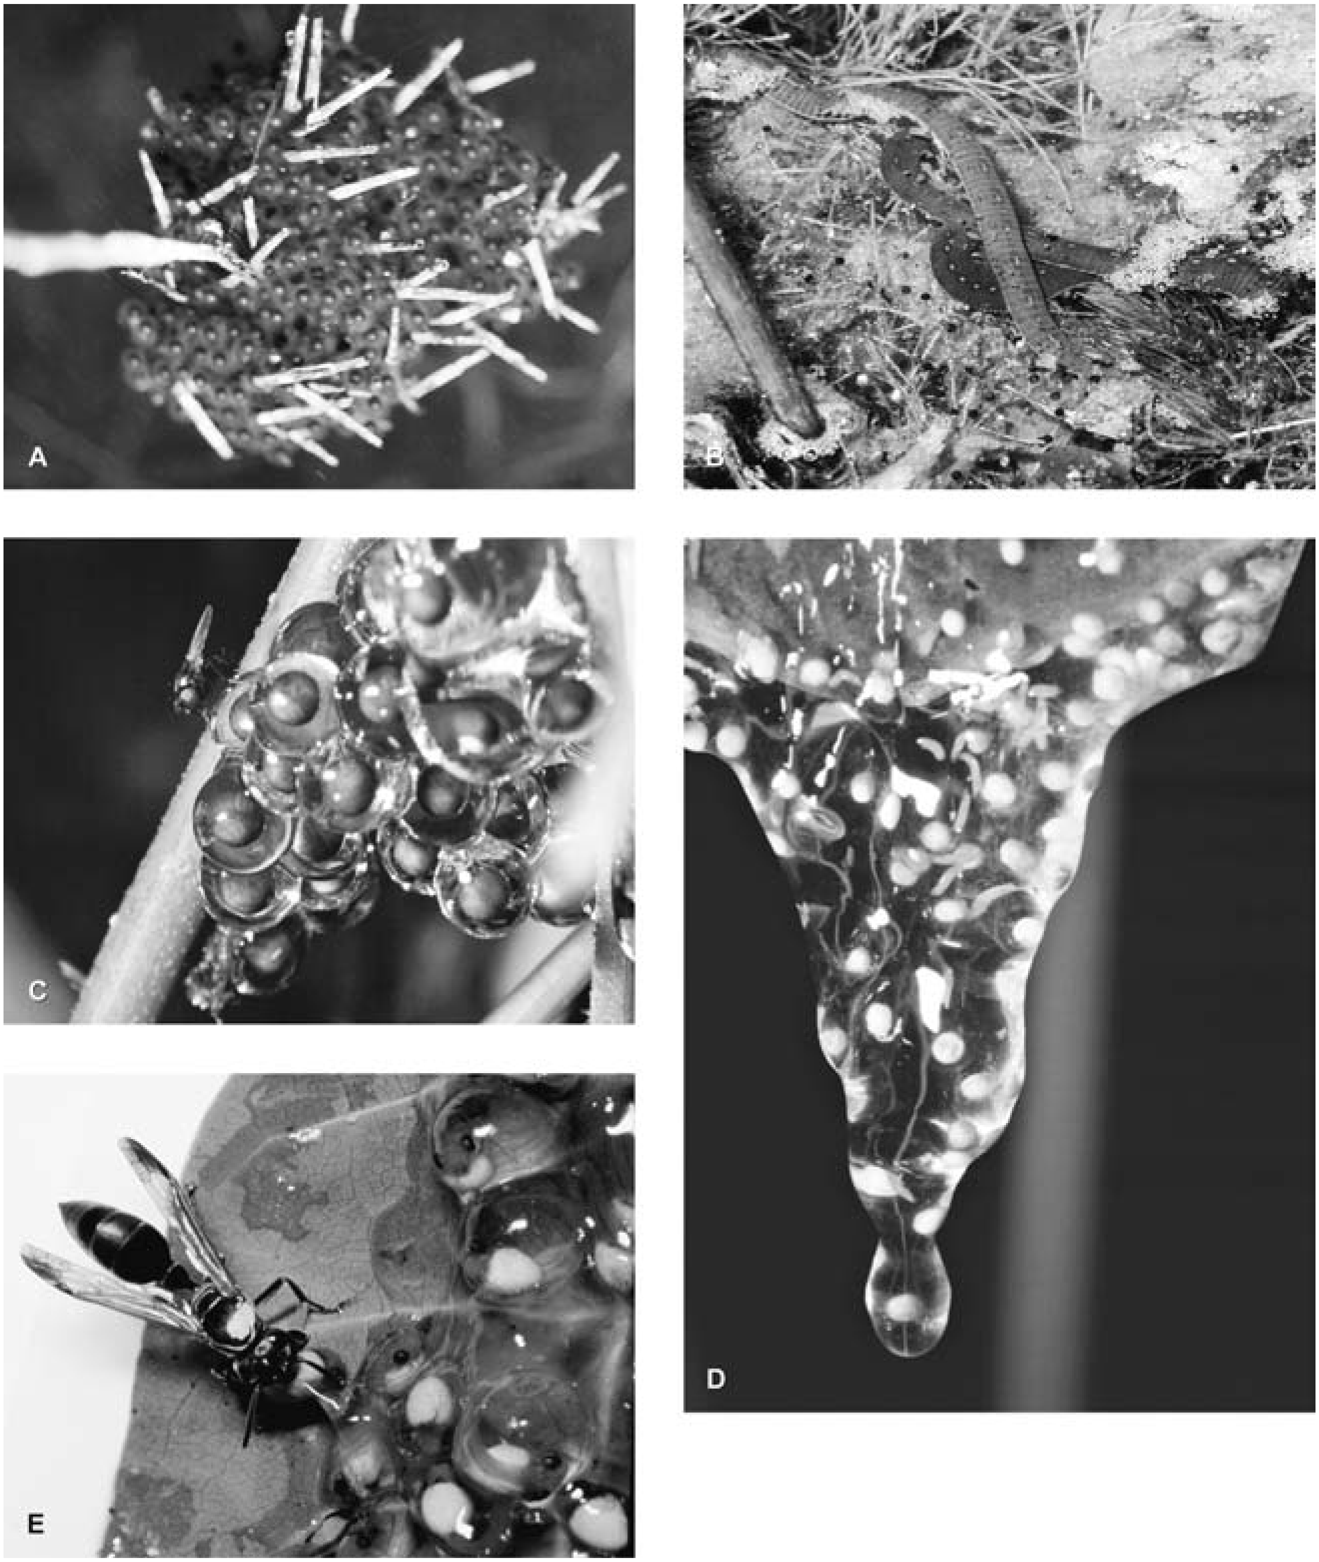

Fig. 14.1. Invertebrate predators of amphibian eggs. (A) Egg clutch of *Rana sevosa* infested with the larvae of caddisflies. (B) Leeches (*Macrobdella*) feeding on eggs of *Rana catesbeiana.* (C) Adult female of an ephydrid fly (*Typopsilopa*) depositing eggs on a clutch of frog eggs (*Hyperolius mitchelli*). (D) Egg clutch of *H. mitchelli* infested with fly larvae, which are the small, white animals at the top of the egg clutch. (E) Wasp (*Polybia rejecta*) removing an egg from an arboreal egg mass of *Agalychnis callidryas.* Photos by Stephen Richter (A), Richard D. Howard (B), James Vonesh (C, D), and Karen Warkentin (E).

on leaves overhanging streams and ponds, or in terrestrial nests (see chapter 10). These modes of reproduction probably reduce predation by aquatic invertebrates, but they expose the eggs to attack from a variety of other predators, including crabs, spiders, carabid beetles, wasps, crickets, and several types of fly larvae (Forester 1979a; Villa 1977, 1980, 1984; Villa, McDiarmid, and Gallardo 1982; M. Hayes 1983; Villa and Townsend 1983; Lin and Lue 1999; Warkentin 2000b; R. Davis and Disney 2003; Menin and Giaretta 2003).

The fly larvae are particularly destructive. Up to 80% of the foam nests of *Physalaemus cuvieri* examined by Bokermann (1957) in Brazil were infested with larvae of an ephydrid fly, *Beckeriella niger.* In another study, predation by these fly larvae resulted in an average mortality in *P. cuvieri* egg clutches of 74% (Menin and Giaretta 2003). Even foam nests of *Leptodactylus fuscus* hidden in burrows are attacked by phorid fly larvae (Downie et al. 1995), and flies in this family attack the foam nests of the myobatrachid frogs *Heleioporus* in Australia (R. Davis and Disney 2003). Phorid fly larvae and staphilynid beetles together caused up to 77% mortality in eggs of two species of *Phyllomedusa* in Brazil (Neckel-Oliviera and Wachlevski 2004). In Central America, 70–100% of *Hyalinobatrachium fleischmanni* clutches were infested with larvae of the drosophilid fly *Hirtodrosophila batracida* (Villa 1977, 1984; this fly originally was identified as a species of *Zygothrica* by Villa, but was later described as a new species, *H. batracida,* by Grimaldi 1994). The *Hirtodrosophila* found in *Hyalinobatrachium* egg masses appear to be obligate egg associates, as are various species of *Gastrops,* but some of the other flies listed in table 14.2 are facultative predators (Villa 1980). In Taiwan, up to 80% of the foam nests of several species of rhacophorid treefrogs were infested with fly larvae of the genus *Caiusa* (Lin and Lue 1999). The fly larvae often consumed all of the eggs in masses reared in the laboratory.

Eggs of several species of *Hyperolius* in Uganda were infested with both ephydrid and phorid fly larvae (Vonesh 2000, 2005a, b; fig. 14.1 C). These frogs lay eggs on vegetation over water. Overall, 40% of more than 1,200 egg clutches were infested. The eggs of several frog species (*H. lateralis* and *H. cinnamomeoventris*) seemed to be preferred over those of other species, especially *H. kivuensis,* although egg masses were attacked indiscriminately in the dry season, when frog eggs were scarce. The fly larvae usually destroyed all of the eggs of the preferred species, whereas some eggs of *H. kivuensis* survived infestation by frog fly larvae. This may be due in part to the more rapid development of this species, with eggs often hatching before the fly larvae consumed the entire clutch. In another species, *A. spinigularis,* predation on eggs by flies and adult frogs induced early hatching by the eggs, and the reduced densities of larvae resulting from egg predation increased larval survival and size at metamorphosis (Vonesh 2005a, b). This in turn made the larvae less vulnerable than expected to predation by dragonfly naiads (*Trapezostigma basilaris*), either because the tadpoles grew more rapidly to a less vulnerable size, or because the lower density of tadpoles decreased the hunting efficiency of the insects (Vonesh and Osenberg 2003).

Predation on Aquatic Larvae

Even if amphibian eggs escape being eaten, there are numerous invertebrate predators ready to attack larvae soon after they hatch. Caddisfly larvae prey on newly hatched tadpoles and salamander larvae that remain near egg masses, but probably are incapable of catching free-swimming older larvae (Rowe et al. 1994). Leeches prey on both large and small tadpoles and sometimes occur in densities sufficiently high to be a major source of mortality (Carpenter 1953b; Brockelman 1969; Berven and Boltz 2001). They also can have nonlethal effects on tadpole fitness by reducing growth rates and prolonging the larval period (Berven and Boltz 2001; Schalk, Forbes, and Weatherhead 2002). A free-living flatworm, *Phagocotus gracilis,* occurs at very high densities (up to 656 worms per square meter) in streams in Kentucky, where it is a significant predator on newly hatched larvae of *Ambystoma barbouri* (Petranka, Kats, and Sih 1987; Sih and Moore 1993). Even aquatic snails have been reported to prey on tadpoles (Peltzer and Lajmanovich 2003).

In most freshwater habitats, the most important invertebrate predators on amphibian larvae are arthropods (fig. 14.2 A–C), including crayfish (Figiel and Semlitsch 1991; Veith 1993; Gamradt and Kats 1996; Axelsson et al. 1997), freshwater shrimp (Warkentin 1995, 1999a; Downie, Livingstone, and Cormack 2001), freshwater crabs (Kuzmin 1999), spiders (Bleckmann and Lotz 1987), dragonfly naiads (Aeshnidae, Corduliidae, Libellulidae), aquatic bugs (Belostomatidae, Nepidae, Notonectidae), and the larvae of aquatic beetles (Dytiscidae, Hydrophilidae; see many references cited in table 14.2). Larval mosquitoes (*Culiseta longiareolata*) fed on newly hatched toad tadpoles (*Bufo viridis*) in desert rain pools in Israel. Conversely, larger *Bufo* tadpoles preyed on early stage mosquito larvae, and the two species competed for food as well (L. Blaustein and Margalit 1994). In aquatic habitats where tadpoles compete with mosquito larvae, mosquitos sometimes avoid depositing eggs in pools with tadpoles present (L. Blaustein and Kotler 1993; Mokany and Shine 2003a). Mosquito larvae (*Culex*) also feed on eggs of the Siberian newt (*Salamandrella keyserlingii;* Kuzmin 1999).

Arthropod predators of amphibian larvae include both active foragers and sit-and-wait predators that use different sensory modes to locate and capture prey. Crustaceans, including crayfish and freshwater shrimp, tend to be active hunters that forage on the bottom of ponds (Figiel and Semlitsch 1991; Gamradt and Kats 1996; Axelsson et al. 1997;

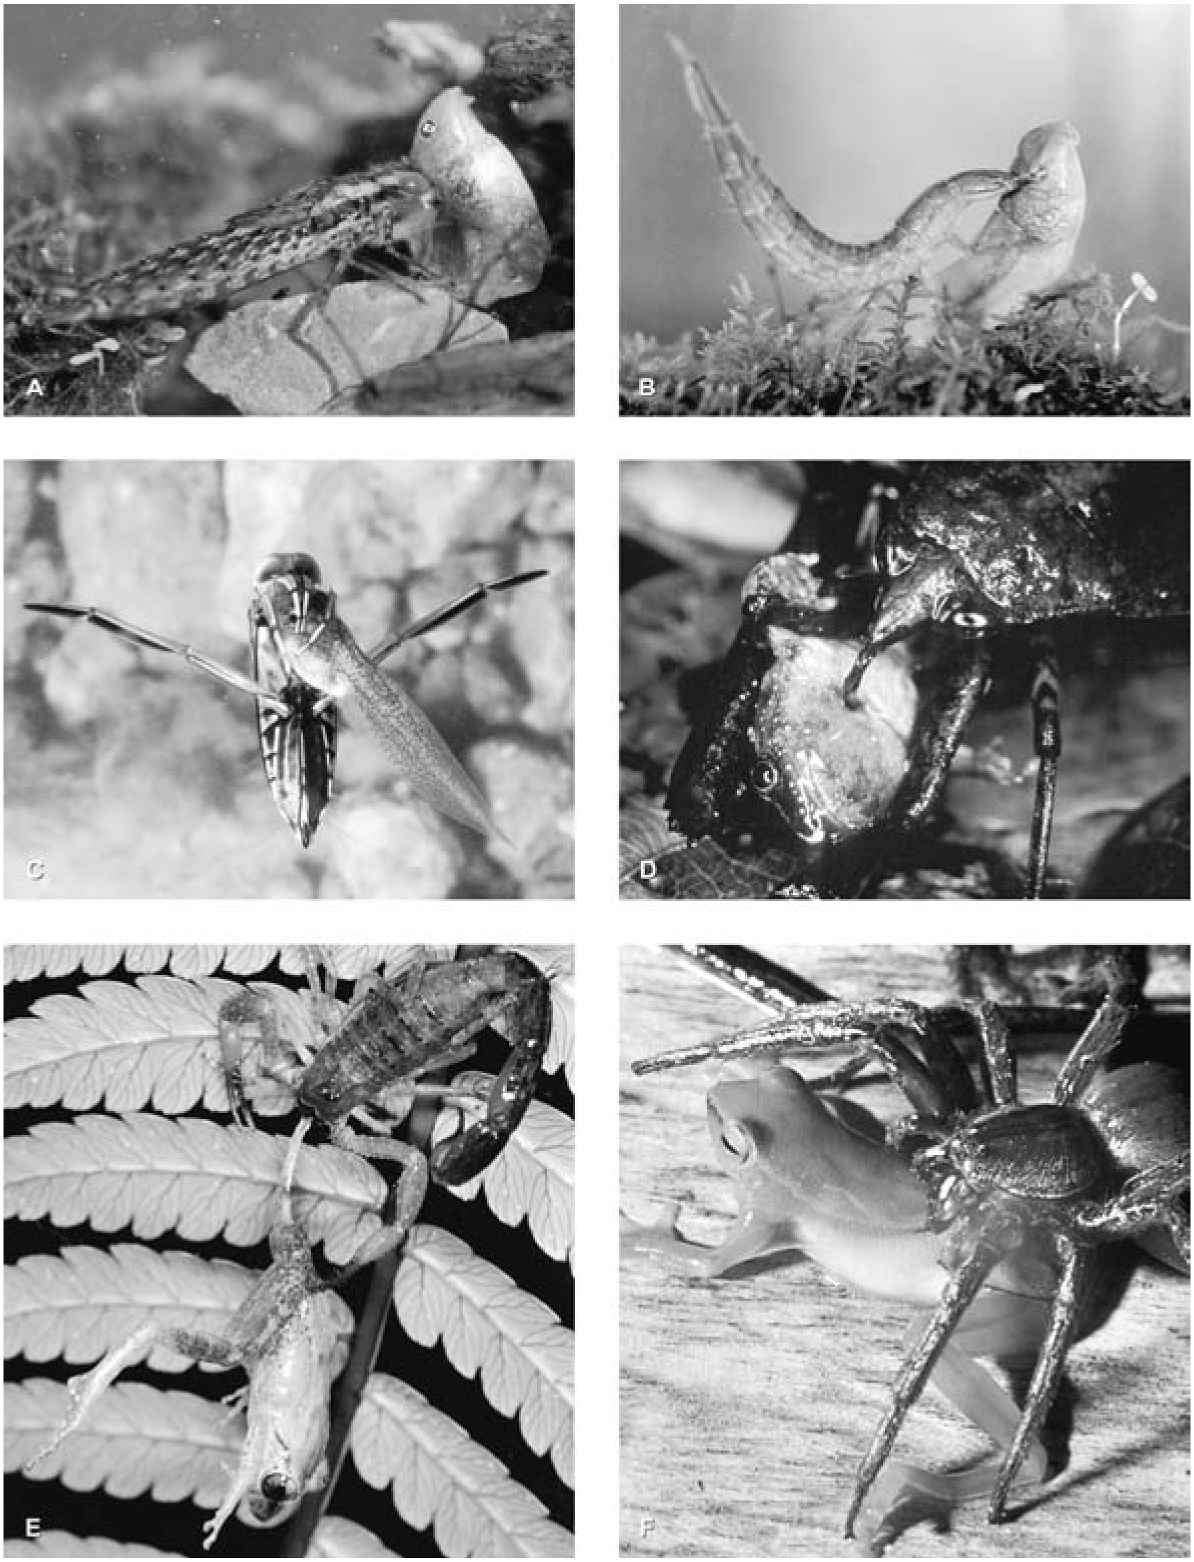

Fig. 14.2. Invertebrate predators of larval and terrestrial amphibians. (A) Dragonfly naiad (*Anax*) feeding on a tadpole. (B) Larvae of a water beetle (*Dystiscus*) feeding on a tadpole. (C) A backswimmer (*Notonecta*) feeding on a tadpole. (D) Giant water bug (Belostomatidae) feeding on an adult microhylid frog (*Chiasmocles shudicarensis*). (E) Scorpion feeding on a Puerto Rican frog (*Eleutherodactylus coqui*). (F) Spider feeding on a frog (*Sphaenorhynchus lacteus*). Photos by Rick Relyea (A, B), Karen Warkentin (C), Walter Hödl (D, F), and Rafael Joglar (E).

Warkentin 2000b). At least some species detect prey mainly by chemical cues (Harpaz and Steiner 1990). Some aquatic bugs, including notonectids and some belostomatids (e.g., *Hydrocyrius*), are active hunters in the water column and probably detect prey visually or by means of tactile cues (Rödel and Linsenmair 1997). Other belostomatids (*Belostoma, Lethocerus*) are ambush predators that lurk in vegetation and detect prey mostly by visual and tactile cues, as are nepids such as *Ranatra* (P. Bailey 1986; Rödel and Linsenmair 1997). Larvae of dytiscid beetles are active hunters that use both chemical and tactile cues to locate and capture prey (Formanowicz 1987; Resetarits 1998).

Dragonfly naiads (fig. 14.2 A) include species that use both active foraging and ambush tactics. In general, libellulids and corduliids tend to sit and wait for prey near the bottoms of ponds, whereas aeshnids are more likely to climb into aquatic vegetation, where they use a combination of stalking and ambushing techniques (Pritchard 1965; Resetarits 1998; P. Corbet 1999). Aeschnids have better-developed eyes than do libellulids and corduliids, and often rely on visual cues to detect and orient toward prey (Pritchard 1965, 1966; Sherk 1977; Chovanec 1992a). Nevertheless, they are capable of detecting and striking at prey using tactile cues alone, or in combination with visual cues (Pritchard 1965; Kanou and Shimozawa 1983; S. Richards and Bull 1990a). Either visual or tactile cues allow them to use movements to detect prey, so active amphibian larvae are particularly susceptible to predation by these insects (Caldwell, Thorp, and Jervey 1980; S. Lawler 1989; Azevedo-Ramos et al. 1992; Chovanec 1992b; Skelly 1994).

Predation on Juveniles and Adults

Predation by invertebrates on juvenile and adult amphibians probably is less common than predation on eggs and larvae, but it still can have an important effect on population dynamics (Toledo 2005, summarizes recent data, including some unpublished examples not included in table 14.2). Juvenile amphibians are subjected to predation by several kinds of invertebrate predators (fig. 14.2 D–F), including centipedes (M. Stewart and Woolbright 1996), scorpions (M. Stewart and Woolbright 1996), amblypygids (Formanowicz et al. 1981), spiders (Neill 1948b; Butler and Main 1959; Sharma and Sharma 1977; Formanowicz et al. 1981; Vonesh 2005b), giant water bugs (Hirai and Hidaka 2002), and carabid beetles (Littlejohn and Wainer 1978; Ovaska and Smith 1988; J. Robertson 1989; Kuzmin 1999). Invertebrate predation on juvenile amphibians probably is underreported, simply because such predation is difficult to observe. A number of kinds of invertebrate predators readily capture adult amphibians, especially when they are aggregated at breeding sites. Among the most important such predators are spiders (fig. 14.2 F; Goin 1943; Bhatnagar 1970; M. Hayes 1983; J. Mitchell 1990; Stewart and Woolbright 1996; R. Owen and Johnson 1997), giant water bugs (fig. 14.2 D; Belostomatidae; Hinshaw and Sullivan 1990; Haddad and Bastos 1997), and leeches (Merilä and Sterner 2002). Giant water bugs can kill between 4% and 8% of adult frogs in small breeding congregations on a single night, and massive mortality of adult anurans and nests from leech infestation has been reported as well (Merilä and Sterner 2002). There are brief reports of attacks on small frogs by mantids (Ridpath 1977; Buttenhoff 1995), crabs (Ryan, Tuttle, and Taft 1981; Stewart and Woolbright 1996; Kuzmin 1999), carabid beetles (Littlejohn and Wainer 1978; Robertson 1989; Kuzmin 1999), and rove beetles (Staphylinidae; Jung et al. 2000), but the impact of these predators on amphibian populations is unknown.

An interesting feature of invertebrate predation on amphibians is the frequent occurrence of trophic loops, in which a species of amphibian is both a predator of and prey for a species of invertebrate. This occurs most frequently when an invertebrate eats eggs, larvae, or juveniles of an amphibian, but adults of the amphibian species prey on the invertebrate (Polis and Myers 1985; Reagan, Camilo, and Waide 1996). For example, many species of fly larvae prey upon amphibian eggs, but some adult frogs probably prey on adult flies as well. Dragonfly naiads are major predators of ranid tadpoles, but large ranid frogs frequently prey on both larval and adult dragonflies, especially those just emerging from the water (Geelen, van Gelder, and Sax 1970; Stewart and Sandison 1972; Corse and Metter 1980; Werner, Wellborn, and McPeek 1995; Kuzmin 1999; personal observations). Adult frogs sometimes eat other tadpole predators as well, including spiders and aquatic bugs.

In the Luquillo Rainforest of Puerto Rico, several kinds of invertebrates prey on eggs or juveniles of *Eleutherodactylus coqui.* These include a centipede (*Scolopendra alternans*) and a crab spider (*Stasina portoricensis*), both of which are eaten occasionally by adult coquis. The frogs can be significant predators on crab spiders, which decreased in experimental plots in which frog densities increased (Stewart and Woolbright 1996). Small individuals of other invertebrate predators, including an amblypygid (*Phrynus longipes*) and a tarantula (*Avicularis laeta*) are potential prey for adult coquis, which live in the same microhabitats as these species (Reagan, Camilo, and Waide 1996). Adult coquis also eat two genera of ants, *Iridomyrmex* and *Paratrechina,* that eat coqui eggs (Stewart and Woolbright 1996), but the impact of frogs on ant populations is likely to be small.

Invertebrate Parasites

Except for midges and mosquitoes that feed on the blood of frogs, table 14.2 includes only those invertebrate predators that consume all or most of their prey; it does not include parasites of amphibians, some of which can be fatal to their hosts. Internal parasites of amphibians include many types of protozoans (Elkan 1976b), as well as a variety of parasitic worms. The latter include tapeworms (Cestoda), intestinal round worms (Acanthocephala), nematodes that infect the lungs and visceral organs, and many species of monogenean and digenean helminths that infect the lungs, muscles, bladder, and digestive organs (Prudhoe and Bray 1982; Tinsley and Earle 1983; D. Brooks 1984; Duellman and Trueb 1986; Tinsley and Jackson 1986, 1988; Goater, Esch, and Bush 1987; Tinsley 1989; Aho 1990; Yoder and Coggins 1996; McAlpine 1997; McAlpine and Burt 1998; P. Johnson and Sutherland 2003). External parasites include leeches, some of which also live inside the bodies of amphibians as endoparasites (Mann and Tyler 1963), as well as mites, ticks, and chiggers (Rankin 1937; Anthony, Mendelson, and Simons 1994) and parasitic copepods (C. Goin and Ogren 1956). Larvae of sarcophagid, calliphorid, and chloropid flies parasitize adult anurans, and some are thought to be obligate anuran parasites (Askew 1971; Crump and Pounds 1985). A number of freshwater invertebrates attach themselves to amphibians, which then carry them between ponds. These include tiny ostracod crustaceans (Seidel 1989) and bivalve clams (*Pisidium;* Scherff-Norris and Livo 1999). It is not always clear whether this represents a parasitic or commensal relationship. Tadpoles and aquatic salamanders serve as hosts for the parasitic larval stages of freshwater mussels (glochidia; Seshaiya 1941, 1969; A. D. Howard 1951; Watters 1997; Watters and O'Dee 1998). The impact of these animals on their amphibian hosts has not been investigated, however.

Ecological Impact of Parasites

Most papers on amphibian parasites are brief reports of the occurrence of parasites in particular host species, surveys of parasite communities in amphibians of a particular habitat, or studies of parasite life histories. These studies tend to focus mostly on the biology of the parasites, rather than their effect on the hosts. The importance of parasites as a source of mortality and their impact on amphibian population dynamics has seldom been addressed. A detailed discussion of amphibian parasites is beyond the scope of this book, but I will mention a few cases in which the effect of parasites on the physical condition or survivorship of amphibians has been investigated.

Adult *Atelopus varius* in Costa Rica are parasitized by larval sarcophagid flies (*Notochaeta bufonivora*), particularly when the frogs are aggregated near waterfalls (Crump and Pounds 1985; Pounds and Crump 1987). Fly parasitism could be a major source of mortality in the population, but quantitative data are lacking. Larvae of a tachinid fly, *Lucilia bufonivora,* sometimes infest populations of *Bufo calamita* and other anurans and can cause substantial mortality of adults (Meisterhans and Heusser 1970; Sinsch 1998). Gill (1978a) described heavy infestations of leeches in populations of *Notophthalmus viridescens* and speculated that they might be a major factor controlling the population dynamics of newts, either through direct effects of leech attacks or the effects of blood parasites (*Trypanosoma*) transmitted by the leeches. However, subsequent work showed that the trypanosomes had little or no effect on the survivorship of newts or their rates of reproduction (Mock and Gill 1984; Gill and Mock 1985); the effects of leech attacks alone were not investigated. Two studies of the effects of infection with parasitic nematode lung worms (*Rhabdias*) on growth and survival of newly metamorphosed anurans (*Bufo bufo* and *Rana sylvatica*) failed to reveal any significant effect (Goater 1994; Goater and Vandenbos 1997). However, earlier studies with *Bufo bufo* had shown negative effects of heavier infections by the same parasite on locomotor performance, growth, and survival of metamorphs (Goater and Ward 1992; Goater, Semlitsch, and Baernasconi 1993).

Infection by a species of parasitic trematode (*Ribeiroia ondatrae*) has been implicated in developmental abnormalities seen in several species of anurans, especially the presence of extra limbs (Sessions and Ruth 1990; P. Johnson et al. 1999, 2002, 2003; Sessions et al. 1999; P. Johnson, Lunde, Haight, et al. 2001; P. Johnson, Lunde, Ritchie, et al. 2001; Stopper et al. 2002; Blaustein and Johnson 2003a, b; P. Johnson and Sutherland 2003). Although such deformities have received a lot of news coverage and even were the subject of a popular book (Souder 2000), this is not a new phenomenon. There are reports going back nearly 300 years of amphibians with extra limbs (Ouellet 2000; P. Johnson et al. 2003). Not all limb malformation can be attributed to parasite infections; various chemical pollutants may be important as well (Ouellet 2000; Blaustein and Johnson 2003a, b). Nevertheless, a recent study of preserved specimens of deformed anurans from museum collections turned up evidence of *Ribeiroia* infection in a number of historic populations, some of which are from sites where recent infections have been reported (P. Johnson et al. 2003). As with other trematodes, freshwater snails (*Planorbella*) are the intermediate hosts for *Ribeiroia,* so the prevelence of deformed amphibians may be tightly linked to the population dynamics of the snails. There is evidence that in severely eutrophic ponds impacted by fertilizer runoff or other sorts of pollution, snail populations increase, and this may lead to increased parasite infections in amphibians. There also appears to have been an increase in the number of populations of amphibians infected with these parasites in recent years (Blaustein and Johnson 2003a,b; P. Johnson et al. 2003), and the prevalence of deformed individuals is correlated with trematode abundance (Johnson, Lunde, Ritchie, Reaser, and Launder 2001; P. Johnson et al. 2002).

Presumably the fitness consequences for the affected individuals are severe, since their locomotion is impaired and they are likely to be highly susceptible to predation, especially by water birds that are attracted to the awkward movements of deformed frogs. The ecological impact of parasite infections and the resulting limb malformations is not entirely clear. This phenomenon often has been discussed in the context of declining amphibian populations (e.g., Souder 2000; P. Johnson et al. 2002; Blaustein and Johnson 2003a, b). Certainly in some populations, deformities in up to 90% of individuals could result in local population extinctions, but there is little evidence so far that trematode infections have led to widespread declines of amphibian populations (Ouellet 2000). Indeed, some sites where large numbers of deformed frogs were present more than 50 years ago still support frog populations, with many individuals still infected with parasites (P. Johnson et al. 2003). High parasite infection rates are most common in farm ponds and other bodies of water heavily impacted by human activities or grazing cattle, so these parasites cannot explain the widespread decline of amphibian populations in more pristine habitats (see also chapter 16).

Two studies have examined the effects of parasite infections on calling performance and mating success of adult anurans. Hausfater, Gerhardt, and Klump 1990) quantified total numbers of parasitic nematodes and helminths in various organs of gray tree frogs (*Hyla versicolor*). Although many individuals were heavily parasitized, there was no relationship between parasite load and measures of calling performance, such as call duration and calling rate. Furthermore, when males with high and low levels of calling performance were compared for parasite load, there was not a significant difference for any type of parasite. There also was little evidence that parasite infection affected the time of arrival of males at the chorus, chorus attendance, or mating success. Tinsley (1990) studied spadefoot toads (*Scaphiopus couchii*), which usually are heavily infected by a monogenean parasite, *Pseudodiplorhis americanus,* which lives in the urinary bladder. Heavily infected toads can be debilitated by depletion of energy reserves, especially during hibernation. Nevertheless, males in a breeding chorus that were captured in amplexus had the same level of parasite infection as those not seen in amplexus. Mating success also was not related to body size, body mass, fat deposits, or hematocrit. Tinsley (1990) suggested that those males that have been debilitated by parasite infection simply do not come to breeding assemblages at all, whereas males in choruses are not sufficiently impacted by parasites to affect their reproductive success.

The effect of parasitism by mites (*Hannemania eltoni*) on plethodontid salamanders (*Plethodon angusticlavius*) was examined in laboratory experiments by Maksimowich and Mathis (2000). Even though heavily infested salamanders were not noticeably unhealthy, heavily infested males were less aggressive toward other individuals than were males with low parasite loads. If this effect occurs in the field, it could reduce the ability of heavily infested males to defend territories. Females were tested for the effect of mite infestation on foraging behavior with both fruit flies and termites as prey. Heavily infested females took longer to make a first attack on fruit flies than did females with low parasite loads, but this was not true for females presented with termites. The attack delay averaged only about 75 seconds and was not reflected in lower numbers of prey being consumed or in differences in nose-tapping behavior (an indicator of chemosensory exploration). Hence, the ultimate fitness effects of mite infestation are not known, particularly for animals in the field. Nevertheless, in behavioral experiments, there was a tendency for nonparasitized individuals to avoid fecal pellets of heavily parasitized individuals; these pellets are used to mark the territories of individual salamanders (Maksimowich and Mathis 2001).

Predation by Fishes

Fishes often are the dominant predators in permanent ponds and lakes, as well as large streams and rivers, but they normally are absent from temporary ponds and very small streams. They can be voracious predators of amphibian eggs and larvae, and some large species can eat adult amphibians as well. An enormous number of temperate-zone fishes readily feed on amphibians. A partial list includes bowfin (*Amia*), mosquitofish (*Gambusia*), sticklebacks (*Gasterosteus*), catfish (*Ictalurus*), pike (*Esox*), goldfish (*Carassius*), carp (*Cyprinus*), bream (*Abramis*), asp (*Aspius*), chub (*Leuciscus, Semotilus*), darters (*Etheostoma*), shiners (*Notropis*), trout, char, grayling, and other salmonids (*Brachymystax, Hucho, Oncorhynchus, Salmo, Salvelinus, Thymallus*), burbot (*Lota*), sculpins and bullheads (*Cotto, Cottus*), sheatfishes (*Parasilurus, Silurus*), snakeheads (*Ophiocephalus*), bass (*Micropterus*), sunfish (*Enneacanthus, Lepomis*), and perch (*Lucioperca, Perca;* Lewis et al. 1961; W. Lewis and Helms 1964; Lowry 1966; Macan 1966; Voris and Bacon 1966; Grubb 1972; Efford and Tsumura 1973; Kruse and Francis 1977; Werschkul and Christensen 1977; Glandt 1983, 1984, 1985; Petranka 1983; Kruse and Stone 1984; Hayes and Jennings 1986; Giacoma 1988; Semlitsch 1987b, 1988; Semlitsch and Gibbons 1988; Bradford 1989; Blouin 1990; Kats and Sih 1992; Feminella and Hawkins 1994; Horat and Semlitsch 1994; Gamradt and Kats 1996; Lefcourt 1996; Kiesecker and Blaustein 1997b; Kurzava and Morin 1998; Tyler, Liss, Ganio et al. 1998; T. Tyler, Liss, Hoffman, and Ganio 1998; Goodsell and Kats 1999; Kuzmin

1999; Lawler et al. 1999; Jordan and Arrington 2001; Monello and Wright 2001). While the impact of fishes on amphibian populations can be severe, the importance of amphibians in the diet of fishes varies widely. There are no species of fishes known to specialize on the eggs, larvae, or adults of amphibians, and amphibians make up a relatively small proportion of the diet of many generalist predators (e.g., Jordan and Arrington 2001).

Predation on amphibians by tropical fishes has not been studied in detail. Various cypriniform, cichlid, and synbranchid fishes have been cited as potential predators of amphibian eggs and larvae, but actual predation is rarely seen in the field (K. Liem 1961; Heyer 1973; Kluge 1981; Branch 1983; Schlüter 1984; Azevedo-Ramos and Magnusson 1999). A fish of the genus *Hoplias* (Erythrinidae) ate a male toad (*Bufo crucifer*) in a breeding chorus in Brazil (Haddad and Bastos 1997). In East Africa, the introduction of food fishes into mountain lakes has virtually eliminated what once were enormous populations of *Xenopus* (Worthington and Worthington 1933; Tinsley 1973; Tinsley, Loumont, and Kobel 1996). Whether the frogs were eliminated by predation or competition has not been established, however. In tropical Queensland, Australia, eels (*Anguilla*) have been seen feeding on adult frogs (Beumer 1979; Harvey, Morrison, and Hero 1999), and barramundi (*Lates calcarifer*) will feed on tadpoles (Lawler and Hero 1997).

Predatory fishes affect the ecology and behavior of amphibians in several ways. They can influence the choice of breeding habitats and the placement of eggs within breeding sites (see the following). Fishes also can influence the relative abundance of amphibian species in aquatic communities by eliminating one or more species of amphibian larvae, or by altering the interactions between amphibian larvae and other predators (Werner and McPeek 1994; Hecnar and M'Closkey 1997b; Resetarits 1997; Kurzava and Morin 1998; see the following and chapter 15). The presence of predatory fish often causes amphibian larvae to change their activity and choice of foraging microhabitats, thereby affecting growth, survivorship, and the timing of metamorphosis (see the following "Defenses of Larvae"). Fish can be especially devastating predators of amphibian larvae when other predators, such as larval or adult salamanders, bullfrogs, or crayfish, also are present (Gamradt and Kats 1996; Kiesecker and Blaustein 1997b; Kurzava and Morin 1998). This may be in part because certain types of antipredator defenses that are effective against one type of predator are not effective against another. This can result in the combined effects of fish and other predators being greater than the effect of each predator alone.

One line of evidence for fish having a significant impact on amphibians comes from studies of distributional patterns and the effect of introduced fishes on amphibian populations (see also chapter 16). Permanently aquatic paedomorphic salamanders are most successful where fish are absent (see chapter 13). Some populations have been wiped out by introduction of nonnative game fishes (Carr and Goin 1943; Brandon and Bremer, 1967; D. Larson 1968; Sprules 1974a; Dolmen 1978; Marangio 1978; Moriya 1983; Sexton and Phillips 1986; see also chapter 16). Even in metamorphosing populations, predation on eggs and larvae may be sufficiently intense to eliminate salamanders from some habitats, or to prevent them from reproducing successfully. In ponds in the western United States, survival of larval *Ambystoma gracile* and *A. macrodactylum* is greatly reduced by the presence of introduced trout (T. Tyler et al. 1998). Nevertheless, the latter species can persist with trout in low numbers, especially in lakes with nonreproducing (recently stocked) fish (T. Tyler, Liss, Ganio, Larson, Hoffman, Deimling, and Lomnicky, 1998). *Ambystoma macrodactylum* is capable of rapidly recolonizing lakes where trout have disappeared. A study in Montana showed that salamanders were present in five of six high-altitude lakes where trout had gone extinct between 1978 and 1998, but salamanders were found in only two of 12 lakes that still had trout (Funk and Dunlap 1999).

In the eastern United States, spotted salamanders (*Ambystoma maculatum*) regularly coexist with bluegill sunfish (*Lepomis macrochirus*), but growth of *Ambystoma* larvae is reduced in the presence of fish. This apparently results from a combination of competition between larvae and fish for the same prey and microhabitat shifts by salamander larvae to avoid predation by fishes (Figiel and Semlitsch 1990). Banded sunfish (*Enneacanthus obesus*) appear to exclude red-spotted newts (*Notophthalmus viridescens*) from ponds in the Pine Barrens of New Jersey, but in this case, competition for food seems to be more important than predation (Bristow 1991).

In the western United States, introduced fish may be responsible for declines of many local populations of amphibians (see also chapter 16). For example, introduced goldfish (*Carassius auratus*) eliminated most amphibians from ponds in Idaho (Monello and Wright 1999). Both California newt larvae (*Taricha torosa*) and Pacific treefrog tadpoles (*Pseudacris regilla*) are subject to predation by mosquitofish (*Gambusia*) that have been widely introduced as mosquito control agents. When salamander larvae were housed with mosquitofish in stream enclosures, the fish ate nearly all of the larvae within 24 hours (Gamradt and Kats 1996). Predation on tadpoles was high even in streams where mosquito larvae were abundant (Goodsell and Kats 1999). Mosquitofish caused newly hatched tadpoles of *Rana draytonii* to reduce their activity, but the fish preferred invertebrate prey to tadpoles and did not have a significant effect on tadpole survivorship in seminatural ponds (Lawler et al. 1999).

Predation by introduced game fishes may be responsible for declining populations of some ranid frogs in the western United States (Hayes and Jennings 1986; Bradford 1989). Tadpoles of red-legged frogs (*Rana aurora*) do poorly in the presence of introduced smallmouth bass (*Micropterus dolomieui*), especially when introduced bullfrogs also are present (Kiesecker and Blaustein 1997). Introduced game fishes also can alter the structure of anuran populations by preventing dispersal between fish-free habitats (Bradford, Tabatabai, and Graber 1993), thereby increasing the chances that local populations will become extinct (see also chapter 16). Similar patterns are seen in Europe, where the introduction of trout into ponds has eliminated some populations of tree frogs (*Hyla arborea;* Brönmark and Edenhamn 1994). The European pool frog (*Rana lessonae*) requires permanent ponds for reproduction, but is largely excluded from very large ponds because of predation by pike (*Esox;* Sjögren 1991a). Many other European ranids, such as the moor frog *(Rana arvalis*), normally breed in fish-free ponds and are threatened by stocking of fish in breeding ponds (Podloucky 1987). In Australia, many frogs are restricted to temporary ponds that lack fish (M. Healey, Thompson, and Robertson 1997), and survival of their tadpoles can be reduced in the presence of introduced fishes (L. Morgan and Buttemer 1996).

In Europe and Asia, the presence of introduced game fishes is considered to be a major threat to stream-dwelling salamanders in the family Salamandridae and Hynobiidae (Picariello 1993; Kuzmin 1999), as well as amphibians that breed in mountain lakes (Mazzotti 1993; Braña, Frechilla, and Orizaola 1996). Effects of fishes may be due to predation, competition, or both. European newts (*Triturus*) generally are found in fish-free ponds, and many populations have been reduced or eliminated by introduced fish (Esher 1972; G. Bell 1979; Dolmen 1981a, 1982b; Giacoma 1988; Reshetnikov and Manteifel 1997; Kuzmin 1999). However, newts sometimes coexist with fish if invertebrates that serve as alternative prey for fish are sufficiently abundant (Dolmen 1982b). Larvae of *T. cristatus* are more vulnerable than are *T. vulgaris* because they feed in open water, whereas *T. vulgaris* larvae generally stay on the bottom (Dolmen 1982b, 1983a).

Predation by Amphibians

Many species of amphibians prey upon the eggs, larvae, juveniles, or adults of their own or other species of amphibians. Salamander larvae probably are more significant predators of amphibians than are adults, most of which feed mainly on small invertebrates. Conversely, most anuran tadpoles are herbivorous, although even these can be opportunistic predators on eggs and larvae of other amphibians. Large adult anurans, on the other hand, are carnivorous and often take amphibians. Very little is known about the diets of caecilians. Juveniles of an aquatic caecilian, *Typhlonectes compressicauda,* from Brazil eat mostly invertebrates, but also eat the eggs and tadpoles of frogs (*Leptodactylus macrosternum;* Verdade, Schiesari, and Bertoluci 2000).

Predation by Larval Urodeles

Larval and adult salamanders are the most important vertebrate predators of amphibian eggs and larvae in many ponds and lakes that lack fish (J. D. Anderson 1968a; Wilbur 1972; Calef 1973a; Walters 1975; Burton 1977; Morin 1983a, b; Thiesmeier 1990; Holomuzki, Collins, and Brunkow 1994). Salamander larvae are very effective predators, capable of nearly eliminating some anuran eggs and tadpoles from small ponds (Walters 1975; Morin 1983a, 1995; Cortwright 1988; Skelly 1992; Blaustein et al. 1996; Loeb, Collins, and Maret 1994; Maret and Collins 1996). Predation by salamander larvae can alter the species composition and dynamics of communities of anuran tadpoles by favoring species that are least vulnerable to predation and by reducing competition among surviving individuals (Wilbur, Morin, and Harris 1983; Wilbur 1987; Morin 1995; Blaustein et al. 1996; see also chapter 15). Larval salamanders also eat larvae of other species of salamanders in both ponds (Stenhouse, Hairston, and Cobey 1983; Stenhouse 1985a; Cortwright 1988; Kuzmin 1999; Brodman 2004) and streams (Resetarits 1991; Gustafson 1993). Cannibalism of conspecific larvae is relatively common (Degani, Goldenberg, and Warburg 1980; Collins and Cheek 1983; Lannoo and Bachmann 1984a; Simon 1984; Kusano, Kusano, and Miyashita 1985; Semlitsch and Reichling 1989; Crump 1992; Nyman, Wilkinson, and Hutcherson 1993; Degani 1993; M. Parker 1994; Bressi, Dolce, and Stoch 1996; Kuzmin 1999), and some ambystomatids even develop into specialized cannibalistic morphs (see chapter 12). In most cases, however, conspecific larvae make up a relatively small proportion of the diet.

Predation by Adult Urodeles

In the eastern United States, adult red-spotted newts (*Notophthalmus viridescens*) are important predators on eggs and larvae of other amphibians. This species sometimes acts as a keystone predator in communities of larval anurans (Morin 1981, 1983a, b, 1986, 1987b; Morin, Wilbur, and Harris 1983; Wilbur 1987; Alford 1989b; Wilbur and Fauth 1990; Fauth and Resetarits 1991; Kurzava and Morin 1994; Kurzava and Morin 1998; Fauth 1999a). By changing the outcome of competition between species, a keystone predator can maintain a higher diversity of species in a community than would persist in the absence of the predator (see chapter 15). Such predators also may eliminate certain prey species altogether, leading to domination of a community by other species (e.g., Kurzava and Morin 1998). The impact of newts on their prey depends in part on the size of the newts. For example, a smaller subspecies, *N. v. dorsalis,* had less impact on populations of *Bufo americanus* tadpoles than did a larger subspecies, *N. v. viridescens* (Kurzava and Morin 1994). The presence of the smaller subspecies can alter competitive interactions among species of tadpoles, favoring those that are least vulnerable to newt predation (Morin 1981, 1983a; Alford 1989b; Fauth and Resetarits 1991). The larger subspecies, on the other hand, tends to reduce survivorship of all species of tadpoles (Morin 1986, 1987a). In one set of experiments, however, *N. v. viridescens* eliminated tadpoles of *Bufo woodhousii,* resulting in a community dominated by *Pseudacris* tadpoles, with several other species surviving in low numbers (Kurzava and Morin 1998). In South Carolina, another subspecies of newt, *N. v. louisianensis,* had less impact on the structure on larval anuran communities than did newts from North Carolina. In South Carolina, a large salamander, *Ambystoma talpoideum,* which was not present in North Carolina, filled the role of keystone predator. Ponds with this salamander present had a higher diversity of anuran species than did those without *A. talpoideum* (Fauth 1999a).

Red-spotted newts often have complex predator-prey interactions with other species of salamanders. In North Carolina, for example, adult newts are major predators on the eggs of tiger salamanders (*Ambystoma tigrinum;* Morin 1983b), and I have seen newts preying on eggs of *Ambystoma maculatum* as well (unpublished observations). High densities of newts are sufficient to eliminate most *Ambystoma* eggs from small ponds before they can hatch. This in turn may indirectly benefit anuran tadpoles, because *Ambystoma* larvae are capable of eliminating most tadpoles from small ponds (Morin 1983a). The larvae of *A. tigrinum* grow much faster than do those of *Notophthalmus* and eventually reach a size that enables them to feed on newt larvae (Morin 1983b). Newts in North Carolina also live in ponds with *Siren intermedia,* a salamander that can be both a competitor and predator (Fauth, Resetarits, Jr., and Wilbur 1990; Fauth and Resetarits 1991). Sirens prey on larval newts, but it also is possible that adult newts prey on larval sirens (Fauth and Resetarits 1991). Red-spotted newts also prey on their own eggs (R. Harris 1987a), and the presence of sirens may actually increase survivorship of newt eggs by reducing cannibalism by adults (Fauth and Resetarits 1991).

Sirens are unselective predators on anuran tadpoles and will even consume toad tadpoles that are distasteful to many other vertebrate predators (Lefcourt 1998), but the diet is composed mostly of invertebrates (Scroggin and Davis 1956). Sirens also will cannibalize the eggs of their own species (Scroggin and Davis 1956; Collette and Gehlbach 1961). In some circumstances, sirens may act as keystone predators in communities of larval anurans, or they may support the keystone role of newts (Resetarits and Fauth 1998; see chapter 15). When *Siren intermedia* lives in the same ponds as *Ambystoma talpoideum,* both species tend to be the top predators of anuran tadpoles, but sirens will prey upon larval *Ambystoma* as well. Hence, sirens are both competitors and predators of *A. talpoideum,* and the presence of sirens has a negative impact on growth and survivorship of *Ambystoma.* In general, the distributions of the two species among ponds are negatively correlated (Fauth 1999b). *Siren intermedia* generally does not live in the same ponds as a larger member of the same genus, *S. lacertina,* perhaps because of competitive or predatory interactions (Snodgrass et al. 1999). The latter species, in turn, tends not to be found with *Amphiuma means,* another predatory salamander of similar size. The impact of these two species on larval amphibian communities has yet to be studied, but *Amphiuma* is known to eat tadpoles, including toad tadpoles that are distasteful to some other predators (Lefcourt 1998).

In the western United States, aquatic habitats lack the diversity of amphibians found in the southeast. Nevertheless, newts of the genus *Taricha* can have a major impact on populations of other amphibians. Calef (1973a) estimated that newts (*Taricha granulosa*) and larval *Ambystoma gracile* together eliminated over 90% of the *Rana aurora* tadpoles from a 10-hectare lake in British Columbia, with newts being the most important predators. Even when tadpoles escape predation by *Taricha,* the presence of newts can result in reduced levels of feeding activity by tadpoles (D. J. Wilson and Lefcourt 1993), which in turn may reduce growth rates and survivorship (Skelly 1992). Adult *Taricha* also can be voracious predators on eggs and larvae of their own species (Kaplan and Sherman 1980; Marshall, Doyle, and Kaplan 1990; Kats, Elliott, and Currens 1992), although they may avoid eating conspecifics if alternative prey is available (Kerby and Kats 1998). Larval *Taricha* tend to react to the presence of adults by hiding (Elliott, Kats, and Breeding et al. 1993; Kerby and Kats 1998).

European newts (*Triturus*) also eat other amphibians. Adults of several species eat frog eggs and tadpoles, but most species tend to avoid toad eggs and tadpoles (Heusser 1971a; Cooke 1974; Griffiths 1986; Banks and Beebee 1988; Reading 1990; Denton and Beebee 1991; Kwet 1996a; Martínez-Solano 2000). Eggs and tadpoles usually are a much less important component of the diet than are various kinds of invertebrates (Griffiths and Mylotte 1987; Kuzmin 1999), but the impact on local populations of frogs can be severe (Kwet 1996a). Adults of *T. alpestris, T. helveticus, T. vittatus,* and *T. vulgaris* eat conspecific eggs, or those of other newts (Miaud 1993; Kuzmin 1999), but the overall importance of eggs in the diet is relatively trivial (Griffiths 1986; Kuzmin 1999). Adult *Triturus* sometimes feed on the larvae of other newts, but again, they make up a tiny fraction of the normal diet

(Dolmen and Koksvik 1983; Griffiths 1986; Kuzmin 1999). Adults of large species, such as *T. cristatus* and *T. marmoratus,* also feed occasionally on adults of smaller species, such as *T. vulgaris, T. helveticus,* and *T. alpestris* (Hagström 1979; Frazer 1983; Kuzmin 1999; Orizaola and del Valle 2000).

Intra- and interspecific predation on eggs by adults is widespread in plethodontid salamanders (Baldauf 1947; J. Wood and Clarke 1955; Snyder 1971; Simon 1984; Nussbaum 1985; Polis and Myers 1985; Crump 1992). Such predation may be a major selective force favoring the evolution of parental care (see chapter 11). Adults of some large plethodontid salamanders, such as *Desmognathus marmoratus, D. quadramaculatus, Gyrinophilus porphyriticus, Pseudotriton ruber,* and *Eurycea lucifuga,* sometimes prey on smaller salamanders (Martof and Scott 1957; Peck and Richardson 1976; Bruce 1979; Hairston 1986; Bock and Fauth 1992; Formanowicz and Brodie 1993; Secki and Queral-Regil 1997; Bernardo 2002), and there is even a report of an adult red-backed salamander (*Plethodon cinereus*) eating a conspecific juvenile (Maerz and Karuzas 2003). Predation by large species, especially *Desmognathus quadramaculatus,* has been considered a major determinant of microhabitat selection and community structure in streamside assemblages of *Desmognathus* (Hairston 1986, 1987; Southerland 1986a, b; Roudebush and Taylor 1987b; Beachy 1994; see chapter 15 for further details). Both *Gyrinophilus* and *Desmognathus quadramaculatus* will attack smaller salamanders in laboratory experiments, but the latter is a less effective predator than the former (Formanowicz and Brodie 1993). Studies of the natural diet of *D. quadramaculatus* indicate that salamanders are seldom eaten, and most of those consumed are conspecific larvae or juveniles. Predation on adults of other species of *Desmognathus* appears to be rare (Davic 1991; Camp 1997).

Predation by Anuran Tadpoles

Although most anuran tadpoles are herbivores or detritivores, some prey on eggs, tadpoles, or metamorphosing juveniles of their own and other species (Heusser 1970, 1971b; Heyer, McDiarmid, and Weigmann 1975; Crump 1983, 1986b, 1991, 1992; Simon 1984; Polis and Myers 1985; Rödel and Linsenmair 1997; Spieler and Linsenmair 1997; Petranka and Kennedy 1999; Summers 1999b; Babbitt and Meshaka 2000; Vredenburg 2000). A few species have become specialized carnivores or cannibals; these were discussed in chapter 12 (see "Cannibalism and Morphological Polyphenism"). Predation by generalized tadpoles that lack adaptations for a carnivorous diet probably is an underappreciated source of mortality in many amphibian populations (Petranka and Kennedy 1999). For example, most Eurasian anurans have generalized pond tadpoles, but many of these species are known to prey on anuran eggs. Predatory or cannibalistic species include *Rana arvalis, R. dybowskii, R. lessonae, R. ridibunda, R. temporaria, Bufo bufo, B. calamita, Bufo verrucoissimus, Hyla arborea, Pelobates cultripes, Pelobates fuscus, Pelodytes caucasius,* and *Pelodytes punctatus* (Heusser 1971b; Beebee 1977; Sacher 1986; Banks and Beebee 1987b; Tejedo 1991; Kuzmin 1999). Some tadpoles even will eat the relatively distasteful eggs of the natterjack toad (*Bufo calamita*). Predation by tadpoles can result in nearly complete mortality of eggs in some ponds and appears to be a major factor that prevents *Bufo calamita* from successfully colonizing breeding ponds used by other anurans (Banks and Beebee 1987b; Tejedo 1991).

Wood frog (*Rana sylvatica*) tadpoles readily consume conspecific eggs (Petranka and Thomas 1995), and they are voracious predators on the eggs of American toads (*Bufo americanus*) as well, even though the eggs of this species contain toxic chemicals (Petranka, Brannon, Hopey, and Smith 1994). Wood frog tadpoles also prey on eggs and hatchlings of other anurans, including *Rana palustris* and *Hyla chrysoscelis,* as well as eggs of the spotted salamander (*Ambystoma maculatum*). In some ponds, predation on *Ambystoma* eggs by wood frog tadpoles can result in very high levels of mortality (Petranka, Rushlow, and Hopey 1998). This represents an interesting reversal of the usual ecological roles of these two species, because *Ambystoma* larvae often are the most important predators of *Rana sylvatica* tadpoles in temporary ponds (Wilbur 1972; Holomuzki, Collins, and Brunkow 1994). Green frog (*Rana clamitans*) tadpoles, which spend one or more winters in ponds, can sometimes virtually eliminate eggs of wood frogs laid in early spring (Petranka and Kennedy 1999).

Many species of tadpoles in the tropics prey on eggs of other anurans, even when the tadpoles lack specialized mouthparts and other morphological adaptations for a carnivorous diet. For example, the tadpoles of *Leptodactylus pentadactylus* have a generalized morphology, but are voracious predators on the eggs of other frogs, including those of *Bufo alatus* (formerly *B. typhonius*), which may be toxic or distasteful to other predators, including fish (Heyer, McDiarmid, and Weigmann 1975; Wells 1979). Tadpoles of a closely related species, *L. labyrinthicus,* also eat eggs of their own and other species (Silva, Giaretta, and Facure 2005). Tadpoles of several species of frogs from the tropical parts of Australia, including *Limnodynastes ornatus, Litoria alboguttata,* and *Litoria rubella,* prey on the eggs of native species of frogs (Crossland 1998a), as well as those of the introduced toad *Bufo marinus.* The eggs of this species are highly toxic, and consumption of eggs leads to high mortality among native tadpoles (Crossland 1998b; Crossland and Alford 1998). Because these species did not evolve with *Bufo marinus,* they do not exhibit any tendency to avoid these toxic eggs, so the consequences for populations of native frogs could be severe (Crossland 1998b). Tadpoles of *B. marinus* do not, however, appear to be significant predators on eggs, hatchlings, or tadpoles of native Australian frogs (Crossland 1998a).

Predation by tadpoles on the eggs and tadpoles of conspecifics or heterospecifics is particularly common among tropical anurans that breed in ephemeral pools, where rapid drying of pools favors rapid growth. For example, tadpoles of the Neotropical frog *Hyla pseudopuma* often cannibalize eggs and hatchlings of conspecifics (Crump 1983), thereby enhancing their own growth (Crump 1990). Tadpoles of another Neotropical treefrog, *Hyla acreana,* have been observed eating tadpoles of *Hamptophryne boliviana* and a species of *Scinax* in the field, and readily consume tadpoles of these species and those of *Phyllomedusa* and *Allobates* in captivity (McKeon 2005). The Cuban treefrog (*Osteopilus septentrionalis*) breeds in ephemeral drainage ditches in Florida, where tadpoles often occur at very high density. Cannibalism of conspecific tadpoles shortened the larval period and increased size at metamorphosis when tadpoles were fed mostly on a low-quality diet (algae and periphyton). This effect was not seen in tadpoles fed on a high-quality diet (rabbit chow; Babbitt and Meshaka 2000). Similar cannibalism has been described in *Hoplabatrachus occipitalis,* a West African frog that breeds in ephemeral rock pools (Spieler and Linsenmair 1997). Tadpoles of this species are specialized carnivores that also eat insect larvae and tadpoles of other species, in contrast to the generalized morphology and diet of the two hylids. Predation by tadpoles on eggs also is common in restricted habitats such as bromeliads and tree holes, which often harbor obligate egg-eating species (Simon 1984; Lannoo, Townsend, and Wassersug 1987; Crump 1992; Summers 1999b; see chapter 12 for further discussion). Cannibalism also occurs in frogs that lay eggs in shallow aquatic nests, including *Hyla rosenbergi* (Kluge 1981) and *H. faber* (Bernarde and Machado 1999).

Predation by Adult Anurans

Adults of a number of species of frogs that lay terrestrial eggs will cannibalize the eggs of their own species (Tyler 1963a; Weygoldt 1980a; Wells 1981a; Simon 1983, 1984; H. Zimmermann and E. Zimmermann 1983; Townsend, Stewart, and Pough 1984; Summers 1989; Bonilla and La Marca 1996). Intraspecific cannibalism can be a major selective pressure favoring parental attendance of eggs (see chapter 11). Adults of the African hyperoliid frog *Afrixalus fornasini* eat the eggs of other species of frogs, including *Chiromantis xerampelina* and several species of *Hyperolius* (Drewes and Altig 1996; Vonesh and Osenberg 2003; Vonesh 2005a, b). Both of these species lay eggs on plants or tree branches over water, but do not exhibit parental care. The eggs of *Chiromantis* are laid in foam nests, but *Afrixalus* readily attack these eggs by thrusting their heads into the foam mass and pulling out eggs. *Afrixalus fornasini* also eats eggs of conspecifics. Drewes and Altig (1996) suggested that this species' habit of gluing their eggs inside of a folded leaf might afford some protection against cannibalism by conspecifics.

Adults of some aquatic frogs also eat anuran eggs and tadpoles. Pipid frogs, including *Xenopus* and some species of *Pipa,* prey on conspecific eggs or those of other species (McCoid and Fritts 1980; Gascon 1992b). *Xenopus* also eat tadpoles (Wager 1965) and adults of their own or other species (Inger and Marx 1961), but their role as predators in aquatic communities has not been studied in detail. Adult males of *Bombina orientalis* also consume eggs of conspecifics. These eggs are scattered in loosely connected strings on the bottoms of ponds and have little protection against conspecific predation (Marshall, Doyle, and Kaplan 1990). This species also feeds on the tadpoles of other frogs (Kuzmin 1999). Other Eurasian anurans that sometimes prey on eggs or tadpoles or their own or other species include *Bombina bombina, B. variegata, Bufo viridis, Rana lessonae, R. macrocnemis, R. nigromaculata,* and *R. ridibunda* (Kuzmin 1999).

Many medium and large adult frogs probably are opportunistic predators on smaller anurans (fig. 14.3). For example, ranids such as *Rana blairi, R. cascadae, R. catesbeiana, R. clamitans, R. esculenta, R. lessonae, R. luteiventris, R. muscosa, R. perezi, R. pretiosa, R. ridibunda, R. sylvatica,* and *R. vaillanti* prey on juveniles, adults, and even tadpoles of other species of frogs, as well as juvenile conspecifics. The importance of anuran prey varies geographically and seasonally from a trivial proportion of the diet to more than 30% (Korshgen and Moyle 1955; Frommhold 1956; Korshgen and Baskett 1963; Jenssen and Klimstra 1966; Stewart and Sandison 1972; Dushin 1974; Corse and Metter 1980; Frazer 1983; Lizana, Ciudad Pizarro, and Pérez-Mellado 1986; Werner, Wellborn, and McPeek 1995; Kuzmin 1999; Pilliod 1999; K. Pope 1999; Pearl and Hayes 2002; McCallum, Klotz, and Trauth 2003; Rombough, Jordan, and Pearl 2003; Vaughan 2003; Bolek and Janovy 2004). In North America, the bullfrog (*Rana catesbeiana*) undoubtedly is the most significant anuran predator of other amphibians, simply because it is the largest species. Adult bullfrogs are known to eat tadpoles, juveniles, adults, and even eggs of their own species and other species of frogs (Korshgen and Moyle 1955; Korshgen and Baskett 1963; G. Brooks 1964; M. Stewart and Sandison 1972; McKamie and Heidt 1974; Corse and Metter 1980; Bury and Whelan 1984; McAlpine and Dilworth 1989; J. Stuart and Painter 1993; Werner, Wellborn, and McPeek 1995). They also will eat salamanders (Balfour and Stitt 2003) and even newts (*Taricha torosa*), which are well protected from most predators by toxic skin secretions (M. Jennings and Cook 1998).

Fig. 14.3. Large adult *Leptodacylus ocellatus* eating a smaller frog. Photo by Walter Hödl.

The decline of several native ranids in the western United States has been attributed in part to predation by introduced bullfrogs (Moyle 1973; Schwalbe and Rosen 1988; P. Rosen and Schwalbe 1995; P. Rosen et al. 1995), but evidence for this hypothesis is equivocal (M. Jennings and Hayes 1985; Hayes and Jennings 1986). Introduced bullfrogs clearly have a negative impact on some native species, such as the red-legged frog (*Rana aurora*) and yellow-legged frog (*R. boylii*). The impact of bullfrogs appears to result from several factors. These include competition among tadpoles (Kupferberg 1997a), predation by larval and adult bullfrogs on tadpoles of other species (Kiesecker and Blaustein 1997b; Lawler et al. 1999), and the interactive effect of bullfrogs and other introduced predators on tadpoles (Kiesecker and Blaustein, 1998). The impact of predation by adult bullfrogs on the juveniles and adults of native frogs has yet to be determined. Experimental removal of large numbers of adult bullfrogs from a wildlife refuge in Arizona resulted in some increase in the density of *Rana chiriacahuensis* (Schwalbe and Rosen 1988). The natural disappearance of bullfrogs from a park in Canada had a similar effect on the density of green frogs (*R. clamitans;* Hecnar and M'Closkey 1997a). It is not possible to determine from these studies whether the effect of bullfrog removal was due to reduced predation, reduced competition, or a combination of the two (see chapter 16 for further discussion of introduced predators).

A number of large tropical frogs, including the African ranid *Pyxicephalus adspersus,* the South American leptodactylids *Cacophrys, Ceratophrys* and *Lepidobatrachus,* and the South American hylid *Hemiphractus,* have been described as voracious predators of other anurans (Duellman and Trueb 1986). While all are known to eat frogs (A. Loveridge 1947; Wager 1965; Stewart 1967; Duellman 1978; Cei 1980), there is little detailed information on their feeding habits, and the relative importance of anurans in the diet is unknown. *Cacophrys, Ceratophrys* and *Lepidobatrachus* all have very wide mouths and appear to be morphologically specialized for eating large prey, including frogs (Scott and Aquino 2005). Other species that eat anurans at least occasionally include *Bufo marinus* (Jaeger 1976; Tyler 1976), *Leptodactylus chaquensis* (Duré 1999), *L. laticeps* (Scott and Aquino 2005), *L. pentadactylus* (Ryan, Tuttle, and Taft 1981), *L. labyrinthicus* (Vaz-Silva, Silva, and da Silva 2003c), *L. ocellatus* (Gallardo 1964; Kokubum and Rodrigues 2005), and *Trachycephalus venulosus* (Dundee and Liner 1985).

Predation by Turtles

Many freshwater turtles that are carnivores or omnivores prey on amphibians, especially tadpoles. There are at least 21 species of North American turtles that feed on amphibians (Ernst, Barbour, and Lovich 1994). These represent about 44% of turtle species associated with freshwater habitats (excluding marine turtles and herbivorous tortoises). Several species are too poorly studied for their food habits to be known. Turtles that eat at least some amphibians include snapping turtles (Chelydridae), mud turtles (*Kinosternon*), musk turtles (*Sternotherus*), soft-shelled turtles (*Apalone*), and emydid species such as wood turtles (*Clemmys insculpta*), box turtles (*Terrepene*), and pond turtles (*Clemmys, Chrysemys, Pseudemys, Trachemys, Deirochelys, Emydoidea*). Snapping turtles (*Chelydra serpentina*) even have been seen eating the eggs of spotted salamanders (*Ambystoma maculatum;* Spohr 2005). These turtles are frequently considered major predators of frogs and sometimes can have a significant impact on a local population. R. Howard (1978a) reported that large male bullfrogs (*Rana catesbeiana*) were particularly vulnerable to snapping turtle predation when calling in their territories. Ninety-five percent of snapping turtles captured in Florida had eaten tadpoles (Punzo 1975), but amphibians were a minor component of snapping turtle diets in other areas (M. Alexander 1943; Lagler 1943). Amphibians generally make up less than 10% of the diet of other carnivorous turtles, including *Clemmys marmorata* and several species of *Kinosternon* (Mahmoud 1968; Hulse 1974; Punzo 1974; Bury 1986).

Europe has only two genera of freshwater turtles, *Emys* and *Mauremys,* both of which eat amphibians, especially tadpoles (Ernst and Barbour 1989a; Kuzmin 1999). In Spain, *Mauremys leprosa* is largely herbivorous, and less inclined to eat tadpoles than is the more carnivorous *Emys orbicularis* (Gomez-Mestre and Keller 2003). The genus *Mauremys* also occurs in Southeast Asia and Japan, and several species include amphibians in a varied diet. A number of other Asian pond turtles (*Chinemys, Hardella*) also eat some amphibians, as do Asiatic softshell turtles (*Amyda, Lissemys*), but there is little quantitative information on the importance of amphibians in their diet. Australia has only one family of freshwater turtles, the family Chelidae, found in both temperate and tropical regions. Several genera of these side-necked turtles are omnivorous and may include amphibians in their diet. These include the snake-necked turtles (*Chelodina*), the Australian snapping turtles (*Elseya*), and several species in the genus *Emydura* (Worrell 1963; Ernst and Barbour 1989a; Legler and Georges 1993).

Relatively little is known about predation on amphibians by tropical turtles. Central American turtles are members of families or genera also found in North America, and several of these eat frogs and tadpoles in a varied diet of vertebrate and invertebrate prey (e.g., *Chelydra, Kinosternon, Claudius, Staurotypus* (Vogt and Guzman 1988; Ernst and Barbour 1989a; J. Lee 1996; J. Campbell 1998). In the community of turtles studied by Vogt and Guzman (1988) in southern Mexico, both *Kinosternon leucostomum* and *Staurotypus triporcatus* ate tadpoles, but tadpoles made up only a small portion of the diet. I observed an unidentified turtle feeding on an aggregation of *Leptodactylus insularum* tadpoles in Panama (unpublished observations). *Kinosternon* has a distribution extending into South America, where these turtles probably eat tadpoles. Most of the freshwater turtles of South America are side-necked turtles (families Chelidae and Pelomedusidae). Several genera feed on amphibians as part of a carnivorous or omnivorous diet, including *Pelmomedusa, Pelusios,* and *Podocnemis* (Pelomedusidae) and *Hydromedusa, Phrynops,* and *Platemys* (Chelidae; Ernst and Barbour 1989a). In one species, *Phrynops geoffroanus,* amphibians made up less than 1% of the diet (Fachin Teran, Vogt, and de Fatima Soares Gomez 1995).

Wager (1965) saw turtles feeding on aggregations of toad tadpoles (*Schismaderma carens*) in southern Africa. Hatchlings of side-necked turtles (*Pelomedusa subrufa*) were important predators on several species of tadpoles in temporary ponds on a West African savanna (Rödel 1999; Grafe et al. 2004). Benthic tadpoles that spend most of their time on the bottom of a pond were most vulnerable. These include tadpoles of *Hemisus marmoratus* (Hemisotidae), *Hyperolius nitidulus* (Hyperoliidae), and *Ptychadena maccarthyensis* (Ranidae). Tadpoles that inhabit the water column were less vulnerable, except when drying of ponds crowded tadpoles together. African softshell turtles (*Trionyx, Cycloderma*) also include amphibians in a varied carnivorous diet (Ernst and Barbour 1989a).

Predation by Crocodilians

Some juvenile crocodilians prey on amphibians, but adult crocodilians seldom do so, probably because amphibians are too small to be profitable prey for such large animals. Anurans were eaten by Nile crocodiles (*Crocodylus niloticus*) in their first three to four years of life, but never by individuals more than 2.5 m long (Cott 1961). A few remains of small frogs were found in stomachs of adult dwarf crocodiles (*Osteolaemus tetraspis osborni*) collected in a market in the Congo, but the precise habitat where these animals had fed was not known (Riley and Huchzermeyer 2000). Juveniles of both the American crocodile (*C. acutus*) and Morelet's crocodile (*C. moreletti*) sometimes eat some frogs (J. Lee 1996; J. A. Campbell 1998). In Australia, juvenile *C. johnstoni* sometimes ate frogs, but they were only about 2% of the diet (Webb, Manolis, and Buckworth 1982). In contrast, 66% of the prey taken by *Caiman crocodilus* during the wet season in Venezuela were frogs (Gorzula 1978). These were captured in shallow water along the shores of temporary savanna lagoons. In a study of Amazonian crocodilian diets, Magnusson, Vieira da Silva, and Lima (1987) found no evidence of predation on anurans by *Caiman crocodilus, Melanosuchus niger,* or *Paleosuchus palpebrosus,* but they were eaten by juvenile *Paleosuchus trigonatus.* American alligators (*Alligator mississippiensis*) seldom eat frogs, even when they are abundant (Valentine et al. 1972), but they sometimes eat large amphibians such as *Siren lacertina* (Delany and Abercrombie 1986).

Predation by Lizards

Lizards probably are the least significant reptilian predators of amphibians. Most small lizards are insectivorous, while many larger species tend to be herbivorous (Pough 1973). Furthermore, lizards usually are diurnal and often live in relatively dry habitats, whereas amphibians are mainly nocturnal and prefer moist habitats. Nevertheless, a few carnivorous species do eat amphibians occasionally. Wager (1965) reported that frogs are a major food of young monitor lizards (*Varanus*) in South Africa. Several Australian and African species of *Varanus* sometimes eat frogs, but they usually are less than 5% of the diet (King and Green 1979; Shine 1986a; D. Bennett 2002). The same is true for the Bengal monitor (*V. bengalensis*), a largely insectivorous lizard that lives in relatively dry habitats. This species is known to eat nearly 20 species of frog and toads, but anurans comprise less than 1% of its prey (Auffenberg 1994). Another species of monitor lizard (*V. flavescens*) that lives mostly in marshy habitats in India does feed heavily on frogs and toads, with 40% of all identified prey items being anurans (Auffenberg et al. 1989). This species also eats anuran egg masses, a type of food not reported for any other species. *Varanus griseus* feeds occasionally on frogs (*Rana ridibunda*) and toads (*Bufo viridis;* Kuzmin 1999). Other lizards that live near water may take an occasional frog. For example, there are reports of ranid frogs in the diets of *Basiliscus* from Costa Rica (Fleet and Fitch 1974; Cover 1986). Australian water skinks (*Eulamprus quoyii*) have been observed eating both tadpoles and juveniles of the hylid frog *Litoria aurea* (Pyke and Miehs 2001). The large teid lizard *Tupinambis texuixin* lives in a variety of habitats and takes frogs occasionally (J. Murphy 1997). There even are anecdotal reports of small frogs (*Eleutherodactylus*) being eaten by lizards that normally are strictly insectivorous, including *Ameiva exsul, Anolis gundlachi, Anolis cristatellus,* and *Sphaerodactylus klauberi* (Stewart and Woolbright 1996; R. Thomas and Kessler 1996), but these predators probably have little impact on anuran populations. The Eurasian anguid lizard *Ophisaurus apodus* feeds occasionally on toads (Kuzmin 1999).

Predation by Snakes

In contrast to lizards, snakes are major predators of amphibians; in some areas, they may be more important than any other animals (fig. 14.4). Some snakes are generalist predators, but others have narrow food preferences and have evolved morphological adaptations for eating certain kinds of prey (H. Greene 1983, 1997; Pough and Groves 1983; Savitsky 1983; Mushinsky 1987). Many species in both temperate and tropical regions feed primarily on amphibians, particularly frogs. Nearly 50% of the more than 100 species of snakes in the United States and Canada eat some amphibians (Wright and Wright 1957). Only two or three species of European snakes regularly feed on amphibians (less than 10% of the total snake fauna; Steward 1971; Diesener and Reichholf, 1986). This low number probably is related in part to the low diversity of frogs in Europe. Arnold (1972) found that the number of anuran-eating snakes in the Northern Hemisphere is strongly dependent on the number of anuran species. The scarcity of frog-eating snakes in Europe probably also is related to the low diversity of colubrid snakes in the subfamily Natricinae, the principal clade of frog-eating snakes in the Northern Hemisphere (Greene 1997). Natricines are much more common in Asia and often live near water, where frogs are readily available. Pope (1935) listed 28 species of Chinese snakes that eat frogs, the largest number of species to feed on any type of prey, but not all were anuran specialists. This represents about 25% of the Chinese snake fauna known at that time. In neighboring Japan, 13 of 28 species (46%) feed on amphibians, but none is an amphibian specialist (Mori and Moriguchi 1988). Many of these are natricines, although colubrines and some viperids also eat frogs. Frogs are more abundant in the tropics than in temperate regions, and most tropical areas with high anuran diversity have many species of frog-eating snakes (Barbault 1977, 1987, 1991; Duellman 1978; Vitt 1983, 1987; Vitt and Vangilder 1983; Greene 1988; Cadle and

Greene 1993; Luiselli, Akani, and Capizzi 1998; Luiselli 2003; see the following further discussion of specific regions).

Primitive Snakes

Phylogenetic history often is an important determinant of diet in snakes. Among the primitive snake families, small species feed mainly on invertebrates, whereas large species eat a variety of vertebrate prey. Snakes in the families Uropeltidae and Xenopeltidae are entirely tropical in distribution and apparently feed mainly on elongate vertebrates, including caecilians. Remains of caecilians have been found in stomachs of a South American species, *Anilius scytale,* and an Asian species, *Cylindrophus rufus* (Greene 1983). There also are field observations of *C. rufus* feeding on caecilians of the genus *Ichthyophis* (Kupfer, Gower, and Himstedt 2003). Some dwarf boas (family Tropidophiidae) eat anurans, mainly frogs of the genus *Eleutherodactylus* (Greene 1983; Henderson and Crother 1989). *Exiliboa placata,* an inhabitant of cloud forests in southern Mexico, apparently feeds exclusively on frogs and salamanders (Campbell and Camarillo 1992). Most members of the family Boidae eat birds and mammals, but the Puerto Rican boa (*Epicrates inornatus*) and other species of *Epicrates* sometimes eat frogs (Reagan 1984; J. Murphy 1997). Most West Indian boids probably take anurans occasionally (Henderson and Powell 1999).

Colubrid Snakes

The largest family of snakes is the family Colubridae, a group with a worldwide distribution. Colubrids eat almost every available type of prey, including insects, earthworms, slugs, snails, fish, tadpoles, frogs, salamanders, lizards, snakes, birds, and mammals. Variation in diet tends to reflect both phylogenetic history and local abundance of prey. The habit of feeding on small ectothermic vertebrates, such as lizards and frogs, as part of a more generalized diet, is widespread in the family and may represent an ancestral type of diet for at least some clades. A few clades within the family, especially in the Neotropics, include species that tend to specialize on eating frogs (Greene 1988; Cadle and Greene 1993).

Most North American colubrids are members of the subfamily Colubrinae, a large, worldwide assemblage of species that probably is not a monophyletic group. Many colubrines are generalist predators that eat a variety of prey, including amphibians. A good example is the black racer (*Coluber constrictor*), which preys on anurans, reptiles, birds, mammals, and insects. In southern Illinois, anurans accounted for 8% of their annual diet, but up to 22% in midsummer (Klimstra 1959c). Frogs were of minor importance in most parts of Kansas, but in one area where *Rana pipiens* was abundant, frogs made up nearly 13% of the diet (Fitch 1963). Other North American and Eurasian colubrines that sometimes eat amphibians include indigo snakes (*Drymarchon*), North American rat snakes and Eurasian racers (*Elaphe*), coachwhip snakes (*Mastocophis*) Asian banded ratsnakes (*Ptyas*), milk snakes and king snakes (*Lampropeltis*), green snakes (*Opheodrys*), and scarlet snakes (*Cemophora;* Wright and Wright 1957; Klimstra 1959b; Ernst and Barbour 1989b; Trauth and McAllister 1995; Greene 1997; Fitch 1999; Kuzmin 1999; Pauwels 2002; Ryberg and Dayton 2004).

Snakes in the subfamily Natricinae, which is sometimes considered to be a separate family, often are important amphibian predators, although diet tends to vary with local abundance of different prey species. For example, one population of European grass snakes (*Natrix natrix*) in England ate almost nothing but tadpoles, juveniles, and adults of the common toad (*Bufo bufo;* Reading and Davies 1996). Another population in the marshes of southeastern England fed primarily on the introduced frog *Rana ridibunda,* the most abundant anuran in the area (Gregory and Isaac 2004). In Sardinia, the same species fed mostly on *Hyla sarda* (Capula, Rugiero, and Luiselli 1994). In fact, this species feeds on many different species of amphibians throughout Europe and northern Asia (Luiselli and Rugiero 1991; Luiselli and Capula 1997; Kuzmin 1999). Other Eurasian members of this genus, especially *N. maura* and *N. tessellata,* also eat amphibians, as do Asian natricines such as *Amphiesma* and *Rhabdophis* (Santos and Llorente 1998; Kuzmin 1999).

Anurans make up about 90% of the adult diet of the North American water snake *Nerodia erythrogaster* (Diener 1957; Mushinsky and Hebrard 1977; Mushinsky, Hebrard, and Vodopich 1982). Small individuals eat mostly small fish, but shift to anurans as they grow (fig. 14.5). This shift is reflected in changes in preferences for chemical extracts of prey. Young snakes do not prefer one prey type to another, but develop a strong preference for frog extract at eight to nine months of age (Mushinsky and Lotz 1980). *Nerodia fasciata* and *N. sipedon* usually eat a mixture of amphibians and fish (R. Clark 1949; E. Brown 1958; Mushinsky and Hebrard 1977; Camp, Sprewell, and Powders 1980; Fitch 1999), with the former showing an ontogenetic shift from fish to anurans (Mushinsky and Lotz 1980; Mushinsky, Hebrard, and Vodopich 1982). *Nerodia sipedon* in particular is a generalist predator that tends to be quite variable in its dietary habits. Himes (2003) reported that in southern populations, small individuals ate mostly fish, frogs, and salamanders, whereas larger individuals ate mostly fish. E. Brown (1958) found that the proportion of anurans in the diet of *N. sipedon* varied from 17% along streams in New York to over 90% in Michigan bogs. Other North American water snakes, such as *N. taxispilota, N. cyclopion,* and *N. rhombifera,* are primarily fish-eaters and usually avoid amphibians (Mushinsky and Hebrard 1977; Kofron 1978; Camp, Sprewell, and Powders 1980; Manjarrez and Macias Garcia

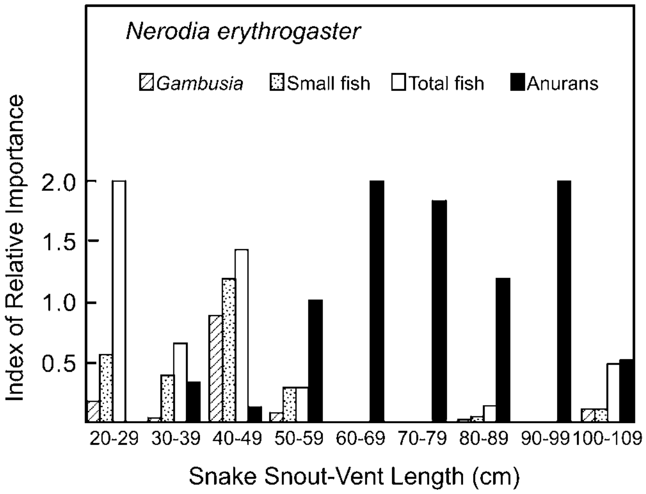

Fig. 14.5. Ontogenetic change in the diet of the water snake *Nerodia erythrogaster.* Juveniles eat mostly fish, whereas adults eat mostly frogs. After Mushinsky, Hebrard, and Vodopich (1982).

1991). Nevertheless, anurans were 66% of the prey eaten by *N. cyclopion* in Florida (Van Hyning 1932) and 45% of the prey of *N. rhombifera* in Texas (Bowers 1966).

Many species of garter snakes (*Thamnophis*) prey on amphibians (Rossman, Ford, and Seigel 1996; table 14.3), and some species may depend on amphibians as their principal food. For example, *Thamnophis elegans* in the Sierra Nevada of California feed mostly on anurans, and are not found in areas from which amphibians have disappeared (W. Jennings, Bradford, and Johnson 1992). Tadpoles and metamorphosing anurans tend to be the most common prey, but some garter snakes prey on larval and adult salamanders as well (Dowdey and Brodie 1989; Lind and Welsh 1990; Murray and Jenkins 1999; Painter, Scott, and Altenbach 1999). Geographic variation in diet often reflects local differences in prey abundance. In California, *T. sirtalis* ate mostly anurans and was most common where these were abundant (Kephart 1982). *Thamnophis elegans* ate a mixture of fish, amphibians, and leeches, but ate mostly anurans at sites where they were abundant. *Thamnophis validus,* from upland regions of Baja California, ate only anurans and tadpoles, whereas those from mainland Mexico ate mostly fish as adults, but fed on amphibians as juveniles (De Queiroz, Henke, and Smith 2001). This ontogenetic shift in diet from anurans to fish is the opposite of that seen in many other natricines, and may reflect a shortage of small fish that would be suitable prey for young snakes.

Even very localized differences in prey abundance can affect prey choice. Two species of *Thamnophis* captured in a marsh in California ate mostly frogs, whereas those captured in a nearby stream ate mostly fish (M. White and Kolb 1974; fig. 14.6). A Canadian population of *T. sirtalis* ate mostly larval and adult amphibians at a natural lake, but ate mostly fish in fish hatchery ponds (Gregory and Nelson 1991). Seasonal variation can be important as well. Garter snakes (*T. radix*) in Missouri fed mostly on earthworms in the spring and fall, but switched to feeding almost exclusively on frogs during the summer, when large numbers of metamorphosing juveniles were available (Rossman, Ford, and Seigel 1996). At a lake in California, metamorphosing *Bufo boreas* were the principal summer prey of *T. elegans,* but the snakes shifted to feeding on fish and leeches in years when toad reproduction failed because of dry conditions (Kephart and Arnold 1982; fig. 14.7).

S. Arnold (1981c) suggested that predation on frogs and fish in riparian habitats represents the ancestral condition for all natricine snakes. Some species have subsequently diverged to specialize on other prey, including slugs and earthworms. A genetic basis for variation in slug-feeding tendencies has been demonstrated in populations of *T. elegans,* with marked geographic differentiation between slug-eating coastal populations and slug-avoiding inland populations (Arnold 1981a, b, c). There also is heritable genetic variation in responses to amphibian prey, but little geographic differentiation. Anuran tadpoles and juveniles elicit strong chemoreceptive and feeding responses from most populations of garter snakes, even in species that feed almost exclusively on earthworms (W. Fox 1952; Dix 1968; Burghardt 1969; Arnold 1978, 1981a). *Thamnophis elegans* also showed moderately strong chemosensory responses to plethodontid salamanders (Arnold 1981c), whereas Burghardt (1969, 1970) obtained weak responses to plethodontids from five species (*T. butleri, T. elegans, T. ordinoides, T. radix,* and *T. sirtalis*). *Thamnophis sirtalis* from the mountains of Virginia and Kentucky apparently feed more frequently on salamanders than on frogs (Uhler, Cottam, and Clarke 1939; Barbour 1950). Their chemosensory responses to salamanders would be worth investigating. Other small natricine snakes (*Virginia* and *Storeria*) have evolved more terrestrial habits. They feed mostly on soft-bodied invertebrates, but sometimes take small frogs, salamanders, and amphibian eggs as well (Wright and Wright 1957; Ernst and Barbour 1989b).

The desert night snake (*Hypsiglena torquata*) of the southwestern United States is a member of the subfamily Dipsadinae, which is largely a Central American clade (sometimes referred to as "Central American Xenodontines"). Although it feeds mostly on lizards, this species also feeds on both anurans (*Bufo, Pseudacris, Scaphiopus*) and salamanders (*Batrachoseps;* Rodriguez-Robles, Mulcahy, and Greene 1999). This snake is closely related to a group of Neotropical snakes that mostly eat frogs. Also in the same subfamily are snakes of the genus *Radinaea,* which eat frogs, salamanders, and their eggs, as well as lizards (Myers 1974). Most species are found from Mexico to northern South America, but one

[a] Percentage of prey volume.

[b] Percentage of stomachs containing prey item.

species occurs in the southeastern United States (*R. flavilata*) and is known to eat *Acris, Hyla,* and other frogs (Myers 1967). Several other North American snakes that sometimes eat amphibians appear to be related to Neotropical lineages in which frog eating is common, but their precise phylogenetic relationships are unclear (Greene 1997). These include ring-necked snakes (*Diadophis punctatus*), which often feed on small plethodontid salamanders (Uhler, Cottam, and Clarke 1939; Barbour 1950; Fitch 1975; Blanchard, Gilreath, and Blanchard 1979; Cupp 1994; Lancaster and Wise 1996) and small frogs (Myers 1965). There even is one report of this snake feeding on the eggs of a plethodontid sala-

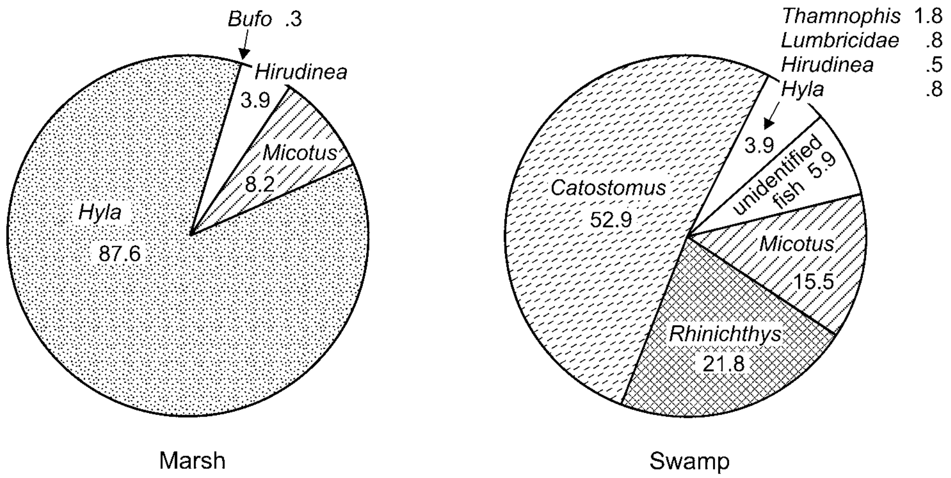

Fig. 14.6. Comparison of proportions of prey in the stomachs of garter snakes from adjacent marsh and stream habitats in California. Garter snakes (mostly *Thamnophis sirtalis*) from a marsh habitat ate mostly frogs (*Pseudacris regilla*), whereas *T. sirtalis* and *T. elegans* from a stream habitat ate mostly fish (*Catostomus* and *Rhinichthys*), but took some frogs as well. After White and Kolb (1974).

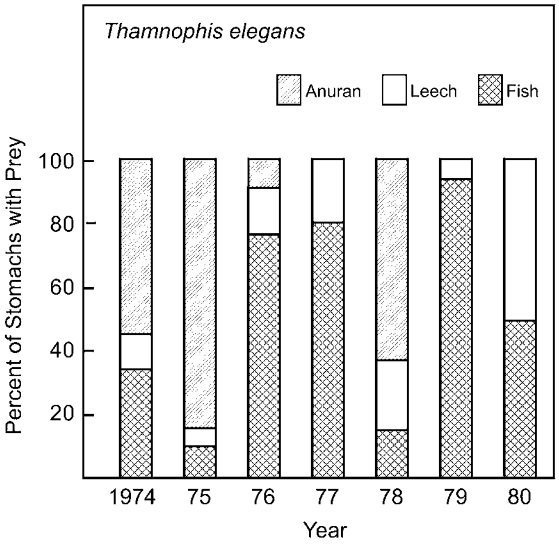

Fig. 14.7. Annual variation in proportion of major prey items in stomachs of garter snakes from a pond in California. In years when anurans (*Bufo boreas*) were scarce (1977, 1979, 1980), the snakes switched to eating mostly fish. After Kephart and Arnold (1982).

mander, *Plethodon albagula* (Milanovich, Trauth, and Mary 2005). Another is the mud snake (*Farancia abacura*), which specializes on amphiumas, sirens, and other aquatic salamanders (Wright and Wright 1957; Ernst and Barbour 1989b).

North American hognose snakes (*Heterodon*) generally are considered to be amphibian specialists (fig. 14.4 B). Many textbooks state that hognose snakes subsist almost entirely on toads. In some areas this is true, with over 95% of the diet being composed of toads (Edgren 1955; Platt 1969). However, hognose snakes do vary their diets in response to changes in prey abundance. For example, at one site in Kansas where toads were scarce but *Rana pipiens* was common, 66% of prey items in stomachs of *H. platyrhinos* were frogs, 28% were toads, and 3% were salamanders (*Ambystoma tigrinum;* Platt 1969). The western hognose snake (*H. nasicus*) is less of a toad specialist than the eastern species, and eats substantial numbers of lizards and some small mammals (Platt 1969). The tropical analogs to hognose snakes are the genera *Xenodon* and *Waglerophis,* which specialize on toads and other large-bodied anurans (Duellman 1978; Vitt 1983; Martins, Sazima, and Egler 1993; Greene 1997). They belong to a largely South American clade (the subfamily Xenodontinae). They resemble hognose snakes morphologically (H. M. Smith and White 1955; Kardong 1979), either because of common ancestry or convergent evolution on a common prey type (Cadle 1984, 1987). These snakes also resemble poisonous pit vipers in morphology and color pattern and may be Batesian mimics of these dangerous snakes (Greene 1997).

Other Neotropical colubrids that frequently prey on anurans include nocturnal tree snakes such as *Imantodes, Leptodeira,* and *Thamnodynastes,* which often capture frogs in bushes and trees near breeding ponds (Duellman 1958, 1963, 1978; Test, Sexton, and Heatwole 1966; Kluge 1981; Vitt and Vangilder 1983; Vitt 1996). *Leptodeira* also eats the arboreal eggs of *Agalychnis, Phyllomedusa* and other frogs (Warkentin 1995; Greene, 1997). The first two genera are members of the "Central American Xenodontine" clade (subfamily Dipsadinae), whereas *Thamnodynastes* belongs to the "South American Xenodontine" clade (subfamily Xenodontinae; Cadle and Greene 1993). Despite their names, both of these clades are widely distributed throughout Central and South America, and the Central American clade extends into Mexico and the United States.

Some diurnal colubrine tree and vine snakes, including *Oxybelis, Xenobelis,* and *Leptophis,* also prey on frogs, usually seeking them out in diurnal retreat sites (Duellman 1963, 1978; Henderson, Nickerson, and Hoevers 1977; Lopez, Giraudo, and Arzmendia 2003; Muniz and Silva 2005). Terrestrial Neotropical snakes that feed mainly on anurans or their eggs include *Chironius, Dendrophidion, Drymobius, Simophis* (Colubrinae), *Coniophanes, Pliocercus, Rhadinaea, Urotheca* (Dipsadinae), *Liophis,* and *Lystrophis* (Xenodontinae; Duellman 1963, 1978; Myers 1974; Henderson and Hoevers 1977; Vitt 1983; Seib 1984, 1985; Greene 1988; Michaud and Dixon 1989; Sazima et al. 1992; Cadle and Greene 1993; Martins et al. 1993; Bizerra et al. 1994; Mendes Castanho 1996; Cassimiro and Bertoluci 2003; Da Silva, França e Souza, Vaz Silva, and Rodrigues Silva 2003; M. Lopez, Giraudo, and Arzmendia et al. 2003; Solé and Kwet 2003; Manzanilla et al. 2005). A number of other genera include frogs as at least a minor part of their diets, including *Drymoluber, Mastigodryas, Scaphiodontophis* (Colubrinae), *Amastridium, Nothopsis* (Dipsadinae), *Oxyrhophus, Helicops, Hydronastes, Philodryas, Tropidodryas* (Xenodontinae), and *Sordellina* (lineage uncertain; Cadle and Greene 1993; Da Silva et al. 2003a; M. Lopez 2003; Hartmann and Marques 2005; Menin 2005). Nearly all of the genera that have amphibians as a minor component of the diet feed mostly on other ectotherms, especially lizards and sometimes fish.

In the West Indies, lizards (*Anolis*) and frogs (*Eleutherodactylus*) are the most abundant vertebrate prey for snakes, and as in some South and Central American snake communities, there is an association between predation on lizards and predation on frogs (Henderson and Sajdak 1996; Henderson and Powell 1999). Lizards make up about 75% of the prey of West Indian colubrids, frogs about 21% (Henderson 1984; Henderson and Crother 1989; Henderson and Sajdak 1996). *Alsophis, Chironius, Darlingtonia, Ialtris, Liophis, Mastigodryas,* and *Uromacer* eat frogs, but there are surprisingly few frog specialists. However, on Hispaniola, *Darlingtonia haetina* feeds almost exclusively on *Eleutherodactylus* (Henderson and Schwartz 1986), and *Chironius* is a frog specialist as well (Henderson and Powell 1999). *Uromacer catesbyi* feeds primarily on the hylid frog *Osteopilus dominicensis* (70% of diet), but eats *Anolis* as well (Henderson, Schwartz, and Noeske-Hallin 1987; Henderson et al. 1988). The most widespread genus of colubrid snakes in the West Indies is the genus *Alsophis.* Species throughout the range of this genus feed mainly on *Anolis* lizards, with frogs generally being the second most abundant type of prey (Henderson and Sajdak 1996). The low number of snake species that feed mostly on frogs may be due in part to the distribution of frogs and snakes. *Eleutherodactylus* are most abundant at mid-elevations, whereas snake diversity peaks at lower elevations (Henderson and Crother 1989).

Diets of colubrid snakes in the Old World Tropics are not as well known as those in the New World, but there are many species that eat substantial numbers of anurans. Colubrine and natricine colubrids are found in both the temperate and tropical parts of Asia, and as previously mentioned, a number of species, especially natricines, eat frogs found in rice paddies and natural ponds, or along streams. Some colubrines, such as the mangrove tree snake (*Boiga dendrophila*) include frogs in a varied diet of vertebrate prey (Greene 1997). Several other subfamilies of colubrids are found mostly in southern and Southeast Asia, the Indonesian Archipelago, and northern Australia. These include homolopsine water snakes. These are mostly fish eaters, but some species also eat frogs, tadpoles, and even frog eggs. A study of one species, *Enhydris plumbea,* in rice paddies in Borneo revealed that frogs were the most common prey (Voris and Karns 1996). Also found in Southeast Asia is the small subfamily Xenoderminae, which includes the Javan mudsnake (*Xenodermis javanicus*), a fossorial species that feeds on frogs (Greene 1997).

Many African colubrids also feed on anurans, but the diets of most African snakes have not been studied in detail. A study of the amphibian and reptile community of the Lamto Savanna in West Africa showed that more than a third of the snake species fed mostly on frogs, especially during wet season, when frogs were breeding (Barbault 1974b, 1977). These snakes were sufficiently abundant to have a major impact on anuran populations (Barbault 1987, 1991). Most of the frog-eating snakes were colubrids, but some pythons, vipers, and elapids fed on frogs as well. Frog-eating colubrids included representatives of several distinct clades, including colubrines (*Chlorophis, Philothamnus, Gonionotophis, Dromophis, Crotaphopeltis*), natricines (*Natriceteres*), and psammophiines (*Rhamphiophis*), found in a variety of habitats (terrestrial, arboreal, fossorial). In an assemblage of snakes in a swamp rainforest in Nigeria, there are three semiaquatic genera of colubrids (*Afronatrix, Grayia, Natriciteres*) that eat mostly frogs, a terrestrial snake (*Crotaphytopeltis*) that eats some toads, and two species of filesnakes (*Mehelya*) that eat juvenile toads (Luiselli, Akani, and Capizzi 1998; Akani and Luiselli 2001). Toads also have been found in the stomachs of several species of *Mehelya* from southern Africa, and in two species of a closely related genus, *Gonionotophis* (Shine et al. 1996).

Viperid Snakes

Most viperid snakes are adapted for feeding on birds and mammals as adults (Pough and Groves 1983), but their broad heads and large gapes make them well suited for preying on large-bodied amphibians as well. Juvenile viperids often feed on ectothermic prey, including invertebrates, lizards, and frogs. As adults, they usually switch to mostly endothermic prey (Sexton 1956–57; Dixon and Soini 1986; Mushinsky 1987; Sazima 1992; H. Greene 1997; Daltry, Wuster, and Thorpe 1998; Nogueira, Sawaya, and Martins 2003). Juveniles often have conspicuous yellow or pink tips on their tails that are used as lures to attract frogs or lizards (W. Neill 1960; Greene and Campbell 1972; Heatwole and Davison 1976; Schuett 1984; Carpenter and Gillingham 1990; Sazima 1991, 1992; Greene 1992; J. Murphy 1997).

The North American cottonmouth (*Agkistrodon piscivorus*) preys mainly on ectothermic vertebrates, and amphibians often are a major component of the diet. In Kentucky, sirens and ranid frogs made up 75% of the diet (Barbour 1956). In southern Illinois, amphibians were about 26% of the diet, but up to 40% in midsummer (Klimstra 1959a). Amphibians made up 20–30% of the food in stomachs of cottonmouths from several southern states (Burkett 1966; Himes 2003, 2004). Copperheads (*A. contortrix*) are found in drier habitats, but they sometimes eat frogs, especially when young (Ernst and Barbour 1989b; Fitch 1999). Bullfrogs exhibit limited resistance to copperhead venom, and greater resistance to copperhead than to cottonmouth venom, probably due to the greater toxicity of the latter (Heatwole, Poran, and King 1999). It is not known, however, whether this resistance is sufficient to allow frogs to escape predation after being struck by one of these snakes. Some Asian crotaline pitvipers, especially *Gloydius* and *Trimeresurus,* feed mostly on frogs (Pope 1935; Mao 1970; Mori and Moriguchi 1988; Kuzmin 1999). Another crotaline, the Malayan pitviper (*Calloselasma rhodostoma*), has a varied diet of mammals, birds, lizards, frogs, and invertebrates, with frogs being eaten most frequently by small individuals in most populations (Daltry, Wuster, and Thorpe 1998). In Java, frogs made up about 63% of the prey of small individuals, whereas mammals made up 75% of the prey of large snakes. Many Neotropical viperids, such as *Bothrops, Botriechis,* and *Porthidium,* feed on anurans at least occasionally, with frogs being most important for juvenile snakes (Sexton 1956–57; Duellman 1978; J. Campbell and Solorzano 1992; McCoy and Censky 1992; Sazima 1992; Martins and Gordo 1993; Greene 1997; J. Murphy 1997; Nogueira, Sawaya, and Martins 2003). Several rattlesnakes eat frogs occasionally, but they probably are important prey only for *Sistrurus,* which are frequently found in bogs and swamps (Wright and Wright 1957; Klauber 1972; Ernst 1992). Frogs were the most important prey of a population of *Sistrurus miliarius* in Florida (Roth, May, and Farrell 1999), but *Sistrurus catenatus* in a drier habitat in Wisconsin did not eat frogs (Keenlyne and Beer 1973). The Florida snakes were attracted to chemical cues from frogs in field experiments.

Predation on amphibians by most Old World viperine snakes is not well documented. Most species appear to feed primarily on endothermic prey, but there are exceptions. The African night adders (*Causus*) feed mainly on anurans (Barbault 1974b; Greene 1992, 1997; Luiselli et al. 2004), and anurans are a minor component of the diet of the puff adder (*Bitis arietans;* Barbault 1974b). Both juvenile and adult Eurasian vipers (*Vipera aspis, V. berus, V. lebetina,* and *V. ursinii*) feed on anurans (Saint Girons 1980; Monney 1993; Kuzmin 1999). Asian saw-scaled vipers (*Echis carinatus*) also prey on frogs (*Rana ridibunda*) and toads (*Bufo viridis;* Kuzmin 1999).

Elapid and Atractaspid Snakes

In Australia, the snake fauna is dominated by poisonous elapids, and these have radiated into most of the niches occupied by colubrids and viperids on other continents. Since much of Australia is arid, lizards are the predominant prey of many species, but frogs often are the next most important prey (table 14.4). *Denisonia devisi, D. maculata, Hemiaspis dameli, Notechis scutatus,* and *Pseudechis porphyriacus* are

Table 14.4 The importance of frogs in the diets of some Australian elapid snakes

Species (source no.)	Total prey (%)	Frogs (%)	Other major prey
Acanthophis antarcticus (4)	34	6	Lizards, mammals
Austrelaps labialis (10)	53	17	Lizards
A. ramsayi (10)	59	17	Lizards
A. superbus (10)	98	34	Lizards
A. superbus (1)	43	61	Lizards
Caciogus squamulosus (3)	69	6	Lizards
Demansia atra (2)	22	27	Lizards
D. psammophis (2)	75	7	Lizards
D. devisi (8)	42	88	Lizards
D. maculata (8)	18	95	
Drysdalia coronata (5)	32	53	Lizards
Ecliopsis curta (6)	54	31	Lizards
Elapognathus minor (9)	6	66	Lizards
Hemiapsis damelii (11)	21	95	
H. signata (11)	105	23	Lizards
Notechis scutatus (1)	90	92	Nestling birds
Pseudechis porphyriacus (1)	296	83	Lizards
Pseudonaja textilis (1)	32	6	Lizards, mice
Tropidechis carinatus (7)	27	41	Mammals

Notes: Numbers show percentage of total prey items in stomachs. Most data are from preserved museum specimens except data from Shine (1977), which are from freshly collected specimens.

primarily frog predators. However, diets vary with changes in prey availability. For example, *Notechis scutatus* preys on both frogs and lizards at several mainland sites, but feeds mainly on small mammals, nestling birds, and lizards on offshore islands where frogs are scarce (Shine 1987a).

Some elapid snakes in other parts of the world eat amphibians as well. In a savanna community in West Africa, African gartersnakes (*Elapsoidea sundevalli*) fed exclusively on frogs, and frogs were a minor item in the diet of cobras (*Naja nigricollis;* Barbault 1974b). Both *Naja nigricollis* and *N. melanoleuca* in Nigeria included frogs in a varied diet of vertebrates in both swamp forest habitat and in human-inhabited areas (Luiselli, Akani, and Capizzi 1998; Luiselli, Angelici, and Akani 2002). In some parts of central Asia, anurans are important prey of another cobra, *N. oxiana* (Kuzmin 1999). Other Old World elapids that eat some frogs and toads include desert blacksnakes (*Walterinessia*) of the Middle East and tropical Asian kraits (*Bungarus;* Greene 1997). Most New World coral snakes (*Micruroides, Micrurus*) are predators on elongate vertebrates, especially snakes, lizards, and amphisbaenas. They apparently do not eat amphibians very frequently (Greene 1984, 1997), but the diets of most species are not well studied.

Venomous snakes in the genus *Atractaspis* are closely related to elapids, but are generally placed in a separate family. These are burrowing snakes that feed mostly on other elongate, fossorial vertebrates, including snakes and amphisbaenians, as well as small mammals such as shrews and rodents. There is one report of *Atractaspis aterrima* from Tanzania having consumed a caecilian (*Scolecomorphus kirkii*), but it is not known whether caecilians are an important component of the diet (Gower et al. 2004).

Predation by Birds

Hundreds of species of birds are potential predators of amphibians, but it would be impossible to enumerate all of these without a major survey of the ornithological literature (for lists of avian predators and bibliographies, see Kabisch and Belter 1968; Cook 1987; Shea 1987; Ross 1989; J. Martín and López 1990; Kuzmin 1999). In Europe, more than 90 species of birds have been reported to eat frogs, eggs, and tadpoles (Kabisch and Belter 1968; J. Martín and López 1990). At least 30 species of Australian birds are known to eat frogs or tadpoles, but this probably is an underestimate for this region (Shea 1987). On Barro Colorado Island in Panama, a relatively small area of tropical forest, 16 species of birds were found to have eaten frogs (all members of the genus *Eleutherodactylus*), but generally these were incidental items in diets composed mostly of insects (Poulin et al. 2001).

Birds in at least 15 nonpasserine orders prey on amphibians. These include cassowaries (Casuariiformes), loons (Gaviiformes), grebes (Podicipediformes), cormorants and darters (Pelicaniformes), herons, egrets, bitterns, ibis, storks, and spoonbills (Ciconiiformes), ducks (Anseriformes), sandpipers, gulls, and terns (Charadriiformes), cranes, rails, coots, and bustards (Gruiformes), quails, pheasants, and turkeys (Galliformes), kingfishers, kookaburras, rollers, bee-eaters, motmots, and todies (Coraciiformes), woodpeckers, barbets and puffbirds (Piciformes), cuckoos (Cuculiformes), frogmouths (Caprimulgiformes), hawks, kites, and eagles (Falconiformes), and owls (Strigiformes; Kabisch and Belter 1968; Perrins and Middleton 1985; W. Cook 1987; Shea 1987; J. Martín and López 1990).

Many families of passerine birds (order Passeriformes) include species that sometimes eat amphibians: Atrichornithidae (scrub-birds), Campephagidae (cuckoo-shrikes), Cinclidae (dippers), Corvidae (crows, ravens, jays, magpies), Cracticidae (Australian magpies, butcherbirds, and currawongs), Dendrocolaptidae (woodcreepers), Emberizidae (tanagers), Formicariidae (ant birds), Furnariidae (ovenbirds), Icteridae (American blackbirds), Laniidae (shrikes), Mimidae (catbirds and thrashers), Motacillidae (wagtails), Muscicapidae (thrushes), Orthonychidae (whipbirds), Paridae (tits), Paruliidae (wood warblers), Ploceidae (weavers), Sturnidae (starlings), Troglodytidae (wrens), Tyranidae (kingbirds, kiskadees, and tyrant flycatchers), and Vireonidae (vireos). For most of these groups, the importance of amphibians in the diet is unknown, as is their impact on amphibian populations. Groups of birds that are likely to be important predators of amphibians are summarized in the following.

Wading and Fishing Birds

Among the nonpasserine birds, herons, bitterns, and storks probably are major predators of amphibians. Hancock and Kushlan (1984) listed 60 species of herons and bitterns (family Ardeidae) around the world; at least 41 include amphibians in the diet. Amphibians are of minor importance for some species, but are a staple food for others. Jenni (1969) found that anurans were the principal prey of Little Blue Herons (*Florida caerulea*) in Florida, comprising 54% of the food delivered to nestlings. Frogs also were a significant part of the diet of cattle egrets (*Bubulcus ibis;* 32%), but were of minor importance for snowy egrets (*Leucophoyx thula;* 5%) and Louisiana herons (*Hydranassa tricolor;* 0.2%) living in the same area. The importance of amphibians in heron diets varies geographically within the same species, no doubt reflecting the habitats used by the birds and the availability of prey. For example, anurans comprised an average of 34% of the food delivered to cattle egret chicks at various sites in Florida (Jenni 1973), with some variation in the species taken most frequently. Cattle egrets in South Africa were much more insectivorous, with only 13% of the diet composed of amphibians (Siegfried 1971), but in another study in South Africa, frogs (juvenile *Pyxicephalus adspersus*) made up a large proportion of the diet (Kopij 2003). In the same region, frogs (*Rana* and *Xenopus*) were a major part of the diets of sacred ibis (*Threskiornis aethiopicus*) and African spoonbill (*Platalea alba*) chicks (Kopij, Kok, and Roos 1996; Kopij 1997).

Mukherjee (1969, 1971a, b, 1974) analyzed stomach contents of water birds from India and found that 12 of 16 species ate some amphibians. These included four species of herons, two egrets, a bittern, a stork, a grebe, a cormorant, an anhinga, and a coot. Amphibians made up 2–28% of the diets of these birds, with large ranid tadpoles being the principal amphibian prey. Amphibians were the most important prey of two species, the chestnut bittern (*Ixobrychus cinnamomeus;* 27% of the diet) and the night heron (*Nycticorax nycticorax;* 28%). In northern Italy, spadefoot toads (*Pelobates fuscus*) made up 24% of the diet of the same species of night heron during the spring breeding season and were important food for nestlings (Vasvari 1935/38; cited in Nöllert 1984). In the Ukraine, fire-bellied toads (*Bombina bombina*) accounted for up to 25% of the diet of night herons (Kuzmin 1999). Various other water birds feed on almost all species of European amphibians, with frogs comprising up to 40% of the diet in some herons (Vasvari 1927/28, 1929/30, 1935/38; Kabisch and Belter 1968; J. Martín and López 1990; Kuzmin 1999). In New Zealand, the Australian bittern (*Botaurus poiciloptilus*) and the White-faced heron (*Egretta novaehollandiae*) feed primarily on the introduced Australian treefrog, *Litoria aurea* (Hancock and Kushlan 1984). The hammerhead (*Scopus umbretta*), a wading bird of African savannas, frequently preys on frogs, including *Xenopus* that the birds captured while skimming along the surface of a lake (Wager 1965). This species also eats the schooling tadpoles of a toad, *Schismaderma carens.*

Amphibians probably are of minor importance in the diets of most nonciconiiform water birds. Mukherjee (1969, 1974) found that amphibians always made up less than 10% of the diet of aquatic birds such as coots, anhingas, cormorants, and grebes. The moorhen (*Gallinula chloropus*), a species of rail, preys on the eggs of *Rana temporaria,* sometimes eliminating most of the eggs from a pond (Savage 1961). Purple gallinules (*Porphyrula martinica*) fed on eggs of *Agalychnis spurelli* laid on vegetation over a pond in Costa Rica (N. Scott and Starrett 1974). *Agalychnis* tadpoles, which form large surface-feeding aggregations (see chapter 12), are preyed upon by green kingfishers (*Chloroceryle americana;* Wassersug 1971; N. Scott and Starrett 1974). Belted Kingfishers (*Megaceryle alcyon*) eat *Rana catesbeiana* tadpoles (Terres 1968), and the Australian azure kingfisher (*Alcedo azurea*) eats tadpoles of the myobatrachid frog *Mixophyes fasciolatus* (Bolitho and Retallick 1996). Gulls, terns, and sandpipers are occasional predators on frogs, tadpoles, and newts (Creutz 1963; Kabisch and Belter 1968; Schardier and Jackson 1982; Beebee 1983; Stangel 1983; J. Martín and López 1990; Sinsch 1998; M. Jones, Goetti, and Livo 1999).

Ducks and Swans

Several species of swans and ducks prey on tadpoles and small frogs, but in most cases, the importance of amphibians in the diet is unknown. Potential predators in the Northern Hemisphere include mute swans (*Cygnus olor*), mallard (*Anas platyrhynchos*), black duck (*A. rubripes*), gadwall (*A. strepera*), pintail (*A. acuta*), shoveler (*A. clypeata*), red-crested pochard (*Netta rufina*), pochard (*Aythya ferina*), widgeon (*Mareca penelope*), and several species of mergansers (*Mergus;* Kabisch and Belter 1968; Bellrose 1976; J. Martín and López 1990). Widgeon (*Mareca penelope*) prey on *Bufo calamita* in Britain (Beebee 1983), and mallard (*Anas platyrhynchos*) eat frogs, toads, tadpoles, and even spadefoot toad eggs (Kabisch and Belter 1968; Mueller 1980; Steiof and Tietje 1985; Mjelstad and Sactersdal 1989; Kwet 1996a; Sinsch 1998; Jones, Goetti, and Livo 1999; M. Hayes and Rombough 2004). R. Savage (1961) attributed a decline in populations of *Rana temporaria* in several ponds in Britain to mallard predation, but provided no direct evidence. Similarly, Martof (1956a) asserted that mallard and black ducks (*Anas rubripes*) "feed avidly on tadpoles and frogs and can easily deplete the frog populations of small ponds." The hooded merganser (*Mergus cucullatus*) is sometimes called the "frog duck" because of its propensity for preying on anurans (A. Wright 1920). Although mergansers eat mostly fish, they also feed on aggregations of hibernating leopard frogs (*Rana pipiens;* Breckenridge 1944).

Hawks, Kites, and Eagles

Various species of raptors feed on amphibians, but few rely on them as a major source of food. One exception is an Asian hawk, *Accipiter soloensis,* which feeds on frogs in rice fields and is sometimes called the grey frog hawk (L. Brown and Amadon 1968). Other raptors that sometimes eat frogs and toads include many species of *Accipter* and *Falco,* kites (*Chondrohierax, Elanoides, Elanus, Ictinia, Milvus*), harriers (*Circus*), eagles (*Aquila*), bald eagles (*Haliaeetus leucocephalus*), many hawks of the genus *Buteo,* and the black hawk (*Buteogallus anthracinus*), savanna hawk (*Heterospizias meridionalis*), and caracara (*Polyborus plancus*) of the Neotropics (L. Brown and Amadon 1968; Kabisch and Belter 1968; Ross 1989; Franca e Souza et al. 2003; Machado and Galdino 2005). Another Neotropical species, the crane hawk (*Geranospiza caerulescens*) has very long legs that it uses to extract tree frogs from leaf axils of bromeliads (Bokermann 1978). In Guatemala, frogs were a relatively minor part of the diet of this species (16% of prey items) and were eaten mainly in wet weather when the frogs are particularly active (Sutter et al. 2001).

The importance of amphibians in the diets of raptors varies considerably. In the Lamto Savanna of the Ivory Coast, a region with dense populations of anurans during the wet season (Barbault 1972), frogs formed only a small proportion of the diets of most raptors, with only the black kite (*Milvus migrans*) being a significant predator (Thiollay 1976). Tree frogs (*Hyla cinerea* and *H. squirella*) were the most frequent prey delivered to nestling swallow-tail kites (*Elanoides forficatus*) in Florida (N. Snyder 1974), and frogs also are eaten by hook-billed kites (*Chondrohierax uncinatus*), black-shouldered kites (*Elanus caeruleus*), and Mississippi kites (*Ictinia mississippiensis*) (D. Ross 1989).

North American red-shouldered hawks (*Buteo lineatus*) and broad-winged hawks (*B. platypterus*) take considerable numbers of amphibians, which may comprise more than 20% of the diet in spring and summer (S. Ernst 1945; R. Stewart 1949; Craighead and Craighead 1969; Mosher and Matray 1974; Rosenfield, Gratson, and Carson 1984; D. Ross 1989). Broad-winged hawks eat substantial numbers of toads (*Bufo americanus*), which generally are well protected by toxic skin secretions. In these species, and in other raptors, the importance of amphibians in the diet may be underestimated by analyses of regurgitated pellets. For example, in Massachusetts, anurans were only about 0.5% of the items identified in pellets of red-shouldered hawks, but nearly 20% of the prey carried to the nest (Portnoy and Dodge 1979). Estimates of numbers of anurans consumed by broad-winged hawks derived from direct observations also are higher than those derived from pellet analysis (D. Ross 1989).

Red-tailed hawks (*Buteo jamaicensis*) and marsh hawks (*Circus cyaneus*) probably are important predators of amphibians in some areas (Bent 1961). In Puerto Rico, 42% of the prey items brought to nestlings of red-tailed hawks were frogs (*Eleutherodactylus coqui;* Santana and Temple 1988), but frogs were a minor item in the diet in various parts of North America (Ross 1989). Other North American hawks that eat significant numbers of frogs include black hawks (*Buteogallus anthracinus*), white-tailed hawks (*Buteo albicaudatus*), zone-tailed hawks (*B. albonotatus*), ferruginous hawks (*B. regalis*), and American kestrels (*Falco sparverius;* Ross 1989). In a study of American kestrels in California, the birds captured mostly mammals in a relatively dry, cold winter, but shifted to eating mostly frogs and insects in a warm, wet winter when mammals were scarce (Collopy 1977; Collopy and Koplin 1983). Bald eagles (*Haliaeetus leucocephalus*) normally eat mostly fish, but there are observations of eagles eating pickerel frogs (*Rana palustris*) in Maine (Applegate 1990) and sirens (*Siren lacertina*) in Florida (McEwan and Hirth 1980). Another fish-eating species, the osprey (*Pandion haliaetus*), occasionally takes frogs as well (Ross 1989).

Owls

One might expect owls to be important predators of amphibians because of their nocturnal habits. However, most species feed primarily on small mammals and birds, and amphibians usually are a minor component of the diet. Amphibians are eaten occasionally by North American barred owls (*Strix varia*), screech owls (*Otus asio*), and great horned owls (*Bubo virginianus;* Hamerstrom and Hamerstrom 1951; Bent 1961; Rising and Schueler 1980; Ross 1989; Beane 2005). Burrowing owls (*Athene cunicularia*) sometimes eat spadefoot toads (*Scaphiopus*) and other amphibians (Sperry 1941; Gleason and Craig 1979; J. Tyler 1983). Frogs are taken occasionally by barn owls (*Tyto alba*), especially those that hunt in marshy areas (Calderón and Collado 1976; Rey, Esteban, and Sanchiz 1994; Pailley and Pailley 1995; Pezzo and Morimando 1995), but they usually are a minor source of food (Bunn, Warburton, and Wilson 1982). However, in one collection of barn owl pellets from Surinam, Haverschmidt (1962) found the remains of 55 *Leptodactylus ocellatus,* the second most numerous type of prey. Puerto Rican screech owls (*Otus nudipes*) are considered to be important predators of frogs, especially the very abundant *Eleutherodactylus coqui* (Stewart and Woolbright 1996; Pérez-Rivera 1997). In one study, *E. coqui* comprised 40% of the prey items brought to nestlings of this species (N. Snyder, Wiley, and Kepler 1987). In some areas, frogs are important prey of European tawny owls (*Strix aluco;* Uttendörfer 1939; Schnurre 1956, 1957; Wehner 1962), and individuals may specialize on frogs in the breeding season (Betts 1927; Wendland 1984). Tawny owls and little owls (*Athene noctua*) also eat newts (Smallcombe 1934; Trimnell 1945). Other European owls that feed on amphibians at least occasionally include the eagle owl (*Bubo bubo*), long-eared owl (*Asio otus*), short-eared owl (*A. flammeus*), and scops owl (*Otus scops;* J. Martín and López 1990).

Passerine Birds

Although passerine birds in many families prey on amphibians, none relies on them as a principal source of food. Shrikes (*Lanius*) eat frogs, toads, salamanders, and newts, impaling them on thorns along with lizards and other small vertebrates (Ross 1989; Hernández 1995; Jensen 2003). Shrikes will even consume amphibians with toxic or distasteful skin secretions, such as *Salamandra salamandra* and various species of *Triturus* and *Bufo* (Hernández 1995). Corvids and icterids probably are significant predators as well. Many species of crows, ravens, magpies, and jays include amphibians in their diets (Goodwin 1976). Hooded crows (*Corvus corone*) sometimes catch frogs (*Rana tem-*

poraria) during the breeding season and tear them to pieces, leaving only the oviducts and eggs of the females (M. Smith 1969). Common ravens (*Corvus corax*) attack toads (*Bufo boreas*) in breeding aggregations, killing more than 20% of the toads in one chorus (Olson 1989). Beasley and Carothers (1974) observed mixed flocks of red-winged and Brewer's blackbirds (*Agelaius phoeniceus* and *Euphagus cyanocephalus*) feeding on young *Rana pipiens.* Crows, jays, and grackles have been seen attacking aggregations of *Bufo* and *Scaphiopus* tadpoles (Ideker 1976; Beiswenger 1981; Harestad 1985) and metamorphosing *Pseudacris* (Tordoff 1980). In Puerto Rico, icterids such as grackles and orioles eat frogs (*Eleutherodactylus;* Wetmore 1916; Pérez-Rivera 1997).

Several other kinds of passerine birds prey on anurans in the tropics. In Puerto Rico, predators of *Eleutherodactylus* include a kingbird (*Tyrannus caudifasciatus*), a flycatcher (*Myiarchus antillarum*), the red-legged thrush (*Turdus plumbeus*), the pearly-eyed thrasher (*Margarops fuscatus*), a vireo (*Vireo altiloquus*), and a warbler (*Dendroica adelaidae*), as well as the nonpasserine tody (*Todus mexicanus;* Wetmore 1916; Stewart and Woolbright 1996; Pérez-Rivera 1997). Red-legged thrushes also eat other frogs, such as *Leptodactylus albilabris,* and in one study, frogs and lizards comprised more than 8% of all prey items (Rolle 1963). On Barro Colorado Island, Panama, the most frequent avian predators of *Eleutherodactylus* were ant birds (family Formicariidae), woodcreepers (family Dendrocolaptidae), and a few species of flycatchers (family Tyrranidae). In contrast to the tendency of some birds to attack amphibians at aquatic breeding sites, predation on the terrestrial-breeding *Eleutherodactylus* peaked in the dry season, when frogs were most abundant in the leaf litter and arthropods were least abundant (Poulin et al. 2001). In Argentina, kiskadees (*Pitangus sulphuratus*) and woodcreepers (*Xiphocolaptes major*) have been seen eating tadpoles and frogs (Carrizo 1990; Crump and Vaira 1991), while a cuckoo (*Guira guira*) was seen eating an adult *Physalaemus fuscomaculatus* (Kokubum and Zacca 2003).

Passerine birds can be important predators of terrestrial salamanders. Plethodontid salamanders (*Plethodon cinereus* and *Desmognathus ochrophaeus*) made up 25% of the food brought to nestlings by hermit thrushes (*Hylocichla guttata;* Coker 1931). There are anecdotal reports of plethodontid salamanders being captured by American robins (*Turdus migratorius;* Brandon and Huheey 1975; A. Wilson and Simon 1985) and a tufted titmouse (*Parus bicolor;* Prescott 1985), and both American robins and catbirds (*Dumetella carolinensis*) consumed salamanders placed in outdoor trays during an experimental study (Brodie and Brodie 1980). California scrub jays *(Aphelocoma coerulescens*) have been seen eating plethodontid salamanders (*Aneides, Batrachoseps;* Rubinoff 1996; Reaser 1997), but their impact on salamander populations is unknown. A number of passerine birds, including blue jays (*Cyanocitta cristata*), common grackles (*Quiscalus quiscula*), and brown thrashers (*Toxostoma rufum*) readily eat salamanders in captivity, and have been used in experimental studies of Batesian mimicry (Huheey 1960; Brodie and Howard 1973; R. R. Howard and Brodie 1973; Hensel and Brodie 1976; Tilley, Lundrigan, and Brower 1982). Unfortunately, information on the frequency of avian predation on salamanders in the wild is not available.

Predation by Mammals

The list of potential mammalian predators of amphibians probably is not as long as the list of avian predators, but some mammals can have a significant impact on local populations of amphibians. Many mammals in the order Carnivora have catholic diets that include amphibians, but there are few carnivores that rely on amphibians as a principal source of food. Small carnivores, such as weasels, badgers, otters, skunks, and mongooses often are generalist or opportunistic predators that readily switch between different types of prey in response to geographic, yearly, or seasonal variation in prey abundance (Erlinge 1986; Palomares 1993; Roper 1994). Studies of the diets of such predators in a single location or in a single year may suggest that the predator specializes on a particular type of prey, but in fact, the diet often reflects local availability of prey.

Mustelids

A generalist predator that often eats large numbers of amphibians is the European polecat (*Mustela putorius*). Studies of this species in forested regions of Switzerland and Poland revealed a preponderance of anurans in the diet (Jędrzejewski, Jędrzejewska, and Szymura 1989; D. Weber 1989a), and it has been characterized as a specialist predator of anurans (D. Weber 1989b). In Poland, heavy reliance on amphibians during the winter set the polecat apart from other carnivores living in the same habitat, most of which depended heavily on mammals (Jędrzejewski, Jędrzejewska, and Szymura 1989). Yet this species exhibits considerable variation in diet composition (Lodé 1997). In Switzerland, animals that foraged near farmhouses or trash dumps ate very few anurans (D. Weber 1989b). In Poland, polecats in a mature forest fed almost exclusively on hibernating anurans in winter, which they found by traveling along streams. In very cold weather, however, they switched to feeding on small mammals, because streams were frozen over (Jędrzejewski, Jędrzejewska, and Brzeziński 1993). In Belarus, amphibians were eaten most frequently in the spring, but did not appear in the winter diet at all, when polecats relied almost entirely on small mammals (Sidorovich et al. 1998). In an area of western France that included marshes, meadows, and forest, polecats fed mostly on voles and rats that were captured in meadows and forest (Lodé 1991, 1993). In the spring and early summer, however, the animals spent more time in marshes, where they fed heavily on anurans captured in breeding aggregations (Lodé 1996, 2000). Polecats also used marshes more frequently when rodents were scarce (Lodé 1994), and they shifted their daily patterns of activity to correspond with times when anurans were most active (Lodé 1995). Calling males are most vulnerable, and polecat predation can alter sex ratios of frogs in choruses (Lodé et al. 2004).

Another generalist predator that sometimes eats substantial numbers of amphibians, and sometimes eats very few, is the European badger (*Meles meles*). Badgers eat earthworms, arthropods, amphibians, reptiles, small mammals, and a variety of plant foods, but the proportion of each type of food is highly variable (Long and Killingley 1983; Kruuk 1989; Roper 1994; Roper and Mickevicius 1995; Neal and Cheeseman 1996; Revilla and Palomares 2002). Toads (*Bufo bufo*) were the second most important prey of badgers in central France, making up nearly 30% of the diet overall, and up to 80% at some times of year (C. Henry 1983, 1984a, b). In the spring, badgers fed mostly on toads aggregated at breeding sites, and they also were an important source of food in the summer when earthworms were scarce (C. Henry 1984b). The badgers ate the toads from the ventral side, avoiding the poisonous parotoid glands (C. Henry 1984a). The numbers consumed can be significant; C. Henry (1983) estimated that one badger could eat 56 kg of toads per year, or about 1,360 individuals. Amphibians also were an important component of the diet of badgers in Spain (Ibañez and Ibañez 1980), Finland (Kauhala, Laukanen, and von Rege 1998), and Belarus (Sidorovich and Pikulik 1997). Amphibians were a minor component of the diet in Denmark (Andersen 1954), England (Shepherdson, Roper, and Lüps 1990), and most parts of the former Soviet Union (Roper and Mickevicius 1995). In several other parts of Europe, badgers seldom ate amphibians at all (Ciampalini and Lovari 1985; Roper 1994). In Taiwan, amphibians were the most important prey of the ferret badger (*Melogale moschata;* Chuang and Lee 1997).

Otters in various parts of the world are opportunistic predators of amphibians. Most otters feed primarily on fish, crabs, or crayfish, but their diet varies considerably in different habitats (Jędrzejewska, Brzeziński, and Jędrzejewski 2001). Amphibians often are a lower ranked food source that is consumed when other prey are scarce (K. Greer 1955; Ewer 1973; Rowe-Rowe 1977; Chapman and Feldhamer 1982; Chanin 1985; Mason and Macdonald 1986; Adrian and Delibes 1987; J.-M. Weber 1990; Beja 1991; Reid et al. 1994; Helder-Jose and Andrade 1997; Pardini 1998; Anoop and Hussain 2005). In studies of European otters (*Lutra lutra*) in Poland, however, frogs were as important in the diet as were fish (Brzeziński, Jędrzejewski, and Jędrzejewski 1993; Jędrzejewska, Brzeziński, and Jędrzejewski 2001). Those otters lived along small forest rivers, in contrast to the large rivers or coastal areas studied by many other workers. Otters in Belarus also ate substantial numbers of anurans, especially along fast-flowing forest streams (Sidorovich and Pikulik 1997; Sidorovich et al. 1998). Frogs are particularly vulnerable to otter predation in the winter and spring. Frogs hibernating on the bottoms of ponds, streams, and ditches constitute up to 65% of winter prey of otters in some parts of Europe (Erlinge 1967, 1969, 1972; Callejo Rey et al. 1979; Chanin 1985; Mason and Macdonald 1986; Weber 1990; Brzeziński, Jędrzejewski, and Jędrzejewski 1993; Sidorovich et al. 1998; Jędrzejewska, Brzeziński, and Jędrzejewski 2001). European otters also feed on frogs during the breeding season, and may travel some distance to find breeding aggregations (Jenkins and Harper 1980; Fairley 1984; J.-M. Weber 1990; Jędrzejewska, Brzeziński, and Jędrzejewski 2001). In Scotland, there was a strong positive correlation between the density of anurans in the habitat and the proportion of anurans in the diet of otters (J.-M. Weber 1990).

In areas where both frogs (*Rana*) and toads (*Bufo*) are abundant, European otters tend to eat mostly frogs and avoid toads (Erlinge, 1968; López-Nieves and Hernando 1984; Fairley and McCarthy 1985; Adrian and Delibes 1987; de Jongh 1988; J.-M. Weber 1990; Sidorovich and Pikulik 1997). Nevertheless, otters can be a significant source of mortality for toads in some circumstances. During the spring, a population of otters in the mountains of Spain fed mostly on toads (*Bufo bufo*) captured in breeding aggregations (Lizana and Pérez-Mellado 1990), perhaps because their preferred prey (fish) are scarce at high altitudes (Ruiz-Olmo 1998). Like the French badgers discussed previously, otters in this population have learned to manipulate toads to avoid eating parts where poison glands are concentrated. Otters in Poland also captured toads (*B. bufo*) in breeding aggregations (Jędrzejewska, Brzeziński, and Jędrzejewski 2001), and those in Belarus ate toads (*B. bufo* and *B. viridis*) when preferred prey species were scarce (Sidorovich and Pikulik 1997).

Outside of Europe, otters seem to eat fewer amphibians. North American river otters (*Lutra canadensis*), for example, feed mostly on fish and crustaceans and sometimes do not eat amphibians at all, even in habitats where amphibians are likely to be common (Melquist and Hornocker 1983; Tumlison and Karnes 1987). In some populations, amphibians are a minor component of the diet, appearing mostly during the spring breeding period of frogs (Greer 1955; Reid et al. 1994), although otters were observed feeding on Oregon spotted frogs (*Rana pretiosa*) in both late winter and late summer (M. Hayes et al. 2005). The Neotropical river otter (*Lontra longicaudis*) feeds mostly on fish and crustaceans, with amphibians comprising less than 3% of the diet (Helder-Jose and Andrade 1997; Pardini 1998). In southern Africa, the Cape clawless otter (*Aonyx capensis*) eats mostly crabs, but in some habitats, frogs are as important as fish as a secondary food item (Rowe-Rowe and Somers 1998). In the same region, spotted otters (*Lutra maculicollis*) eat mostly fish and crabs, with frogs being important secondary prey in wet areas (Rowe-Rowe 1977; Rowe-Rowe and Somers 1998), but less so in drier habitats (Somers and Purves 1996). Several species of otters in Asia feed mostly on fish, but take amphibians occasionally (Kruuk et al. 1994; Hussain and Choudury 1998; Anoop and Hussain 2005).

Mink often live in the same habitats as otters and can be significant predators on amphibians as well, but frogs are eaten less frequently than mammals, fish, and crayfish (Gerell 1968; Ewer 1973; Erlinge 1969, 1972; Jenkins and Harper 1980; Wise, Linn, and Kennedy 1981; Chapman and Feldhamer 1982). In Sweden, introduced American mink (*Mustela vison*) preyed on frogs mostly during the spring breeding season, and at times when preferred foods were scarce. There also was evidence of predation on hibernating frogs in some areas (Gerell 1968). In much of Europe, the American mink has become common, while the native European mink (*M. lutreola*) has declined. Where these two species live together in Belarus, European mink ate significantly more anurans than did American mink, with anurans being the most important prey for European mink in fall, winter, and spring (Sidorovich and Pikulik 1997; Sidorovich et al., 1998). In the Białowieża Forest of Poland, American mink ate substantial numbers of anurans, especially in winter (Jędrzejewska, Brzeziński, and Jędrzejewski 2001). The abundance of frogs in the diet of these mink appears to reflect their abundance along the small forested streams of the forest. Indeed, across much of Europe, the proportion of amphibians in the diet of American mink tends to be much higher for populations along rivers and streams than for those living in lakes and ponds.

Other mustelids, such as weasels, martens, and skunks, take amphibians opportunistically, but amphibians usually are not a major component of the diet (Ewer 1973; Corbet and Southern 1977; Chapman and Feldhamer 1982; Reig and Jędrzejewski 1988; Jędrzejewski, Jędrzejewska, and Brzeziński 1989; Redford and Eisenberg 1992; Pulliainen and Ollinmäki 1996b; Sidorovich and Pikulik 1997; Kuzmin 1999). As with otters and mink, however, these predators sometimes can take a considerable toll on hibernating frogs (Pulliainen and Ollinmäki 1996a) or breeding aggregations of anurans (Groves 1980).

Mongooses

Mongooses (Herpestidae) are omnivores that can be opportunistic predators of amphibians. In the West Indies, introduced mongooses (*Herpestes*) eat frogs and toads (C. Williams 1918; J. Myers 1931; Pimentel 1955). In Hawaii, they even feed on introduced cane toads (*Bufo marinus;* Baldwin, Schwartz, and Schwartz 1952), a highly toxic species that can be fatal if eaten by dogs, pigs, carnivorous marsupials, varanid lizards, snakes, and other predators (Dryden 1965; Covacevich and Archer 1975; M. Tyler 1976; McCoid, Hensley, and Witteman 1994; McCoid 1995; Burnett 1997). Egyptian mongooses (*Herpestes ichneumon*) living in a wetland habitat in southern Spain ate spadefoot toads (*Pelobates cultripes*) in the wet season, but they never were the most important component of the diet (Palomares 1993). The large African water or marsh mongoose (*Atilax paludinosus*) eats mostly crabs, but also takes significant numbers of frogs (Rowe-Rowe and Somers 1998; Ray and Sunquist 2001). The crab-eating mongoose (*Herpestes urva*) of Taiwan also supplements its diet of crabs with frogs (Chuang and Lee 1997).

Other Carnivores

Relatively few other carnivores are known to eat amphibians in large numbers. Cats seem an unlikely type of predator on amphibians, but some small cats do eat them. Up to a third of the scats of Tsushima Island leopard cats (*Felis bengalensis*) in Japan contained remains of amphibians, with the frequency being highest in the winter, and amphibians were part of the diet of Iriomote cats (*Felis iriomotensis*) from Japan as well (Kitchener 1991). Frogs were found in 77% of the scats of servals (*Felis serval*) in the Ngorongoro Crater in Tanzania, and were the second most frequent type of prey after small mammals (Geertsema 1985). Frogs made up about 11% of the diet of ocelots (*Felis pardalis*) in Venezuela (Bisbal 1986), and they may be eaten occasionally by margays (*F. wiedii*) as well (Azevedo 1996).

Even domesticated cats eat amphibians occasionally. In a survey of cat-owning British households during a single spring and summer season, 986 cats were reported to have brought nearly 600 amphibians back to their homes, of which most were ranid frogs (probably mostly *Rana temporaria*). Overall, it was estimated that the approximately 9 million household cats in Britain bring about 5 million amphibians and reptiles back to homes each year, of which 75–80% are frogs (Woods, McDonald, and Harris 2003). This figure undoubtedly underestimates the actual mortality caused by cats, since many prey items probably are consumed away from the home. The estimate also does not include feral cats, which are likely to obtain all of their food by hunting.

In Venezuela, remains of anurans (*Bufo, Eleutherodactylus, Hyla, Leptodactylus, Pseudis*) were found in the diet of crab-eating foxes (*Cerdocyon thous;* Bisbal and Ojasti 1980; Sunquist, Sunquist, and Paneke 1989). The omnivorous South American maned wolf (*Chrysocyon brachyurus*) eats mostly mammals, birds, and fruit, but it also eats toads (Guix 1993). In some areas, the Eurasian raccoon dog (*Nyctereutes procyonides*), a species that frequents the shores of ponds and streams, eats substantial numbers of anurans, especially during the spring breeding season (Stroganov 1969; Ewer 1973; Viro and Mikkola 1981; Kauhala 1996; Kauhala, Laukanen, and von Rege 1998; Kuzmin 1999; Kauhala and Auniola 2001). In other areas, frogs are a minor part of the diet (Jędrzejewski, Jędrzejewska, and Szymura 1989).

Among the procyonids, the North American raccoon (*Procyon lotor*) is frequently cited as a major predator of frogs, but detailed studies of food habits have shown that frogs constitute a surprisingly small proportion of the diet, with more than 50% being composed of plants (Ewer 1973; Chapman and Feldhamer 1982). Nevertheless, raccoons are attracted to breeding aggregations of anurans, or sites where frogs are trapped by drying ponds (Fitch 1958; Schaaf and Garton 1970; M. Jones, Goetti, and Livo 1999). Crab-eating raccoons (*P. cancrivorus*) sometimes eat anurans as well (Guix 1993). Coatis (*Nasua narica*) take an occasional frog or caecilian, but do not seem to be major amphibian predators (Kaufmann 1962). Genets (*Genetta genetta*) are the only viverids found in Europe, and are most common in the Mediterranean region, especially the Iberian Peninsula. They eat mostly small mammals, but other types of prey, including amphibians, are taken occasionally. The frequency of amphibians in the diet is highest on two Mediterranean islands, Ibiza and Cabrera, where alternative prey may be scarce (Virgos, Llorente, and Cortes 1999). Other carnivores that take amphibians occasionally include foxes (*Vulpes, Alopex*), wolves (*Canis lupis*), and bears (*Ursus*) (Jones, Goetti, and Livo 1999; Kuzmin 1999), but it seems unlikely that amphibians are major prey for any of these animals.

Shrews and Moles

Many insectivores probably feed on amphibians at least occasionally. In Poland, up to 40% of the winter diet of the water shrew (*Neomys fodiens;* fig. 14.8) is composed of hibernating frogs captured in ditches (Wolk 1976). Dead frogs are frequently stored for future use (Buchalczyk and Pucek 1963) and are more completely consumed as winter progresses and food availability declines (Wolk 1976). Several other European shrews include amphibians as a minor item in the diet (Aitchison 1987; Kuzmin 1999). The North American water shrew (*Sorex palustris*) eats salamanders (*Dicamptodon;* Nussbaum and Maser 1969), as does *Blarina brevicauda,* which has been used in tests of amphibian antipredator secretions (Brodie, Nowak, and Harvey 1979; Brodie and Formanowicz 1981). *Blarina* appears to be a minor predator of amphibians in the field, however (Hamilton 1930). Musk shrews (*Suncus*) in India eat frogs and toads (Dharmakumarsinhji 1946; Kunte 1996). There are anecdotal reports of European moles (*Talpa europaea*) capturing anurans (Mellanby 1971; Kuzmin 1999), and the Russian desman (*Desmana moschata*) preys on a number of kinds of amphibians (Kuzmin 1999). The North American shrew mole (*Neurotrichus gibbsi*) is reported to eat salamanders (Nowak and Paradiso 1983).

Fig. 14.8. European water shrew (*Neomys fodiens*), a voracious predator on frogs hibernating underwater. This species often caches excess frogs for future use during the winter. Photo by Milos Andera.

Rodents

Many species of rodents are partially carnivorous (Landry 1970). Muskrats (*Ondatra*) occasionally feed on frogs and salamanders along with other animals such as crayfish and mussels (Landry 1970; Kuzmin 1999). The Australian water rat (*Hydromys*) is known to eat anurans, including introduced *Bufo marinus* (Tyler 1976; Woolard, Vestjens, and MacLean 1978). An African water rat (*Colomys goslingi*) lives in the vicinity of running water and appears to be largely carnivorous; captive individuals eagerly captured and ate tadpoles (Dieterlen and Statzner 1981). There also several aquatic rats in South America (*Ichthyomys, Anotomys, Neusticomys, Daptomys*) that are thought to be carnivorous (Nowak and Paradiso 1983), although captive *Ichthyomys* showed relatively little interest in tadpoles (Voss Sliva L., and Valdeo L. 1982). The common Norway rat (*Rattus norvegicus*) and black rat (*Rattus rattus*), introduced all over the world by humans, are known to prey at least occasionally on frogs and toads (M. Smith 1969; M. Tyler 1976; Frazer 1983; Stewart and Woolbright 1996). There even are reports of chipmunks (*Tamias*), red squirrels (*Tamiasciurus hudsonicus*), and hamsters (*Cricetus*) taking frogs, toads, and salamanders (Landry 1970; B. D. Sullivan 1991; Kuzmin 1999), but their impact is likely to be trivial.

Bats

Some large bats eat small vertebrates, including frogs, but most also eat insects, and none is known to feed exclusively on frogs (Norberg and Fenton 1988). In the Old World, frogs are eaten by false vampire bats in the family Megadermatidae (*Megaderma, Macroderma, Cardioderma;* Brosset 1962; Douglas 1967; Vestjens and Hall 1977; Advani 1981; Marimuthu, Habersetzer, and Leippert 1995). Radio-tagged false vampire bats (*Megaderma lyra*) in India captured both frogs and insects (Audet et al. 1991). Remains of many ranid frogs (*Ptychadena*) and a few clawed frogs (*Xenopus laevis*) have been found beneath roosts of an African nycterid bat, *Nycteris grandis* (Fenton, Thomas, and Sasseen 1981; Fenton et al. 1990). In the Neotropics, the phyllostomid bat *Trachops cirrhosus* preys on frogs that it locates by homing in on their calls (Tuttle and Ryan 1981; see chapter 7 for further details). At one pond, *Trachops* captured 95 *Physalaemus pustulosus* in slightly more than 14 hours, and were the most important predators on calling males (Ryan, Tuttle, and Taft 1981). This bat shows a strong preference for edible frogs over poisonous species and can distinguish between them by their calls (Page and Ryan 2005). Four species of bats known to eat frogs (*Trachops,* two species of *Megaderma,* and *Cardioderma cor*) all have unusual accessory submandibular salivary glands unlike glands found in other bats. These may produce salivary secretions that neutralize the toxic skin secretions of the frogs eaten by the bats, although this has not been demonstrated experimentally (Tandler, Phillips, and Nagato 1996; Tandler, Nagato, and C. J. Phillips 1997).

Primates

Amphibians appear to be of little significance in the diets of most primates, but they provide supplemental protein for a few species. Several species of African monkeys (*Cercopithecus mitis, Cercocebus torquatus, Cercocebus diana*) have been observed feeding on the foam nests of rhacophorid tree frogs, *Chiromantis xerampelina* and *C. rufescens,* as well as the gelatinous egg masses of some hyperoliid frogs (Huntly 1985; Rödel et al. 2002). In the Ivory Coast, sooty mangabeys (*Cercocebus torquatus atys*) were observed systematically searching vegetation over water for frog eggs, suggesting that frog eggs could be a regular item in the diet, and monkey predation could have a major impact on egg survivorship (Rödel et al. 2002). Capuchin monkeys (*Cebus apella*) were suspected as predators on arboreal egg masses of *Phyllomedusa bicolor* in Brazil (Neckel-Oliviera and Wachlevski 2004).

Some monkeys also feed on adult anurans. African patas monkeys (*Erythrocebus pats*) were seen feeding on toads in Senegal (Galat-Luong 1991). Japanese macaques (*Macaca fuscata*) sometimes eat both frogs and lizards (Suzuki et al. 1990), as do stumptail macaques (*M. arctoides;* Estrada and Estrada 1977). Frog remains made up 8% of the stomach contents of *Galago alleni,* a nocturnal prosimian studied by Charles-Dominique (1977) in Gabon. All five diurnal monkeys studied by Terborgh (1983) in Peru preyed on frogs, but these made up only 1–3% of all prey items. In Colombia, one of these species, *Cebus apella,* extracted frogs from hiding places in hollow bamboo stalks after enlarging the entrances to the retreats with their teeth (Izawa 1978). The monkeys rubbed the frogs on tree branches after killing them, possibly to remove noxious skin secretions. A closely related species, *C. albifrons,* has been seen capturing frogs from the water-filled axils of plants (Defler 1979). Tamarins (*Saguinus*) and marmosets (*Callithrix*) also eat frogs occasionally, but they make up a very small proportion of the diet (Digby and Barreto 1998; Heymann, Knogge, and Tirado Herrera 2000; Passamani and Rylands 2000; A. Smith 2000; Canale and Lingnau 2003).

Other Mammals

Mammals in several other orders are potential predators of amphibians. A somewhat surprising one is the nine-banded armadillo (*Dasypus novemcinctus*), which eats a variety of frogs, salamanders, and even amphiumas (Fitch, Goodrum, and Newman 1952; Breece and Dusi 1985; Wirtz, Austin, and Deklee 1985). Another unusual predator is the European wild boar (*Sus scrofa*), which occasionally digs up and consumes spadefoot toads (*Pelobates fuscus;* Briedermann 1976; cited in Nöllert 1984) and other anurans (Kuzmin 1999), as well as highly toxic fire salamanders (*Salamandra salamandra;* Carretero and Rosell 1999). The North American opossum (*Didelphis virginiana*) and a number of South American opossums include amphibians in a varied diet of small vertebrates, invertebrates, and plants (Chapman and Feldhamer 1982; Streilein 1982; Nowak and Paradiso 1983; Redford and Eisenberg 1992). In Panama, the four-eyed opossum, *Philander opossum,* used acoustic cues to locate frogs at a breeding chorus (Tuttle, Taft, and Ryan 1981). Some carnivorous Australian marsupials, such as quolls (*Dasyurus*), eat anurans and consequently are threatened by the spread of the highly toxic introduced cane toad (*Bufo marinus;* Burnett 1997).

Man the Frog Hunter

In some areas of the world, humans are significant predators of amphibians. Frogs probably have been at least a minor component of the human diet for most of our evolutionary history. Frog bones have been found associated with hominid remains and concentrations of other vertebrate bones at Olduvai Gorge in Tanzania, although it is nearly impossible to determine whether frogs actually were eaten (Isaac and Crader 1981). Amphibian bones often turn up in archaeological digs, but it is not always clear that they represent remains of human food. For example, bones of five genera of frogs have been found at Paleolithic sites in Spain, but they may have been eaten by black kites (*Milvus migrans*) nesting near humans, not by humans themselves (Freeman 1981). Remains of *Bufo marinus* often are found at archaeological sites in Central America (Coe and Diel 1980; R. Cooke 1984; Hamblin 1984). There has been some debate over whether these toads were used as food, or collected for their poisonous skin secretions to be used as psychoactive drugs (Dobkin de Rios 1974; Furst 1976; Kennedy 1982; W. Davis and Weil 1992).

Many hunting and gathering people, as well as those that combine hunting and agriculture, probably take amphibians for food whenever they are encountered. It is not uncommon for such people, especially those living in rain forests, to consider nearly all animals edible (Hayden 1981). For example, various groups of South American Indians eat frogs, toads, tadpoles, and even anuran eggs, but amphibians seldom represent more than a minor source of protein (Wassen 1934; Clastres 1972; Dufour 1983; Hill and Hawkes 1983; Abrams 1987). The Wayapi of French Guiana eat 16 species of frogs and the eggs of eight species, but amphibians constitute a trivial proportion of their total diet (Lescure, Grenand, and Grenand 1980). In Peru, the Cashinahuas eat large tree frogs (*Phrynohyas coriacea*) after roasting them in banana leaves (Duellman and Thomas 1996). Some groups of Indians in Amazonian Peru and Brazil also collect another large tree frog, *Phyllomedusa bicolor,* and use its skin secretions in hunting magic. The secretions are introduced into fresh burns on the skin, resulting in violent illness, followed by a state of euphoria (Daly et al. 1992). The impact of this practice on populations of the frog is unknown. Some North American Indians used bullfrogs (*Rana catesbeiana*), leopard frogs (*Rana pipiens*), wood frogs (*Rana sylvatica*), and even hellbenders (*Cryptobranchus alleganiensis*) as food (Waugh 1916; Wassen 1934; Speck and Dodge 1945; McCoy 1982), but little detailed information is available.

Reports on the use of amphibians as food by humans in other parts of the world are sketchy. David Livingstone reported that people in southern Africa captured *Pyxicephalus adspersus* at breeding ponds after heavy rains and ate them with “great eagerness” (Livingstone 1858, p. 48); this practice has continued in recent times (Mitchell 1946, cited in Stewart 1967). In West Africa, local people prize the giant frog, *Conraua goliath,* in part because it is very difficult to catch (Zahl 1967; Sabater-Pi 1985). In arid regions of the Sudan, where sources of protein are scarce, local people prepare a variety of fermented foods based mostly on sorghum, with added ingredients that include frogs, fish, caterpillars, locusts, and cow urine (Dirar 1994).

In a few areas, amphibians are a more significant component of the diet. Before the introduction of black bass as a food fish into some East African lakes in Uganda, Rwanda, and Zaire, *Xenopus* were used as a substitute for fish by people living near the lakes (Worthington and Worthington 1933; de Witte 1941). Similar use is made of aquatic frogs of the genus *Telmatobius* by people living near high Andean lakes (Crump 2003), and the Mexican axolotl (*Ambystoma mexicanum*) has been used for food since Aztec times (see chapter 13). Frogs are an important resource for some people in the highlands of New Guinea, where mammalian prey is scarce. Both children and adults spend considerable time systematically hunting for frogs along streams, and they have developed an elaborate taxonomy to name them (Bulmer and Tyler 1968). Adult frogs are smoked, baked, or roasted over hot coals, while tadpoles may be roasted or stewed (M. Tyler 1976). In some parts of New Guinea and New Britain, large ranid frogs are hunted with dogs, which are used to drive frogs from hiding places along streams. Human predation on several frogs in New Guinea, including *Rana arfaki* and *R. jimiensis,* is so intense that the species have become rare and may be endangered (M. Tyler 1976). Frogs also are eaten as occasional delicacies by some native Australians (M. Tyler 1976). The Nuaulu people of eastern Indonesia combine swidden agriculture with collection of wild plants and animals in the forest. An exceptionally large treefrog, *Litoria infrafrenata,* is sometimes eaten, but is not a major food (Ellen, Stimson, and Menzies 1976).

Frogs are eaten in many other parts of Asia, although they probably are not a major source of food. In ancient times, people in southern China ate frogs, a habit that was detested by their northern cousins (M. Freeman 1977; Schafer 1977). In some parts of China, a special soup prepared from frogs collected while breeding was associated with sexual power (Eberhard 1968). In modern Asian countries, including China, Japan, the Philippines, and Malaysia, frog consumption is limited mainly to large and abundant ranid frogs (Okada 1927; Angel 1947; Heang 1984), many of which are readily captured in rice fields. China is a major market for frog legs imported from other Asian countries, with up to six million *Hoplobatrachus rugulosus* (Ranidae) shipped from Thailand to China each year (Jensen and Camp 2003). In Okinawa, frogs were once considered sufficiently important as a source of food for frog catching to be a hereditary profession (Okada 1927), and there were professional frog catchers in ancient China as well (see frontispiece; Eberhard 1968). Some tribal people in India use several species of anurans in traditional medicines (Azmi 1990).

Consumption of frogs has a long history in Western and Central Europe. Medieval monks were allowed to eat meat on only a limited number of days each year, but got around the restriction by classifying aquatic animals such as frogs and beavers as fish (Tannahill 1973). The use of frogs as food undoubtedly originated among farmers and peasants who collected wild frogs to supplement the meager protein in their diets, but they soon became established as a regular item on the tables of city dwellers and the aristocracy. At a banquet given in Paris for Elizabeth of Austria in 1571, 1,000 frogs were served along with a wide assortment of fish and shellfish (Tannahill 1973). By the eighteenth century, the use of frogs for food was so commonplace that Linnaeus named one of the most frequently eaten species *Rana esculenta,* the edible frog. In modern times, consumption of frogs has been most common in France, Belgium, Holland, Germany, Switzerland, and Italy (Angel 1947; Dubois 1983a), although frogs are eaten to a limited extent in most European countries. Frogs never have been a popular food in Britain, and during their many long wars with the French, the British often disparaged their enemies as "frog-eaters" or simply "frogs" (Hackwood 1911).

The impact of human consumption of frogs in Europe is hard to estimate because these populations also are threatened by habitat destruction, pollution, and collecting for scientific research. Nevertheless, frog populations have declined in some European countries to the point where conservationists and government agencies are now discouraging their use as food (Dubois 1983a; Honnegger 1981, 1984; Thielcke et al. 1985). The effects of western European consumption of frog legs have been felt in other countries as well. As populations in western and central Europe have declined, restauranteurs and grocers have turned to Greece, Turkey, India, Bangladesh, Indonesia, and other countries as sources of imported frog legs (Jensen and Camp 2003). Thielcke et al. (1985) reported that 96,000 kg of frogs were imported into Switzerland in 1976, representing about a million individuals. Imports into France have been even higher, ranging from 2,700 to 4,500 metric tons per year from 1976 through 1982 (Dubois 1983a). By the 1980s, export of frog legs from India reached as high as 4,400 tons per year (about 4 million kg), representing some 13,000 tons (12 million kg) of frogs. A survey conducted among local farmers suggested that populations of large ranid frogs had declined or disappeared in many parts of India (Abdulali 1985), and there is increasing concern about declining frog populations in India (Oza 1990; Gore and Prayag 1993) and other Asian countries such as Indonesia (Patel 1993; Veith et al. 2000).

In the late nineteenth century, frogs were a regular item on menus in many parts of the United States, and many states had a thriving frog collecting industry. Chamberlain (1898) estimated that at least a million frogs were taken annually for food in the late 1890s, with frogs being a commercially important fisheries product in at least 15 states. By 1900, frogs were the single most valuable product of the fisheries industry in Minnesota (A. Wright 1920). The majority of frogs used for food came from states in the Mississippi River drainage, although states such as New York and California had major frog industries as well. Before 1900, the most heavily exploited species in California was *Rana draytonii,* with harvests totaling nearly 120,000 frogs (22,000 kg) in 1895 (Jennings and Hayes 1985). By 1900, this species had undergone a dramatic decline from which it has never recovered. The scarcity of native frogs may have been the reason for the introduction of bullfrogs (*Rana catesbeiana*) from the eastern United States into California (Jennings and Hayes 1985). The current level of exploitation of frogs for food is difficult to estimate because detailed harvest records are not available for most states, and local populations often are severely threatened by illegal poaching. In addition, collection of frogs for research and educational use is now a substantial enterprise that may have a greater effect on populations in North America than exploitation for food. In some states, ranid frogs, desmognathine salamanders, and ambystomatid larvae are sold in bait shops, but the impact of this largely unregulated trade on amphibian populations is unknown (Jensen and Camp 2003).

The Impact of Predation on Amphibian Populations

From the preceding survey, it is clear that amphibians are vulnerable to a wide variety of predators at all stages of their lives. However, quantitative data on the demographic impact of predation are scarce, and measuring the impact of specific predators is even more difficult. Studies that provide estimates of mortality in amphibian populations often include lists of potential predators, but they seldom provide quantitative estimates of the impact of those predators on survivorship (e.g., Peterson et al. 1991; Ramirez, Vogt, and Villarreal-Benitez 1998). The study of amphibian demography is complicated by the complex life cycles of most species, with different stages being exposed to very different physical and biological environments. To understand what factors regulate the sizes of amphibian populations, one must study processes occurring at all life history stages (Wilbur 1980; Hellriegel 2000). Many ecologists have divided the typical amphibian life history into two major stages, one occurring in the water and the other on land (Wilbur 1980; Werner 1986). However, when considering the impact of predation on amphibian populations, it is more useful to think of the life history as being composed of four stages: (1) embryos, (2) larvae, (3) metamorphosing juveniles, and

(4) adults. Predation can be a significant source of mortality at any of these stages, but not necessarily at all stages for any given species. At present, we do not have complete information on sources of mortality at all stages of the life cycle for any species of amphibian.

Embryonic Mortality

Embryonic mortality in aquatic-breeding amphibians often is extremely variable, both within and among species. For example, embryonic mortality ranging from 2% to nearly 100% has been reported for spotted salamanders (*Ambystoma maculatum*) (Shoop 1974; R. Harris 1980; Stangel 1988; Rowe, Sadinski, and Dunson 1994; Brodman 1995; Stenhouse 1987; Petranka et al. 1998). Stenhouse (1987) observed variation from 0 to 100% mortality among different ponds in the same year. In many ponds, freezing was a more important source of mortality than predation, but in some cases, sources of mortality could not be determined. Nevertheless, it is clear that certain predators can have devastating effects on spotted salamander embryos. Survivorship of embryos in ponds containing wood frog (*Rana sylvatica*) tadpoles was 91% for egg masses enclosed in predator exclusion cages, but only 14% for those not in cages (Petranka et al. 1998). Mortality of spotted salamander embryos exceeded 90% in ponds with dense populations of caddisfly larvae, but little or no mortality in ponds that lacked these predators (Rowe, Sadinski, and Dunson 1994).

Other salamanders exhibit similar variation in embryonic mortality. Brodman (1995) found consistently low mortality (< 15%) for *Ambystoma jeffersonianum* in a semipermanent pond in Ohio over several years. Freezing contributed to high mortality (62%) of eggs in a population of *Ambystoma tigrinum* studied by J. Anderson, Hassinger, and Dalrymple (1971), but there was evidence of predation by caddisfly larvae as well. Some *Ambystoma* eggs are vulnerable to predation by adult newts (*Notophthalmus*) and fish, which can virtually eliminate eggs from permanent ponds (Morin 1983b; Petranka 1983; Semlitsch 1988). In stream-breeding populations of *A. barbouri,* embryonic mortality was low (16–20%), and only about 3% of the eggs were eaten by predators (Petranka 1984b). Similar low mortality has been observed in the stream-breeding hynobiid salamander *Ranodon sibiricus* (31%; Bannikov 1958) and the pond-breeding species, *Hynobius nebulosus* (14–33%; Kusano 1980). In contrast, extremely high embryonic mortality (97%) was found in a pond-breeding population of newts (*Triturus vulgaris*), and there was evidence that predation was a major source of mortality (G. Bell and Lawton 1975).

Mortality of aquatic frog eggs is also highly variable. In Marion Lake, British Columbia, only about 5% of all *Rana aurora* eggs died prior to hatching, despite a long period of development (more than one month) in a lake inhabited by predatory newts and ambystomatid salamanders (Calef 1973a). All of the mortality appeared to be due to fungal infection, freezing, and desiccation, not predation. Licht (1974) found similar low mortality (9%) in *Rana aurora* eggs laid in permanent water where invertebrate predators were abundant. Mortality of *R. pretiosa* eggs in the same habitat was higher (29%), but the difference was due to more frequent desiccation of *R. pretiosa* eggs, not to greater predation. Mortality also was low, averaging 3%, in clutches of *Heleioporus albopunctatus* eggs in Western Australia, despite attacks by fly larvae (R. Davis and Roberts 2005). R. D. Howard (1978b) observed very high mortality in egg masses of bullfrogs (*Rana catesbeiana*) that were attacked by leeches, but little or no mortality in other clutches.

Although temporary ponds lack predatory fish, they often are filled with other types of predators, particularly aquatic insects that rapidly colonize new ponds, and many of these prey on amphibian embryos (see table 14.2). In general, invertebrate predator densities are lower in temporary than in permanent water (Heyer, McDiarmid, and Weigmann 1975; Crump 1981b; Woodward 1983), and small pools often have fewer predators than large ones (D. G. Smith 1983; A. H. Roth and Jackson 1987). Usually desiccation is the most important source of embryonic mortality, but predation can be significant in ponds that do not dry up. Amphibian larvae, including conspecifics, can be major predators of anuran eggs in some ponds (see previous discussion of predation by amphibian larvae). For example, Banks and Beebee (1988) found that less than 3% of *Bufo calamita* eggs laid in shallow sand-dune ponds were killed by predators, whereas 26% of the eggs laid in a more permanent heathland pond were eaten. Among the most important predators were tadpoles of *Rana temporaria* and *Bufo bufo,* which are capable of eliminating *Bufo calamita* eggs from some ponds (Banks and Beebee 1987b). An increase in numbers of *B. bufo* in Britain has been accompanied by a dramatic decline in *B. calamita,* possibly because of predation on eggs (Beebee 1979b). The latter species breeds most successfully in very shallow temporary ponds that are not used by *B. bufo,* but these ponds are more vulnerable to desiccation (Banks and Beebee 1987a, 1988). In Spain, predation by tadpoles of *Pelobates cultripes* and *Pelodytes punctatus* resulted in mortality of more than 50% for *Bufo calamita* embryos, and these predators eliminated all toad eggs in one pond (Tejedo 1991). In North Carolina, American toads (*Bufo americanus*) are prevented from breeding in ponds containing wood frog (*Rana sylvatica*) tadpoles, which are capable of consuming several thousand toad eggs in less than an hour at natural tadpole densities (Petranka, Hopey, Jennings, Baird, and Boone 1994).

Nonaquatic oviposition or oviposition in very small pools has been interpreted as a means of reducing predation on eggs (Lutz 1947; Salthe and Duellman 1973; Salthe and Mecham 1974), but rates of predation sometimes exceed those in species that breed in large bodies of water. For example, embryonic mortality was high (82%) in *Ramanella montana,* a microhylid frog from India that lays eggs in tree holes just above the water surface or on floating dead leaves. Several kinds of invertebrates were observed feeding on the eggs, including snails, caddisfly larvae, and millipedes (Krishna, Krishna, and Vijayalaxmi 2004). Mortality of centrolenid eggs, much of it attributable to predation by drosophilid fly larvae, ranged from 14% to nearly 70% (Villa 1977, 1984; McDiarmid 1978; Greer and Wells 1980; Jacobson 1985). Similarly, embryonic mortality was high (72%) in the East African frog *Hyperolius spinigularis,* which lays eggs on emergent vegetation in water or on leaves over water. The main sources of mortality were predation by frogs (*Afrixalus;* 41%), predation by fly larvae (12%), desiccation (10%), and predation by insects (3%; Vonesh 2005a). Predation by *Afrixalus* was particularly high early in the breeding season, with 73% of clutches being attacked, compared to 13–37% later in the season. Embryonic mortality in some species is reduced by parental care, as it is in frogs such as *Eleutherodactylus coqui* (Townsend, Stewart, and Pough 1984) and *Cophixalus parkeri* (Simon 1983; see chapter 11). However, some terrestrial breeders have low embryonic mortality even without parental care. Embryonic mortality was only 3–5% in three species of *Pseudophryne* in Australia, and there was no evidence of predation (Woodruff 1976b). These species lay eggs in a moist, cold environment where predators are scarce.

Marbled salamanders (*Ambystoma opacum*) lay eggs on land in areas that are later flooded. Embryonic mortality is variable, but can be up to 60–90% in some populations (Stenhouse 1987; M. Jackson, Scott, and Estes 1989; Petranka 1990). Freezing and failure of rains to flood nests appear to be the most important sources of mortality, but protection of eggs from predators by attending females also is important (M. Jackson, Scott, and Estes 1989; Croshaw and Scott, 2005). Specific predators have not been identified, however. Embryonic mortality can be relatively high (80–90%) in four-toed salamanders (*Hemidactylium scutatum*), another species that lays eggs on land (Harris and Gill 1980; Harris et al. 1995). Brooding by females enhances embryonic survival, again suggesting that protection against predators might be important. However, females often desert their eggs if they are flooded by heavy rains, and much of the mortality occurs in water, rather than in terrestrial nests. Natural embryonic mortality has not been measured for most salamanders that lay eggs on land, but experimental removal of attending parents in several species of plethodontid salamanders resulted in high mortality, much of it apparently due to predation (see chapter 11).

Larval Mortality

The larval period of aquatic-breeding amphibians generally is much longer than the egg stage, so the larvae are potentially exposed to many kinds of predators between hatching and metamorphosis. Many species probably are confronted with a choice of oviposition sites along a gradient from highly ephemeral rain pools to permanent ponds, lakes, and streams. There may be an optimum trade-off between the risk of predation in permanent sites and the risk of desiccation in temporary ones (Heyer, McDiarmid, and Weigmann 1975; Wilbur 1980; D. C. Smith 1983; Woodward 1983; Petranka 1984b; Banks and Beebee 1987a, 1988; A. H. Roth and Jackson 1987; Semlitsch 1987d). However, the persistence of ponds and the abundance of predators vary among breeding sites and from year to year at the same site (Shoop 1974; Petranka 1984b; D. C. Smith 1983; Stenhouse 1985a; Semlitsch 1987d; Banks and Beebee 1988). This makes it impossible for amphibians to anticipate the conditions under which larvae will develop (see chapters 13 and 15 for further discussion).

Mortality rates of larvae from hatching to metamorphosis are summarized in table 14.5. With the exception of a population of *Polypedates* from Malaysia and *Hemisus marmoratus* from West Africa, all of the species are from the temperate zone, but there is no reason to expect survivorship of tropical species to be very different. Mortality generally is very high, with less than 10% of hatchlings surviving to metamorphosis in most populations, but there is considerable year-to-year variation in mortality rates. In species with high embryonic mortality as well, survivorship from egg to metamorphosis can be less than 1%. While desiccation obviously is an important source of mortality in temporary ponds, predation also can be high in temporary water (e.g., *Bufo calamita, Hemisus marmoratus, Polypedates leucomystax, Ambystoma maculatum,* and *A. tigrinum*). Furthermore, there is no obvious difference in overall mortality rates among habitats; survivorship is low in permanent ponds, temporary ponds, and in streams.

In many larval populations, there is a dramatic decrease in population size soon after hatching (Herreid and Kinney 1966; Calef 1973a; Licht 1974; Cecil and Just 1979; Viertel 1980; Yorke 1983). This has led many authors to assume that amphibian larvae exhibit Type III survivorship curves—that is, a pattern in which age-specific mortality decreases rapidly with age (Deevey 1947). However, this interpretation results from confusion over arithmetic and logarithmic scales used to plot survivorship curves (Petranka 1985). In absolute terms, much of the mortality in a larval population

Table 14.5 Estimates of larval mortality in natural populations of amphibians, with the most likely major causes of mortality

Species (source no.)	Breeding habitat	Mortality (%)	Causes of mortality
Anurans			
Bufo bufo (10)	Permanent pond	80–98	Predation
B. calamita (8)	Temporary pond	99	Predation
B. calamita (18)	Temporary pond	95–99	Desiccation, predation
Crinia signifera (22)	Permanent pond	90	Predation
Hemisus marmoratus (24)	Temporary pond	1–36	Predation by turtles
Pelobates fuscus (23)[a]	Temporary pond	96–100	Unknown
Philoria frosti (15)	Temporary pond	70	Desiccation
Polypedates leucomystax (13)	Temporary pond	97	Starvation, predation
Pseudacris triseriata (12)	Temporary pools	0–100	Desiccation (small pools); predation (large pools)
Rana aurora (4)	Permanent lake	95	Predation
R. aurora (5)	Permanent pond	95–99	Predation
R. catesbeiana (9)	Permanent pond	82–87	Predation
R. pretiosa (5)	Permanent pond	93–99	Predation
R. sylvatica (2)	Temporary pond	95	Unknown
R. sylvatica (20)[a]	Temporary pond	92–99	Competition, predation, desiccation
Urodeles			
Ambystoma annulatum (21)[a]	Semipermanent pond	> 99	Predation
A. barbouri (14)	Permanent stream	94–99	Predation, floods, desiccation
A. maculatum (17)	Temporary pond	99	Desiccation, predation
A. maculatum (6)	Temporary pond	49–99	Desiccation
A. maculatum (19)	Temporary pond	96	Unknown
A. opacum (17)	Temporary pond	76	Desiccation
A. talpoideum (16)[a]	Temporary pond	96–100	Desiccation, predation
A. tigrinum (3)	Temporary pond	92	Predation
Hynobius nebulosus (11)	Permanent pond	80–99	Predation
Ranodon sibiricus (1)	Permanent stream	75	Unknown
Triturus vulgaris (7)	Permanent pond	91	Predation

[a] Estimates of total premetamorphic mortality from oviposition to metamorphosis, but most of the mortality usually is in the larval stage.

does occur early in development, but age-specific mortality rates remain relatively constant in most species (fig. 14.9). Hence, most species exhibit a Type II survivorship curve, as defined by Deevey (1947), not a Type III curve. This is true even though many studies have shown that individual larvae become less vulnerable to predation as they grow (see the following further discussion). However, population survivorship curves integrate all sources of mortality, not just predation, and therefore might not reflect a pattern predicted solely from the susceptibility of individuals to predation (Petranka 1985). The survivorship curves in fig. 14.9 are only for the larval portion of the life cycle. Since mortality rates generally are much lower for adults than for larvae, survivorship curves for the entire life span would more closely resemble a Type III curve (see the following).

Mortality of Metamorphosing Juveniles

Quantitative estimates of mortality rates in metamorphosing juveniles are almost impossible to obtain because the an-

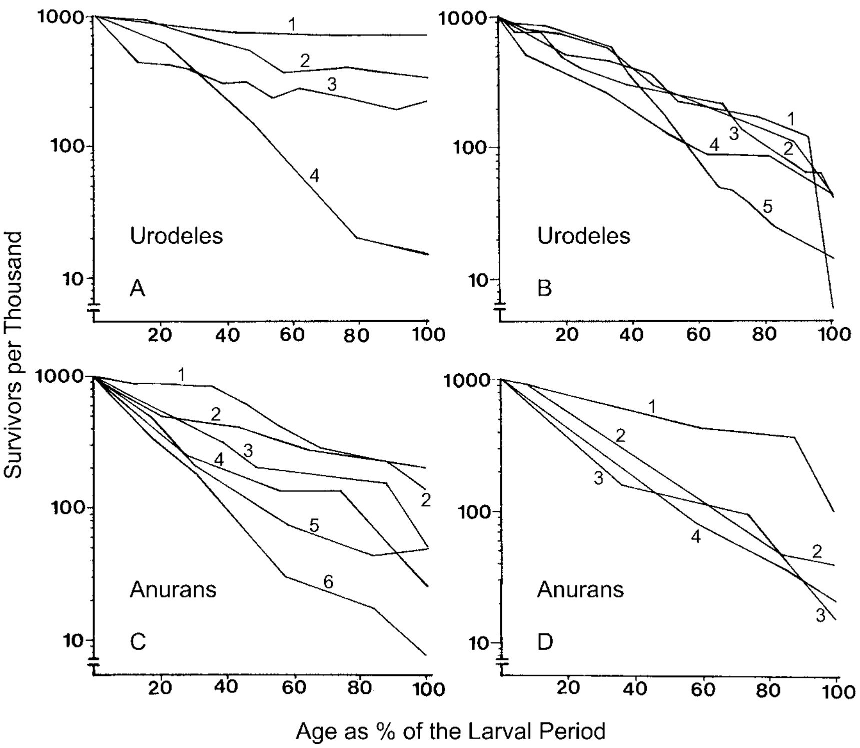

Fig. 14.9. Survivorship curves for several larval amphibian populations. (A) *Hynobius nebulosus* in four different years (1–4). (B) *Ambystoma barbouri* in three different years (1, 3, and 5) and two different cohorts of *Triturus vulgaris* from the same pond (2, 4). (C) Four species of anurans: *Polypedates leucomystax* (1), *Rana catesbeiana* (2), *Rana aurora* (3, 4), and *Rana pretiosa* (5). (D) Four populations of *Rana sylvatica* from Alaska. After Petranka (1985).

imals disperse soon after emerging from the water. Nevertheless, the period of metamorphic transformation appears to be a particularly risky stage for many species. The animals are small and slow moving, and aerobic capacities for sustained locomotion may be poorly developed (Taigen and Pough 1981; Pough and Kamel 1984). Metamorphosing anurans that have all four legs, but still retain much of the tail, are inferior to tadpoles in holding a position in the water and inferior to transformed individuals in jumping ability on land (Wassersug and Sperry 1977). When garter snakes (*Thamnophis sirtalis*) were presented with premetamorphic tadpoles and metamorphosing individuals of *Pseudacris triseriata,* they were much more effective at capturing metamorphosing frogs, even though they struck more often at the tadpoles (Wassersug and Sperry 1977).

The greater success of snakes in capturing metamorphosing frogs was reflected in their diets in the field, which consisted mainly of metamorphic stages (fig. 14.10). Similar results were obtained at several sites where *Bufo boreas* tadpoles were transforming; snakes were much more likely to consume metamorphosing frogs than premetamorphic stages (fig. 14.11; Arnold and Wassersug 1978). Metamorphosing frogs and toads also are vulnerable to a variety of other predators, including birds and mammals attracted to aggregations (Fitch 1958; Beasley and Carothers 1974; Tordoff 1980; Harestad 1985), invertebrates (Jackman et al. 1983; Crump 1984a), and even conspecific tadpoles (Crump 1986b). High mortality during metamorphosis may have been a major selective pressure favoring the evolution of short metamorphic transformation in many species (Szarski 1957; Wassersug and Sperry 1977; Downie, Bryce, and Smith 2004). In 12 species of anurans with a mean larval period of 62 days, the time spent in transformation averaged only about 9 days, or 15% of the larval period (Wassersug and Sperry 1977).

Adult Mortality

In contrast to aquatic larvae, which do not disperse from the breeding area until metamorphosis, adult amphibians are free to move to other areas. Consequently, it often is difficult to distinguish adult mortality from emigration. Even when adult survivorship can be estimated with some precision, it may be impossible to determine the causes of mortality. Predation usually is considered to be important, but the evidence generally consists of scattered observations of animals being eaten by predators, followed by lists of potential predators seen in the area (e.g., Martof 1956a; F. Turner 1960a; Heusser 1968b; Licht 1974). Other sources of adult

mortality, such as disease and winter kills (Kelleher and Tester 1969; R. D. Howard 1988a), often are ignored.

Survivorship of postmetamorphic individuals can be determined from recaptures of marked individuals, or by examining the age structure of the population. Mark-recapture studies have been most successful with species that return to the same pond each year to breed. Sometimes, most of the population can be collected by hand (e.g., Pearson 1955; F. Turner 1960a; Heusser 1968b; W. Brown and Alcala 1970; Licht 1974; Gittins 1983c) or intercepted with a drift fence surrounding the breeding pond (e.g., Husting 1965; G. Bell 1977; Gill 1985; Caldwell 1987; Kuhn 1994a). There are several potential sources of error in using mark-recapture data to calculate survivorship. The census effort may not be complete, so only part of the marked cohort is recaptured each year. Individuals may not return to the same breeding site and therefore will be lost from the recapture sample, or they may not breed every year, so surviving animals will not be counted in a short-term study. There may be sex differences in frequency of breeding, with one sex (often males) returning every year to breed, while the other returns less frequently, making comparison of male and female survivorship difficult.

Probably the first source of error, incomplete counting, is the one most commonly encountered in such studies. Some workers have simply equated "minimum survivorship" with the proportion of marked individuals recaptured in a subsequent year. However, if the probability of recapturing any surviving individual is substantially less than 100%, then these data almost certainly will underestimate actual survivorship, because marked individuals that are still alive will be missed by chance (Turner 1962). There are various statistical techniques available to adjust mark-recapture data for the probability of recapture and to use estimates of total population size to calculate annual survivorship (Seber 1973; Southwood 1978; Begon 1979), or to use capture-recapture data to model survivorship probabilities (K. Wood et al. 1998; B. Schmidt and Anholt 1999; Henle 2001, 2005; B. Schmidt, Schaub, and Anholt 2002; Schmidt, Feldmann, and Schaub 2005). Unfortunately, many studies of amphibian populations have not employed these techniques. Estimates of adult survivorship based on unadjusted recapture percentages (table 14.6) generally are quite low compared to corrected estimates (table 14.7). Interspecific comparisons of adult survivorship based on figures published in the literature can be quite misleading if the methods used to calculate survivorship are not considered (e.g., Duellman and Trueb 1986). Even the data in table 14.7 are not strictly comparable, because some studies used only relatively simple corrections for the probability of recapture, whereas others used more sophisticated statistical models to estimate survivorship (e.g., B. Schmidt, Schaub, and Anholt 2002).

Keeping in mind the limitations of the data, it appears that annual adult survivorship in medium to large amphibians sometimes is better than 50% and in some cases approaches 90%, although in harsh environments, year-to-year variation in adult survival can be considerable (e.g., Grafe et al. 2004). Estimates of annual survivorship in salamanders derived from the age structure of the population, rather than mark-recapture data, are similar. For example, estimated annual survivorship was 41% for *Eurycea wilderae* (Bruce 1988a), 81% for *Plethodon jordani* (Hairston 1983b), and 79% for *Salamandra luschani* (Olgun, Miaud, and Gautier 2001). Some small amphibians apparently have much lower annual survivorship than the medium to large species shown in table 14.7, but reliable data are scarce. Caldwell (1987) concluded that small *Pseudacris* are essentially annual species once they reach sexual maturity, with only a small fraction of the population surviving to a second breeding season. Age estimates for spring peepers (*P. crucifer*) in breeding choruses suggest that some adults survive to

(*continued*)

breed for two or three years, but most disappear after their first year (Lykens and Forester 1987; Zimmitti 1999). Small plethodontid salamanders, however, sometimes live longer than do larger species. Estimated annual survivorship of small species of *Desmognathus,* such as *D. wrighti, D. ocoee,* and *D. orestes,* was higher than for larger and more aquatic species such as *D. monticola* and *D. fuscus* (table 14.7).

Most of the data in table 14.7 are for temperate-zone species. Data for tropical species are scarce, but there is some evidence that even relatively large tropical anurans suffer much higher rates of predation than do temperate-zone amphibians. For example, Kluge (1981) never recaptured an adult male *Hyla rosenbergi* in two successive years, and he concluded that many individuals lived for only a few months after entering a breeding chorus. The population appeared to be under heavy pressure from a variety of predators, including snakes, caimans, mammals, and larger frogs. Similarly, most adults survived for less than a year in a population of *Leptodactylus pentadactylus* from Brazil (Galatti 1992) and a population of *Rana vaillanti* from Mexico (Ramirez, Vogt, and Villarreal-Benitez 1998). In contrast, many North American ranids of similar size live up to 10 years (see the following). The reasons for the low survivorship of these relatively large frogs are unclear, but the abundance of tropical snakes that feed mostly on frogs probably contributes to high mortality (Vitt and Vangilder 1983; Greene 1988; Cadle and Greene 1993). Some small African frogs (*Phrynobatrachus* and *Arthroleptis*), which are about the same size as *Pseudacris,* apparently live only two to seven months after reaching sexual maturity (Barbault and Trefaut Rodrigues 1978b, 1979a, b; Barbault and Pilorge 1980). Adult mortality has been attributed mainly to predation (Barbault 1984, 1987), but the evidence is circumstantial. In tropical savannas, adults of some small species have difficulty surviving the severe dry season (Geise and Linsenmair 1986; Rödel 1996), so physi-

[b]Survivorship of females only.

[c]Recaptures not adjusted for probability of recapture, but census is relatively complete.

cal factors alone could result in nearly annual turnover in the population.

The data discussed so far provide an estimate of overall adult survivorship, but not age-specific mortality. The latter can be estimated from mark-recapture data if the ages of marked individuals are known (e.g., F. Turner 1960a; Tilley 1980; Gill 1985). More commonly, age-specific survivorship is estimated by constructing a life table based on the age distribution of the population (e.g., Organ 1961a; Briggs and Storm 1970; Danstedt 1975; G. Bell 1977; Hairston 1983b; Gibbons and McCarthy 1984; Khonsue, Matsui, and Misawa 2002; Marunouchi, Kusano, and Ueda 2002). The disadvantage of this method is that it assumes a stable population size and a stable age distribution. Hence, the method is inappropriate for many aquatic-breeding species that experience boom or bust population cycles, with high recruitment of juveniles in some years and virtually no recruitment in others (e.g., Shoop 1974; Semlitsch 1983b, 1987d; Caldwell 1987; Stenhouse 1987). This method is more appropriate for some terrestrial salamanders that have relatively stable populations (Hairston 1983b, 1987).

For many years, one difficulty in estimating age-specific survivorship was the lack of reliable methods to age adult amphibians (F. Turner 1962; Halliday and Verrell 1988). Traditionally, most workers estimated ages from size distributions, coupled with growth rates of marked individuals (e.g., Briggs and Storm 1970; G. Bell 1977; Hairston 1983b; Shirose et al. 1993; Shirose and Brooks 1995a, b). In some salamanders, males can be crudely aged from the number of lobes on the testes (Organ 1961a; Danstedt 1975; Bruce 1976), but the relationship between age and number of testis lobes is not very precise (Tilley 1977). The best technique is the use of growth rings on bones to age adults. These rings form due to slower growth at certain seasons of the year, either during the winter or in extended dry periods. Bone growth rings can be counted in most temperate-zone species and in tropical frogs that live in regions with distinct wet and dry seasons, but they may not be visible in tropical species that live in continuously wet habitats.

This technique has been available for some time and is now widely used for studies of amphibian populations (Senning 1940; Schroeder and Baskett 1968; Kleinenberg and Smirina 1969; Barbault et al. 1979; Francillon 1979; Castanet and Pilorge 1980; Hemelaar 1981, 1983, 1985; Hemelaar and van Gelder 1980; Dolmen 1982a; Gittins, Steeds, and Williams 1982; Gibbons and McCarthy 1984; and references cited in table 14.8). It is particularly useful when phalanges can be used for aging, because these can be removed without killing the animal, allowing the same animals to be used for aging and for mark-recapture studies. In many amphibian populations, mortality appears to be relatively constant across all age classes of adults (Hairston 1987; Galatti 1992; Jehle, Hödl, and Thonke 1995), indicating that most species have Type II adult survivorship curves (Deevey 1947). In some cases, however, smaller, and presumably younger, individuals suffer higher mortality than do larger, older individuals (Shirose and Brooks 1995a).

If predation is an important source of mortality, then one might expect mortality to be higher in the sex that is most conspicuous to predators or in the poorest condition because of energy expenditures during the breeding season. For example, predators such as bats, possums, and frogs are known to locate male frogs by their calls (see previous discussion and chapter 7), so one might expect to find higher rates of mortality in male than in female frogs. The opposite pattern might be expected in many salamanders, because males of most species do not have conspicuous signals equivalent to frog calls, and females probably expend more energy in reproduction (see chapter 10).

In fact, it is hard to generalize from the existing data. A fairly common pattern in skeletochronological studies of age structure in large ranid frogs is for females to be slightly older than males (e.g., Khonsue et al. 2001a, b; Marunouchi, Kusano, and Ueda 2002), but this is not always the case (e.g., Khonsue, Matsui, and Misawa 2002). The same pattern was found in several subtropical hylid frogs from Australia and a myobatrachid frog (Morrison, Hero, and Browning 2004). It is not always clear, however, that sex differences in maximum age can be attributed to differential predation on males. Similar studies of salamanders often reveal relatively little difference in age, if any, between males and females (e.g., Lima, Arntzen, and Ferrand 2000; Miaud, Guyétant, and Faber 2000), but there also are populations in which females apparently live longer than males (e.g., *Salamandra luschani:* Olgun et al. 2001) and others in which males apparently live longer than females (e.g., *Desmognathus monticola* and *D. quadramaculatus:* Bruce, Castanet, and Francillon-Vieillot 2002; *Euproctus platycephalus:* Bovero et al. 2003). In none of these cases are the causes of sex differences in logevity understood.

Mark-recapture studies have sometimes been used to estimate differences in age-specific mortality between the sexes, although many of these studies have not corrected for possible sex differences in recapture probabilities. Males appeared to have higher age-specific mortality rates in populations of *Rana pretiosa* (Licht 1974), *Rana catesbeiana* (Shirose et al. 1993), *R. grylio* (K. Wood et al. 1998), and *Triturus vulgaris* (G. Bell 1977). Apparent female mortality was higher in *Rana cascadae* (Briggs and Storm 1970), *Ambystoma maculatum* (Husting 1965), some populations of *Notophthalmus viridescens* (Gill 1985), and several species of *Desmognathus* (Organ 1961a). Female mortality also appeared to be slightly higher for populations of *Triturus dobrogicus* and *Pelobates fuscus* in Austria, although not consistently so in all years (Jehle, Hödl, and Thonke 1995). There was no apparent difference in male and female mortality in some populations of *Desmognathus* (Tilley 1980), a population of *Rana luteiventris* (F. Turner 1960a), and a population of *Rana temporaria* (Gibbons and McCarthy 1984). Several studies of frogs provide evidence that reproductive activities expose males to higher levels of predation than females. Caldwell (1987) found that survivorship of male *Pseudacris* was much lower than that of females, but only in years when the population was actually breeding. Calderón and Collado (1976) compared the sizes of adult *Rana ridibunda* captured by barn owls (*Tyto alba*) with sizes in natural populations and found that the owls preyed selectively on male frogs, possibly because they were attracted to their calls. In a study of agile frogs (*Rana dalmatina*) in France, Lodé et al. (2004) reported that polecats (*Mustela putorius*) took a much higher toll on males in breeding choruses than on females, resulting in shifts in the sex ratio that altered male mating tactics.

Many amphibians are surprisingly long-lived for such small animals. Large anurans in the temperate zone, many of which do not become sexually mature until they are several years old, often have maximum life spans of five to ten years, while smaller frogs have maximum life spans of about four years (table 14.8). Even relatively small frogs that are well protected against predators by toxic skin secretions may have very long life spans. For example, Płytycz and Bigaj (1993) estimated that some yellow-bellied toads (*Bombina bombina*) live as long as 20 years in the wild. Highly toxic newts and other salamandrids also tend to have long life spans, with many species reaching maximum ages of 12–15 years, and some living as long as 20 years (table 14.8). More surprising is the relatively long life span of plethodontid salamanders, many of which live at least 10–12 years (table 14.8). Some species, such as members of the *Plethodon jordani* and *P. glutinosus* complexes, are well protected by

[a] Maximum longevity calculated from life table data.

noxious skin secretions, but others, such as *Desmognathus,* do not have such skin secretions and are readily eaten by many predators. Their surprisingly long life spans probably are related to their cryptic behavior, which reduces exposure to predators.

Average life expectancies for all of these amphibians are much shorter than the maximum life spans in table 14.8, because only a small percentage of adults will reach these advanced ages. Nevertheless, when compared to other terrestrial vertebrates, life expectancies of many amphibians are impressive. Annual adult survivorship of temperate-zone passerine birds is about 25–80% and averages about 50%; maximum life spans of many species are between 5 and 15 years, similar to those recorded for amphibians (Dorst 1974). Annual survivorship of adult snakes also is relatively high (35–80%), with an average of about 60% and maximum life spans of 4–20 years (W. Parker and Plummer 1987). Annual survivorship of small lizards (< 50 g) generally is much lower (0–83%, average = 28%, $N = 44$), and it is rare for individuals to live more than five years (F. Turner 1977). This figure may be somewhat biased by an overrepresentation of desert-dwelling lizards in the sample. Compared to amphibians, small mammals such as rodents and insectivores are extremely short-lived. Life spans generally are measured in months rather than years. It is rare for more than 10–15% of an adult population to survive one year (French, Stoddart, and Bobek 1975; Fleming 1979), although some tropical rodents have annual survivorship rates as high as 35–45% (Fleming 1975). Given the relatively high rates of survivorship and long life expectancies of some amphibians, it is worth reconsidering whether amphibians really are the "cannon fodder of the animal kingdom," as suggested at the beginning of this chapter (M. Tyler 1976). R. Savage (1961) argued many years ago that frogs lead relatively safe lives as adults compared to other terrestrial vertebrates, despite many statements in the literature to the contrary. Indeed, the real question is how amphibians manage to live so long despite their apparent vulnerability to the vast numbers of predators that feed on them. The final section of this chapter focuses on this question.

Evolutionary Responses to Predation

As mentioned at the beginning of this chapter, predation has been an important selective force in the evolution of many behavioral and life-history traits of amphibians (table 14.1). Several of these are discussed in more detail in other chapters. These include the influence of predation on anuran vocal behavior (chapter 7), egg size and clutch size (chapter 10), parental care (chapter 11), aggregation of aquatic larvae (chapter 12), the length of the larval period and the timing of metamorphosis (chapter 13), and the organization of amphibian communities (chapter 15). The final section of this chapter focuses on adaptations that reduce the vulnerability of amphibians to predation at different stages of the life cycle.

Protection of the Eggs

One might expect amphibian eggs to be particularly vulnerable to predation, because they are small and relatively unprotected, and they cannot move to escape from predators. Yet embryonic survivorship can be surprisingly high in many species. The vulnerability of amphibian eggs to predators depends in part on the types of predators present in the breeding habitat. Some predators may not be very good at finding amphibian eggs because of the sensory modes and foraging tactics used to acquire food. For example, dragonfly naiads that are visually oriented sit-and-wait predators probably are not major predators on amphibian eggs. Actively foraging dytiscid beetle larvae, on the other hand, often use chemical cues to detect prey, and have little difficulty locating and consuming amphibian eggs (Resetarits 1998). Other active predators, such as leeches, caddisfly larvae, crayfish, freshwater shrimp, fish, tadpoles, salamander larvae, and newts, probably can readily find amphibian eggs, especially if they rely on chemical cues to locate prey. Some of these predators may be deterred by protective adaptations of the eggs, including chemical defenses and mechanical defenses of the egg capsule and the surrounding jelly.

Chemical and Mechanical Defenses

Some amphibian eggs contain toxic or distasteful compounds that deter predators, but the effectiveness of these chemical defenses depends on the predator. For example, eggs of *Rana clamitans* and *R. catesbeiana* are distasteful to newts (*Notophthalmus viridescens*) and larval ambystomatids (Walters 1975), but are readily consumed by leeches (R. D. Howard 1978b). The eggs of some species of *Bufo* contain toxic and distasteful chemicals that repel fishes (Licht 1968), but mosquitofish (*Gambusia*) can eat *Bufo valliceps* eggs with no ill effects (Grubb 1972). Some toad eggs also appear to be distasteful to salamander larvae and newts (Walters 1975; Denton and Beebee 1991), but others are readily consumed by anuran tadpoles (Heusser 1970, 1971b; Heyer, McDiarmid, and Weigmann 1975; Wells 1979; Banks and Beebee 1987b). The eggs of *Bufo marinus,* which has been introduced into Australia, are sufficiently toxic to kill the tadpoles of many native frogs. These species appear to have little behavioral avoidance of these toxic eggs, so *Bufo marinus* represents a serious threat to these frogs (Crossland 1998b; Crossland and Alford 1998). Many invertebrate predators, such as crayfish and insects with sucking mouthparts, seem not to be strongly deterred by the chemical defenses of toad eggs (Henrikson 1990; Axelsson et al. 1997). The chemical defenses of newt eggs (*Taricha*) also seem to be ineffective against crayfish (Gamradt and Kats 1996).

Even when eggs lack chemical defenses, they may derive some protection from egg capsules (Salthe 1963) and the jelly surrounding the egg mass. Grubb (1972) found that frogs breeding in permanent water (*Rana pipiens* and *Acris crepitans*) had larger, tougher egg capsules than species breeding in temporary water (*Scaphiopus couchii, Pseudacris clarki, Gastrophryne olivacea,* and *Hyla chrysoscelis*) and were eaten less frequently by mosquitofish. Unfortunately, this comparison is confounded by phylogenetic differences among the species examined, as well as differences in water temperature and oxygen availability that might affect egg structure (see chapters 4 and 10). The thick jelly coats surrounding the egg masses of some ranid frogs and ambystomatid salamanders provide good protection against predation by fishes and various invertebrates, whereas isolated eggs are quickly consumed (Werschkul and Christensen 1977; Ward and Sexton 1981). Thick jelly coats provide little protection against adult newts, which can rip individual eggs out of the masses (Morin 1983b). Caddisfly larvae also make short work of the jelly surrounding egg mass of *Ambystoma maculatum* (personal observations).

Choice of Oviposition Sites

Many amphibian eggs lack both chemical and mechanical defenses. In these species, predation may be an important selective force influencing choice of oviposition sites by females. For example, many species of frogs appear to be limited to reproduction in temporary ponds because their eggs and tadpoles are highly palatable to predators in permanent ponds, especially fish (Licht 1969c; Grubb 1972; Walters 1975; Brönmark and Edenhamn 1994; Alford 1999). Even for species that breed only in temporary ponds, eggs may be in danger from a variety of predators, including invertebrates, tadpoles, salamander larvae, and newts. Consequently, females that can detect the presence of potential predators and avoid laying eggs in sites with predators should have an advantage over females that choose oviposition sites at random. Several investigators have tried to assess the ability of females to detect predators in potential oviposition sites.

In one of the first such studies, Resetarits and Wilbur (1989, 1991) studied the choice of oviposition sites by female *Hyla chrysoscelis* and the choice of calling sites by males. They used an array of artificial ponds (cattle tanks) placed in close proximity to one another. Some of the tanks contained predators and others did not. Resetarits and Wilbur found males were less likely to call in tanks inhabited by black-banded sunfish (*Enneacanthus chaetodon*) and by conspecific tadpoles than in control tanks without predators, but did not avoid tanks with *Ambystoma maculatum* larvae, newts (*Notophthalmus viridescens*), ranid tadpoles, or dragonfly naiads (*Tramea*). They also found fewer eggs in tanks with fish and those with *Ambystoma* larvae, and concluded that females avoided laying eggs in sites inhabited by these predators. Resetarits and Wilbur did not observe the movements of females or pairs in amplexus, nor did they observe actual oviposition. Their experimental design was criticized by Ritke and Mumme (1993), who argued that the individual cattle tanks probably were not treated as separate ponds by the frogs, but as subsections of one large breeding area. The experiment also is somewhat flawed because it used an indirect measure of oviposition site choice, the number of eggs seen in the ponds, rather than direct behavioral observations of females. There is a possibility that some eggs laid in tanks containing predators were consumed before the tanks were checked in the morning.

Crump (1991) conducted a similar experiment with a Neotropical frog, *Hyla pseudopuma.* She found that females laid more eggs in artificial pools without predators (conspecific tadpoles) than in those with predators. She also tested for predation of eggs by tadpoles and found that empty jelly capsules always remained as evidence of a predation event. Her results indicate that females can detect conspecific tadpoles in small pools and avoid depositing eggs in those pools. Females of an African ranid frog, *Hoplobatrachus occipitalis,* also avoid laying eggs in pools inhabited by conspecific tadpoles, which are highly cannibalistic (Spieler and Linsenmair 1997). Natural rock pools that already contained tadpoles were not used as oviposition sites, nor were experimental pools supplied with tadpoles. Females of this species not only could detect potentially cannibalistic tadpoles, but they differentiated between these tadpoles and herbivorous tadpoles (*Ptychadena maccarthyensis*) that did not pose a threat to their offspring. The presence of high densities of herbivorous tadpoles did not deter oviposition by females, whereas low densities of conspecific tadpoles did. These investigators had some evidence that predatory tadpoles are detected by chemical cues in the water, but more experimental work is needed to confirm this. Similar avoidance of pools with conspecific tadpoles has been reported for *Pleurodema borellii* from Argentina (Halloy and Fiaño 2000).

Another anuran that tends to avoid laying eggs in pools containing predatory tadpoles is the American toad (*Bufo americanus*). This species normally breeds in pools that lack predators such as fish (Holomuzki 1995), but the same sites sometimes are used by wood frogs (*Rana sylvatica*), which breed earlier in the spring. Wood frog tadpoles are voracious predators of the eggs and young tadpoles of *Bufo americanus.* Petranka, Hopey, Jennings, Baird, and Boone (1994) demonstrated that the toads always avoided laying eggs in experimental ponds that contained wood frog tadpoles, but readily laid eggs in identical nearby ponds that lacked tadpoles. When toad eggs were placed in experimental or natural ponds containing wood frog tadpoles, the toad eggs and tadpoles were virtually eliminated within a few days.

Several studies have tested the ability of female frogs to avoid breeding sites inhabited by predatory fish. Wood frogs (*Rana sylvatica*) never laid eggs in experimental ponds containing predatory sunfish (*Lepomis auritus*), but did use nearby fish-free ponds (Hopey and Petranka 1994). Adult frogs were seen in both types of ponds, but males were much more likely to call in ponds without fish. This suggests that males tend to avoid sites with predators, and female choice of oviposition sites probably is influenced in part by where males are calling. Binckley and Resetarits (2002) found that squirrel treefrogs (*Hyla squirella*) avoided using cattle tanks containing banded sunfish (*Enneacanthus obesus*) as oviposition sites, even though the fish were enclosed and therefore unable to prey on eggs or tadpoles. In a similar set of experiments with *Hyla chrysoscelis,* females chose among cattle tanks without fish or with one of five different species of fish in enclosures. Females avoided tanks with four of the fish species, but not one species that apparently is not a serious threat to their eggs (Binckley and Resetarits 2003). Not all frogs can avoid potential egg and tadpole predators, however. The European common frog (*Rana temporaria*) is ecologically similar to the North American wood frog. On an island in Finland, this species breeds in shallow rock pools. Some of these pools are inhabited by threespine sticklebacks (*Gasterosteus aculeatus*), which prey on tadpoles (Laurila 1998). Nevertheless, the frogs did not show any tendency to avoid pools into which sticklebacks had been introduced (Laurila and Aho 1997).

Among dendrobatid frogs, the presence of predators can affect choice of either oviposition sites or tadpole deposition sites. For example, females of *Dendrobates ventrimaculatus,* which breed in leaf axils, avoided sites that contained cannibalistic conspecific tadpoles in pools below potential oviposition sites (Summers 1999b). Downie, Livingstone, and Cormack (2001) reported that males of *Mannophryne trinitatis* avoided depositing tadpoles in pools containing fish (*Rivulus*) or freshwater shrimp (*Macrobrachium*). In some populations, males that were given only pools with predators actually deposited tadpoles in wet leaf litter in preference to pools. Prior evolutionary history with predators appeared to influence responses of the frogs. In areas where shrimp were uncommon, males deposited tadpoles in pools with shrimp, but not in pools with fish.

Some salamanders are able to detect and avoid predators in potential oviposition sites. Species such as *Ambystoma talpoideum* and *A. texanum* scatter eggs on the bottom of a pond. The eggs are highly vulnerable to fish predation, as are the larvae, and these species appear to be excluded from reproducing in sites inhabited by fishes (Petranka 1983; Semlitsch 1988). *Ambystoma barbouri* is one of the few North American ambystomatids to breed in streams, which often are inhabited by predatory fishes. Surveys of natural stream pools in Kentucky revealed that salamander eggs were much more likely to be laid in stream pools without fish than in those with fish. When the fish in one stream were killed by drought, pools that had contained fish in the previous year subsequently lacked fish and were then readily used by salamanders for oviposition (Kats and Sih 1992). Another stream-breeding salamander is the California newt (*Taricha rivularis*). The presence of introduced crayfish (*Procambarus clarkii*) in streams inhibits reproduction by the newts. In this case, the mechanism of predator detection is clear, because the crayfish aggressively attack adult newts, even though they are well protected by poisonous skin secretions (Gamradt, Kats, and Anzalone 1997).

Few investigators have considered the effects of variation among oviposition sites within breeding areas on predation of embryos. An exception is R. D. Howard's (1978b) study of *Rana catesbeiana* in a pond in Michigan. He found that eggs deposited in warm water developed more rapidly than those deposited in cooler water, and they were subjected to lower levels of leech predation. Hence, the quality of oviposition sites defended by males became a major determinant of mate choice by females (see also chapter 8). In other species, females may reduce predation on their eggs by scattering them in mud on the bottom of a pond or concealing them in vegetation. For example, the eggs of *Pseudacris crucifer* and *P. cadaverina* are attached individually to underwater plants (Gosner and Rossman 1960; Gaudin 1965), a mode of oviposition that presumably makes it difficult for predators to locate the eggs. Both North American and Eurasian newts (*Notophthalmus, Triturus*) wrap their eggs individually in folded leaves (S. Bishop 1941b; Steward 1969; Walters 1975). This has been shown to reduce rates of predation on eggs of *Triturus* (Miaud 1993).

Timing of Reproduction

The timing of reproduction also may affect the survival of embryos. Heusser (1970, 1971b) suggested that predation by conspecific tadpoles favors synchronized reproduction in some frogs such as *Rana temporaria,* because earlier hatching tadpoles often consume eggs that are deposited late in the season. Petranka and Thomas (1995) tested this hypothesis by exposing wood frog (*Rana sylvatica*) eggs to conspecific tadpoles that had hatched earlier in the season. Many of the eggs were destroyed by cannibalism. Beringhausen (1998) questioned the generality of this explanation for the evolution of explosive breeding. He found relatively little evidence of predation on eggs by tadpoles of several European anurans. In most cases, the eggs seemed to be well protected from tadpole predation by jelly capsules. Nevertheless, as discussed earlier in this chapter, it is clear that tadpoles of many European anurans are fully capable of consuming eggs of their own or other species.

Cannibalism by conspecific tadpoles need not be the only selective pressure favoring explosive breeding in anurans. The presence of heterospecific predators could favor synchronous breeding as well. Walters (1975) proposed that explosive breeding is advantageous in swamping predators, thereby increasing the probability of survival for individual eggs. This would occur if the number of eggs deposited simultaneously were too large to be consumed by the resident predator population. A similar explanation was offered for the highly explosive breeding behavior of *Bufo alatus* (formerly *B. typhonius*), a tropical toad that breeds in permanent water and does not seem to be stimulated by rainfall or other environmental cues (Wells 1979). These tadpoles are subject to predation by the voracious tadpoles of *Leptodactylus pentadactylus.* Explosive breeding in early spring may allow some species to get through the egg stage before populations of predatory invertebrates or salamander larvae reach peak densities (Wilbur 1972; Wells1977a; Majecki and Majecka 1996; Alford 1999; see chapter 8 for further discussion of explosive breeding in anurans).

Adaptive Plasticity in Hatching of Eggs

Warkentin (1995) described an unusual form of plasticity in hatching time in the eggs of *Agalychnis callidryas,* a tropical tree frog that lays eggs on leaves over water, where they are frequently preyed upon by cat-eyed snakes (*Leptodeira;* fig. 14.4 A). Once the eggs have reached a stage where they can survive independently in the water, they will hatch almost immediately if a clutch is attacked by a snake (fig. 14.12). Many of the tadpoles survive the snake attack by dropping into the water. This comes at a cost, however, because these early-hatching tadpoles are relatively small and not very mobile, and are therefore vulnerable to predation by aquatic predators such as freshwater shrimp (fig. 14.13). Nevertheless, such plasticity in hatching time is favored, because the tadpoles trade almost certain death from a predatory snake against a somewhat higher chance of surviving in the water. *Agalychnis* eggs exhibit similar plasticity in hatching in response to predation by wasps (*Polybia rejecta*), but in this case, the predator attacks individual eggs and usually only

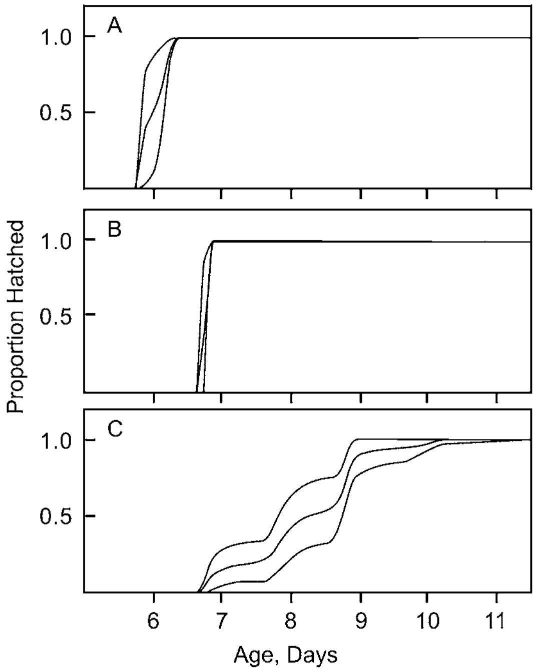

Fig. 14.12. Timing of hatching of egg clutches of *Agalychnis callidryas* with and without snake predation. (A) Eggs attacked by a snake (*Leptodeira septentrionalis*) at day 5. (B) Eggs attacked by a snake at day 6. (C) Control egg clutches that were not attacked. Snake attacks induced earlier and more synchronous hatching than that seen in control clutches. After Warkentin (1995).

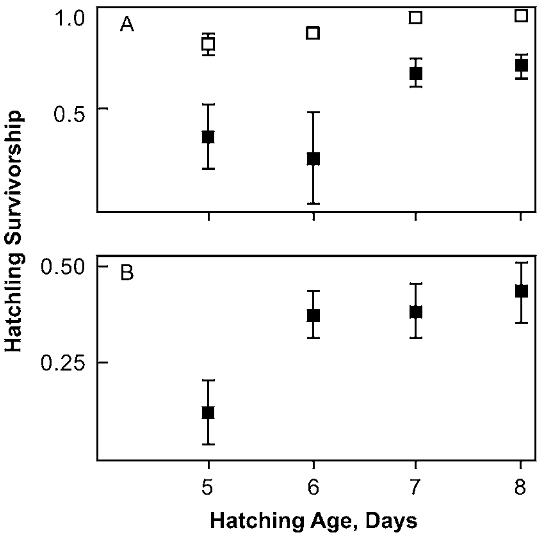

Fig. 14.13. Survivorship of hatchling *Agalychnis callidryas* tadpoles as a function of tadpole age in the presence of aquatic predators. (A) Survivorship of tadpoles with small shrimp (*Macrobrachium americana;* open squares) and large shrimp (solid squares). (B) Survivorship with fish (*Brachyraphis rhabdophora*). Large hatchlings are more likely to survive with both types of predators than are small hatchlings. After Warkentin (1995).

single embryos hatch in response to the predation attempt (Warkentin 2000b). This type of response is not limited to animal predators that create a mechanical stimulus that can trigger early hatching. *Agalychnis* eggs also will hatch early in response to infection with a pathogenic fungus. Eggs that are closest to the fungal infection hatch first, presumably responding to some sort of chemical cue (Warkentin, Currie, and Rehner 2001). Eggs of another tropical frog, *Hyperolius spinigularis,* from East Africa, are subject to predation by other frogs (*Afrixalus fornasini*) and ephydrid flies (*Typopsilopa*). They also exhibit plasticity in hatching, with embryos subjected to predator attacks hatching up to three to four days early and at sizes 20–30% smaller than embryos that complete normal development (Vonesh 2005a).

Embryos of the stream-breeding salamander *Ambystoma barbouri* also exhibit adaptive plasticity in time of hatching, but in this case, hatching is delayed in the presence of aquatic predators that threaten newly hatched larvae. One such predator is a free-living flatworm (*Phagocotus gracilis*), which feeds on newly hatched larvae, but cannot catch older larvae. When salamander eggs were exposed to flatworms, or chemical extracts from flatworms, they hatched later than those not exposed to these stimuli. Larvae emerging from delayed-hatching eggs not only were larger than control larvae, but also hatched at a more advanced stage (Sih and Moore 1993). The eggs of *A. barbouri* also hatch later and at a more advanced stage when exposed to chemical cues from green sunfish (*Lepomis cyanellus*), which are even more voracious predators on the larvae (R. Moore, Newton, and Sih 1996). In contrast, exposure to cues from dragonfly naiads (*Anax junius*), a potential larval predator, had little effect on hatching time in spotted salamanders (*Ambystoma maculatum*), wood frogs (*Rana sylvatica*), or southern leopard frogs (*Rana sphenocephala;* A. R. Anderson and Petranka 2003; J. B. Johnson et al. 2003). Embryos of *R. sphenocephala* did exhibit accelerated hatching in response to crayfish (*Procambarus nigrocinctus*), which are efficient egg predators (J. B. Johnson et al. 2003).

Defenses of Larvae

Once an amphibian hatches from its egg, it often is exposed to a host of aquatic predators. As discussed previously, rates of mortality usually are much higher for larvae than for eggs. In part this is because the larval period is much longer than the period of egg development, but it also is due to the movements of larvae, which are necessary for finding food. The vulnerability and prolonged exposure of amphibian larvae to a wide variety of predators favors the evolution of defensive strategies that reduce the effectiveness of predators. One way to do this is to reduce the likelihood that predators will detect prey in the first place. This can be achieved by means of cryptic coloration that reduces the visibility of a prey species, by active detection and avoidance of dangerous predators, or by behavioral changes that reduce vulnerability to predators. Some tadpoles may simply flee from predators, and natural selection will tend to enhance morphological or physiological traits that are correlated with speed or maneuverability. Rapid growth can be a defense against predators as well, because tadpoles may reach a size that makes them less vulnerable to the most common predators in their habitats. Some larvae also are protected by chemical defenses, and in some cases, advertise their distastefulness with aposematic coloration.

Color Patterns

For most amphibian larvae, cryptic coloration probably is the first line of defense against visually hunting predators. Amphibian larvae in general are not very colorful. Most species have background coloration in various shades of brown, gray, or green, often with mottling, spots, and other markings that match the background of their environments (see illustrations in chapter 12). Some larvae are countershaded, with lighter coloration on the ventral than on the dorsal surface. Many larvae, especially anuran tadpoles, exhibit general features of disruptive coloration that tend to break up the outline of the body or obscure key features such as the eyes. Disruptive color patterns include vertical bars or saddles on the body and tail, and stripes on the body, tail, or around the eye (Altig and Channing 1993). Midwater suspension feeders, including tadpoles of *Xenopus, Rhinophrynus,* and many microhylids and phyllomedusine hylids, often have light, highly reflective coloration or are nearly transparent. Some amphibian larvae have a limited ability to change color to match the reflectance of the background (Altig 1972b; Fernandez and Collins 1988), but color change is less common than in adult amphibians.

Storfer et al. (1999) examined the adaptive value of cryptic coloration in larvae of a salamander, *Ambystoma barbouri.* This species is found both in relatively permanent streams inhabited by predatory fish and in more ephemeral streams that lack fish. Larvae from streams with fish are lighter in color than those from fish-free streams, and behavioral experiments showed that fish could detect dark larvae more easily against a background of silt-covered rocks (fig. 14.14). There is variation in coloration among larvae in streams with fish, however, with some individuals being darker than are others. Some of this variation is due to periodic gene flow from nearby populations in fish-free streams, where darker coloration seems to be favored. The benefits of dark coloration in the absence of predators are not known, but may include thermoregulatory benefits, reduced exposure to ultraviolet radiation in shallow water, or better protection from terrestrial predators.

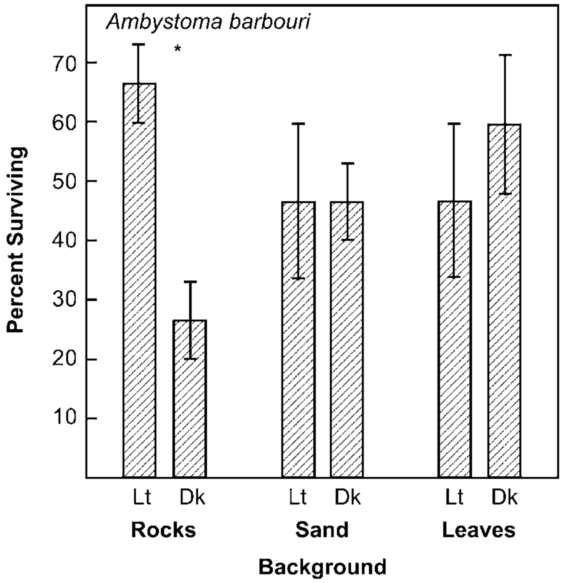

Fig. 14.14. Survivorship of salamander larvae (*Ambystoma barbouri*) of light- and dark-color morphs with fish predators against different backgrounds in laboratory aquaria. Light-colored larvae have an advantage over dark-colored larvae against a rock background resembling that of natural streams where the larvae are found. * indicates a significant difference. After Storfer et al. (1999).

Some tadpoles have markings that appear to serve as deflection marks that redirect attacks of predators toward the tail and away from the body and head (Van Buskirk et al. 2004). These include black tail tips, ocelli (fake eyes), and bright coloration (Caldwell 1982, 1986a; Altig and Channing 1993; McCollum and Van Buskirk 1996; McCollum and Leimberger 1997; Van Buskirk and McCollum 1999). Tadpoles often suffer considerable damage to tails without adverse effects on growth and survivorship (Semlitsch 1990; Wilbur and Semlitsch 1990; Figiel and Semlitsch 1991), although this is not always true (Parichy and Kaplan 1992). In many species, the tip of the tail is the area most likely to be injured, and this is the area that has the least effect on swimming performance (J. Blair and Wassersug 2000). Even if tail injury is somewhat costly, it is likely to be less so than attacks on other parts of the body, most of which are likely to be fatal (Van Buskirk et al. 2003).

Phenotypic Plasticity

Anuran tadpoles exhibit considerable variation in color pattern, even within species. There are a number of examples of ontogenetic changes in color pattern that apparently are related to changes in microhabitat use or vulnerability to predators as tadpoles grow (Caldwell, Thorp, and Jervey 1980; Altig and Channing 1993). In some species, tadpoles differ in color depending on the habitat in which they live. Tadpoles that live in streams may differ in color from conspecifics living in ponds, or those living in clear water may differ from those in murky water. In cricket frogs (*Acris*), black tail tips are most common in populations inhabiting temporary ponds, where dragonfly naiads are the principal predators. Tadpoles living in permanent ponds with fish are more likely to have clear tails (Caldwell 1982). Tadpoles of a Neotropical frog, *Rana palmipes,* have darker coloration on the tail in the presence of predatory water bugs (McIntyre, Baldwin, and Flecker 2004).

Some of this variation in color pattern represents phenotypic plasticity that is induced by direct contact with predators. Tadpoles of gray treefrogs (*Hyla chrysoscelis* and *H. versicolor*) and pinewoods treefrogs (*H. femoralis*) often have deep tail fins with bright orange coloration and dark spots when they live in ponds with dragonfly naiads, but tend to have shallower, unmarked tail fins when such predators are absent (Van Buskirk and McCollum 1999; LaFiandra and Babbitt 2004; fig. 14.15). When tadpoles of *Hyla chrysoscelis* were exposed from an early age to free-ranging dragonfly naiads or to naiads in cages, they gradually developed the phenotypic traits typical of tadpoles in predator-rich ponds (fig. 14.16). In contrast, control tadpoles not exposed to predators retained the phenotype typical of those in predator-poor ponds. Tadpoles that were reared with predators also were less active and spent less time feeding than did those in predator-free treatments, but growth rate was affected only if tadpoles were exposed to free-ranging predators (McCollum and Van Buskirk 1996). Morphological and behavioral responses of *Hyla versicolor* tadpoles change with developmental stage, with younger tadpoles being more likely to alter behavior and older tadpoles being more likely to alter morphology. Nevertheless, there do not appear to be strict developmental windows that constrain the expression of morphological plasticity, because changes in morphology can be induced at almost any developmental stage and are reversible if predators are removed (Relyea 2003c), a pattern seen in other anurans as well (Kishida and Nishimura 2004).

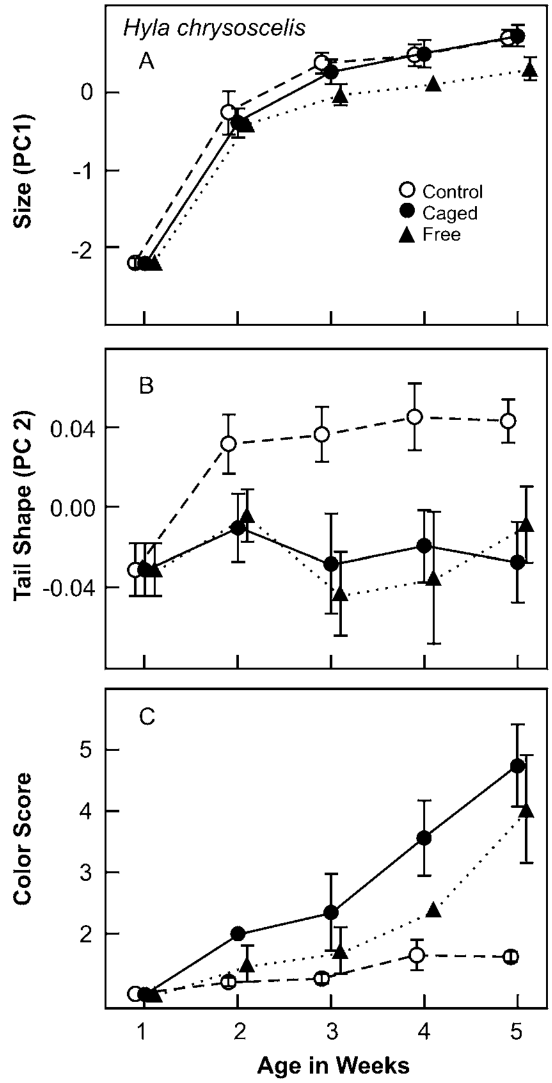

Fig. 14.16. Ontogenetic trajectories of the phenotypes of *Hyla chrysoscelis* tadpoles raised with caged or free-ranging predatory dragonfly naiads or in control treatments without dragonflies. (A) Tadpoles exposed to free-ranging predators were significantly smaller (lower PC1 score) than those exposed to caged predators or no predators. (B) Tadpoles exposed to either caged or free-ranging predators had deeper tail fins (lower PC2 scores) than did control tadpoles. (C) Tadpoles exposed to predators had more colorful tails (higher color score) than did control tadpoles. After McCollum and Van Buskirk (1996).

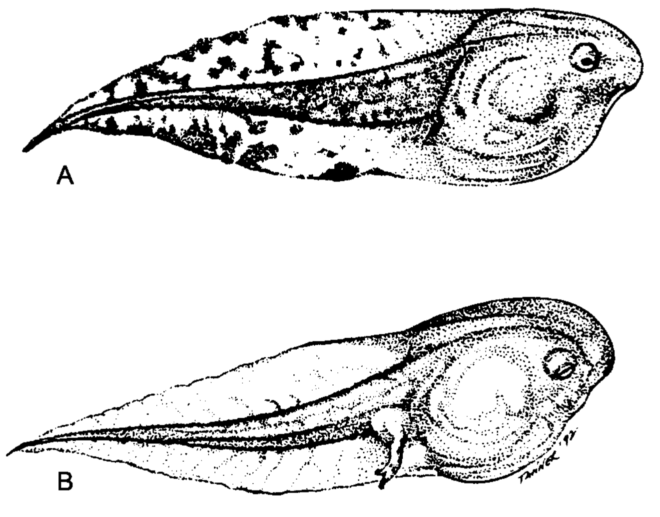

Fig. 14.15. Representative tadpoles of *Hyla chrysoscelis* from ponds (A) with predatory dragonfly naiads and (B) without predatory dragonflies. Tadpoles from ponds with dragonflies develop broader and more colorful tail fins. After McCollum and Leimberger (1997).

Direct contact with free-ranging dragonflies was not necessary to induce changes in phenotype, nor were most phenotypic changes affected by experimentally damaging the tails of young tadpoles (McCollum and Leimberger 1997). Exposure to dragonfly naiads that had previously fed on tadpoles induced these phenotypic changes, whereas exposure to starved naiads did not. This suggests that chemical metabolites derived from feeding on tadpoles might be responsible for inducing changes in tadpoles. *Hyla versicolor* tadpoles in natural ponds varied phenotypically in ways predicted from experimental studies similar to those conducted with *H. chrysoscelis*. Tadpoles from a predator-rich pond were more likely to survive in the presence of predators than were those from a predator-free pond (Van Buskirk and McCollum 1999). In laboratory tests, tadpoles were exposed to dragonfly naiads to induce the development of the phenotype with broad tail fins and colorful markings. These were then exposed to both dragonfly naiads and tiger salamander larvae (*Ambystoma tigrinum*) as predators, as were tadpoles that lacked these features. Tadpoles with the predator-induced phenotype had higher survival with both types of predators than did tadpoles that lacked the predator-induced phenotype (fig. 14.17). The greater survival of the predator-induced phenotype was not due to faster swimming, because these tadpole actually were slower swimmers than were those with shallower bodies and tails (Van Buskirk and McCollum 2000a, b). The larger and more conspicuous tail fins of the predator-induced phenotype apparently serve mainly to deflect attacks of predators away from the rest of the body (Van Buskirk et al. 2003). Tadpoles of *Hyla femoralis* exhibit similar responses, which can be triggered by exposure to both dragonfly naiads that have fed on tadpoles and to chemical cues from injured conspecifics (LaFiandra and Babbitt 2004).

Other frogs exhibit plasticity in tail depth in response to predators, but most lack the variation in color pattern seen in *Acris* and several species of *Hyla*. For example, tadpoles of the European treefrog (*Hyla arborea*) exhibited significant increases in tail depth, mainly in the upper tail fin, when exposed to predatory aquatic beetle larvae (*Dytiscus marginalis;* Lardner 2000). D. C. Smith and Van Buskirk (1995) studied populations of *Pseudacris crucifer* and *P. triseriata* in natural rock pools in Michigan. *Pseudacris crucifer* tadpoles are almost always found in pools with predatory dragonflies, whereas *P. triseriata* usually are in predator-free pools. *Pseudacris crucifer* tadpoles have deeper tail fins and more muscular tails than do *P. triseriata* tadpoles. These traits presumably are correlated with swimming speed and predator avoidance. *Pseudacris triseriata* exhibited much more plasticity in tail depth and muscularity than did *P. crucifer.* Tadpoles of *P. triseriata* that were raised in pools with predators developed deep tail fins and muscular tails like those of *P. crucifer,* whereas *P. crucifer* tadpoles showed little response to variation in predator density. A similar pattern was seen in a study of *Bombina* tadpoles in Europe. The species that typically breeds in temporary pools, *B. variegata,* showed more plasticity in morphology in response to predators than did *B. bombina,* which normally breeds in ponds with predators (Vorndran, Reichwaldt, and Nürnberger 2002). Presumably the species that typically live with predators already have phenotypes that have evolved under selection by predators, and their degree of plasticity may be constrained by the costs of plasticity, such as reduced growth rates (Relyea 2002a).

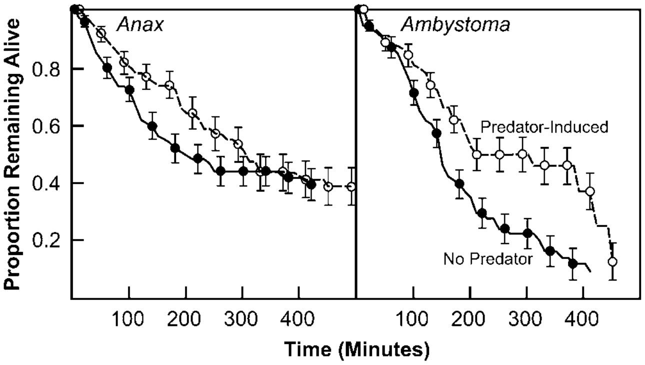

Fig. 14.17. Survivorship curves for the two morphological phenotypes of *Hyla versicolor* tadpoles when exposed to predatory dragonfly naiads (*Anax*) and salamander larvae (*Ambystoma*). Tadpoles with the predator-induced morphology had significantly higher survivorship than did those raised without predators. After Van Buskirk and McCollum (2000a).

Several ranid frogs also exhibit phenotypic plasticity in tail morphology in response to free-living predators or chemical cues from caged predators. Tadpoles of several European species, including *Rana arvalis, R. dalmatina, R. ridibunda, R. lessonae,* and *R. temporaria,* all developed deeper tail fins in the presence of cues from several kinds of predators, including diving beetles (*Dytiscus*), dragonfly naiads (*Aeshna* and *Anax*), backswimmers (*Notonecta*), and newts (*Triturus;* Lardner 2000; Van Buskirk 2001; Van Buskirk and Saxer 2001; Van Buskirk 2002b; Van Buskirk and Arioli 2002). Some tadpoles also respond to predators by changing overall body shape. For example, tadpoles of the Australian frog *Limnodynastes peronii* grow excess tissue around the head and body in response to dragonfly naiads (Kraft, Wilson, and Franklin 2005). A somehat similar response is seen in tadpoles of a Japanese frog, *Rana pirica,* in response to hynobiid salamander larvae (Kishida and Nishimura 2005). The function of this response in *Limnodynastes* is not clear, although Kraft, Wilson, and Franklin (2005) suggested that extra tissue on the dorsal side of the tadpole may help protect the spinal cord from predator attacks. In *R. pirica,* the bulgy morphology of tadpoles exposed to *Hynobius* larvae makes it difficult for the salamanders to swallow the tadpoles.

These kinds of plastic responses can be predator specific. For example, many tadpoles develop higher tail fins in the presence of a variety of predators, but respond to the presence of fish by developing more muscular tails that enhance their ability to escape from these active predators (Teplitsky et al. 2005; Wilson, Kraft, and Van Damme 2005). Investment in increased tail muscle is a graded response to different levels of predator risk (Teplitsky, Plénet, and Joly 2005). Indeed, such gradation in morhological plasticty in response to variation predator threat appear to be common (Van Buskirk and Arioli 2002; Laurila et al. 2004), probably because all induced morphological or behavioral responses to predators incur some cost, even after metamorphosis (Van Buskirk 2000; Van Buskirk and Saxer 2001). Given this fine-tuning of plastic responses to predators, one might expect tadpole morphology or degree of plasticity to be closely related to the abundance of predators in natural ponds, but several stuides have shown that this is not necessarily true (Lardner 1998; Van Buskirk and Arioli 2005). One possible explanation for this pattern is that features of local habitats, such as predator abundance, change so rapidly that an evolutionary response to local conditions is precluded.

Several North American ranids, including wood frogs (*R. sylvatica*), leopard frogs (*R. pipiens*), green frogs (*R. clamitans*), and bullfrogs (*R. catesbeiana*), exhibited some plasticity in tail fin morphology in response to dragonfly naiads (*Anax*), but the response of the different species were not identical. Wood frogs exhibited substantial increases in tail fin depth in response to predators, as well as increases in tail muscle depth and width (Van Buskirk and Relyea 1998; Relyea and Werner 2000). Leopard frogs showed a smaller increase in tail fin depth and some increase in tail muscle depth, but not muscle width. Green frogs and bullfrogs showed some changes in overall body shape and size in response to predators, but changes in individual structures such as tail fins generally were not significant (Relyea and Werner 2000). In wood frogs, the predator-induced phenotype had higher survival in the presence of predators than did the noninduced phenotype (Van Buskirk and Relyea 1998), but the adaptive significance of the morphological changes in the other species is not known. The lack of strong responses in tail fin morphology in bullfrogs and green frogs may be related to the fact that these species nearly always live in the presence of predators and have evolved other types of defenses, including behavioral responses and chemical defenses.

Most of the previous studies tested responses of tadpoles to only one type of predator, but morphological plasticity in response to predators is complex and varies as a function of predator type, the number of predator species present, and tadpole species. Some species, such as *Rana temporaria,* exhibit similar morphological responses to several types of vertebrate and invertebrate predators (Van Buskirk 2001). In contrast, wood frogs (*Rana sylvatica*) developed deeper tails in response to dragonfly naiads (*Anax*) and both deeper tails and deeper and shorter bodies in response to mudminnows (*Umbra limi*), but showed no morphological responses to either beetle larvae (*Dytiscus*) or newts (*Notophthalmus viridescens;* Relyea 2001a). When different combinations of predators were presented together, the tadpoles generally responded morphologically as they would to the most dangerous predator alone (Relyea 2003a). American toads (*Bufo americanus*) responded to the presence of mudminnows by developing shallower, longer tails, whereas leopard frogs (*Rana pipiens*) developed deeper tails and shorter bodies in response to the same predator. Even closely related species like bullfrogs (*Rana catesbeiana*) and green frogs (*R. clamitans*) did not respond in exactly the same way to the same predators. This complex variation in morphological responses was accompanied by similar variation in behavioral responses to predators (see the following further discussion).

A surprising result of work by Relyea (2001b) was that overall morphological responses of tadpole species were not closely related to the risk posed to each species by different predators. There were, however, some significant correlations between the risk posed by a particular type of predator and particular morphological traits. For example, wood frogs were more likely to be eaten by mudminnows than were any other species, and they showed the greatest changes in relative tail muscle depth and body length in response to that predator. Green frogs and bullfrogs were the least susceptible to this predator and showed the weakest responses in these morphological traits. Similarly, wood frogs were the most susceptible to predation by dragonfly naiads and exhibited the greatest increase in tail depth in response to those predators, while again green frogs and bullfrogs exhibited little or no response. Other morphological responses were not consistently related to predation risk. One possible reason for such variable results is that prey species do not respond to predators by altering morphology alone; such responses are integrated with behavioral responses such as reduction in activity (see the following). In addition, some species, such as toads, are less palatable to some of the predators than are other species, so they exhibit less pronounced behavioral and morphological changes in response to those predators. Phylogenetic effects clearly have an influence on morphological plasticity, with anurans such as *Bufo* showing relatively little response to predators, and others such as *Hyla* and some *Rana* showing strong reponses. A comparative study of 16 different anuran species that controlled for phylogeny also showed that morphological plasticity tended to be greater in habitats with large temporal variation in predator composition (Van Buskirk 2002a).

There also is evidence for variation among populations of the same species in morphology and degree of morphological plasticity in response to differences in the assemblages of predators present in the habitat. For example, wood frog (*Rana sylvatica*) tadpoles from open-canopy ponds, where predators are relatively abundant, tend to have deeper tails and shorter bodies than to those in closed-canopy ponds, where predators are less abundant (Relyea et al. 2002b).

In addition, there was more variation in morphology among tadpoles from open-canopy ponds, and this reflected greater variation in the abundance and composition of the predator community in these ponds. At least some of this variation was genetic, because phenotypic differences were maintained when tadpoles were reared under the same conditions (Relyea 2002b, 2005a).

Morphological plasticity in response to predators in salamander larvae has not been studied in as much detail. Van Buskirk and Schmidt (2000) exposed larvae of *Triturus alpestris* and *T. helveticus* to dragonfly naiads (*Aeshna*) in experimental ponds. Larvae of both species in ponds with predators developed darker pigmentation on the tail, larger heads, and larger tails than did those in ponds that lacked predators. The predator-induced morph did much better when exposed to free-ranging dragonflies than did those from predator-free ponds, but grew more slowly and took longer to metamorphose. A survey of natural ponds revealed considerable variation in predator density that was correlated with variation in larval head size, as predicted from the experimental results. Not all *Triturus* respond to predators in the same way, however. In a study of six species that live in the same habitats, B. Schmidt and Van Buskirk (2005) found that members of a large-bodied clade (*T. cristatus, T. marmoratus,* and *T. carnifex*) showed somewhat different morphological responses to dragonfly naiads than did members of a more vulnerable, small-bodied clade (*T. vulgaris, T. helveticus,* and *T. alpestris*). Some work also has been done on responses of larval *Ambystoma tigrinum* to diving beetle larvae (*Dytiscus*) and dragonfly naiads (*Anax*). The larvae had shorter bodies and deeper tails in the presence of predator than in predator-free environments, and the response to dragonflies was stronger than the response to diving beetles (Storfer and White 2004).

Behavioral Responses to Predators

In addition to changes in morphology, the presence of predators can induce amphibian larvae to alter their behavior in ways that reduce their chances of being detected or captured by predators. One type of behavioral response is to form schools, which tend to decrease the chances of an individual larva being captured by predators (Rödel and Linsenmair 1997); this behavior is discussed in more detail in chapter 12. Some amphibians reduce their exposure to predators by shifting their activities to times of day when predators are not very active. For example, *Ambystoma gracile* larvae are active during the day in lakes devoid of predatory fish, but are strictly nocturnal and very wary when fish are present (Efford and Mathias 1969; Sprules 1974b; Taylor 1983a). Larvae of the streamside salamander (*A. barbouri*) also tend to become more nocturnal in the presence of fish (Sih, Kats, and Moore 1992).

Amphibian larvae also commonly shift their activities to protected habitats in the presence of predators. Often these refuge habitats provide less food for the larvae than more exposed locations, so the use of refuges can be costly in terms of reduced feeding and growth. For example, *Ambystoma tigrinum nebulosum* larvae changed their use of foraging microhabitats in the presence of dytiscid beetles (Holomuzki 1986a). In a laboratory experiment conducted at night, salamander larvae were active mostly in shallow water when beetles were absent, but shifted into deeper water when beetles were present. Presumably this is because the beetles prefer to forage in shallow water. Stangel and Semlitsch (1987) found that the presence of sunfish suppressed the nocturnal vertical migration of *Ambystoma talpoideum* larvae into the water column, causing the salamanders to restrict their activity to the bottom of the pond; when fish were removed, activity in the water column resumed (fig. 14.18). Larvae raised in the presence of fish obtained less food and were smaller than those raised without fish, even though densities were lower and the fish were not direct competitors (Semlitsch 1987b). Larvae of *Ambystoma maculatum* living in ponds with predatory marbled salamander larvae (*A. opacum*) did not retreat into refuges and consequently were more vulnerable to predation than were *A. talpoideum* larvae living in the same ponds (Walls 1995). Larvae of *Triturus alpestris* and *T. helveticus* spent more time hiding in leaf litter when exposed to cues from predatory dragonflies (*Aeshna;* Van Buskirk and Schmidt 2000) or fish (Orizaola and Braña 2003b), while young larvae of

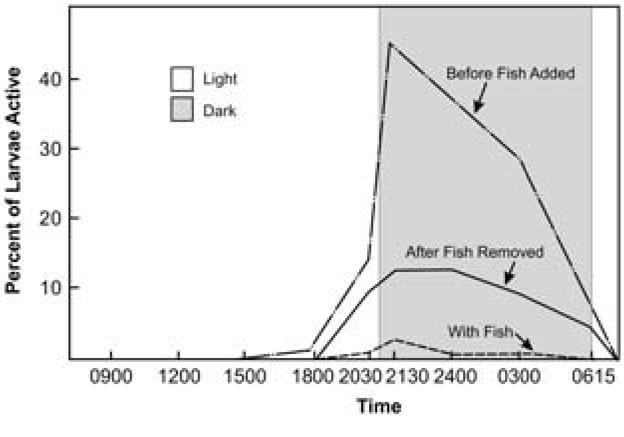

Fig. 14.18. Mean percentage of larval *Ambystoma talpoideum* active in the water column in artificial ponds before, during, and after the introduction of predatory fish (*Lepomis macrochirus*). Each line represents averaged data for three 24-hour censuses before fish were added (23 July–4 August), when fish were present (9–14 August), and after fish were removed (16–22 August). The presence of fish dramatically decreased the vertical migration of salamander larvae in the water column, but migration was partially restored when the fish were removed. After Stangel and Semlitsch (1987).

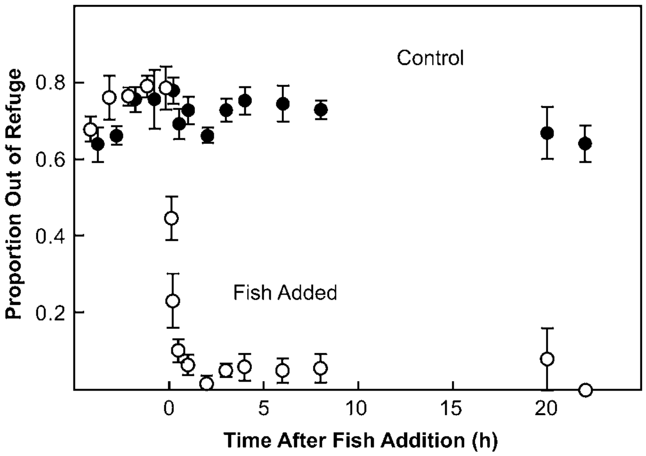

Fig. 14.19. The proportion of *Ambystoma barbouri* larvae out of refugia in pools to which bluegill sunfish (*Lepomis macrochirus*) had been added and in control pools that lacked sunfish. After Sih, Englund, and Wooster (1988).

Dicamptodon tenbrosus in the laboratory spent more time under artificial shelters in the presence of chemical cues from trout than did those in tanks that lacked such cues (Rundio and Olson 2003).

The use of refuge habitats in response to predatory fish has been studied in considerable detail in the streamside salamander (*Ambystoma barbouri*). This species lives in streams that often dry up in the summer, so larvae must be very active to acquire enough food to reach metamorphic size before the stream dries up (Petranka and Sih 1986, 1987; Maurer and Sih 1996). When confronted with predatory fish, the larvae tend to greatly reduce foraging activity and retreat under cover objects (rocks in natural streams; plexiglass refuges in experimental pools; Petranka 1983). The larvae must emerge periodically from these refuges to feed, and when they do so, they are extremely vulnerable to predation by fish. Experimental studies showed that fewer than 5% of larvae were out of refuges at any given time when fish were present (fig. 14.19), yet predation rates still were relatively high (Sih, Petranka, and Kats 1988). Most larvae begin life in pools with relatively few fish, because females avoid laying eggs in pools with fish (Kats and Sih 1992). Nevertheless, many are carried downstream by currents or floods, which may deposit them in pools with fish. These predators can rapidly eliminate actively foraging larvae from a small pool, so a rapid shift to refuge habitats is required for larvae to survive (Sih, Kats, and Moore 1992). Antipredator behavior is only marginally successful in this species—most larvae exposed to fish are eaten. One reason for this is that the behavior of larvae is shaped by the conflicting need for rapid development, which favors active feeding, and predator avoidance, which favors reduced activity and refuge use (Sih, Kats, and Maurer 2000). Populations of larvae in streams with fish exhibit stronger antipredator responses than do those in streams without fish. Nevertheless, gene flow from populations without fish may reduce the effectiveness of antipredator behavior, which is not as well developed in populations that are close to fish-free populations (Storfer and Sih 1998).

Some anuran tadpoles seem to be less inclined to use sheltered refuges than are salamander larvae, probably because they must have access to algae and other food growing in exposed habitats. Nevertheless, mortality of some species is lower in habitats with extensive cover than in more open habitats (Babbitt and Jordan 1996; Babbitt and Tanner 1997). Some tadpoles alter their use of microhabitats in response to predators. For example, Morin (1986) found that *Pseudacris crucifer* tadpoles used more protected microhabitats in the presence of newts, but he did not find any change in larval growth rates. Tadpoles of *Pseudacris regilla* in a river in California tended to shift from algal mats that contained their principal food, epiphytic diatoms, to lower-quality algal mats and sediments at the bottom of the stream when confronted with predatory garter snakes (*Thamnophis hydrophilus;* Kupferberg 1998). This seemed to be less a result of actively seeking more protected microhabitats than of reduced levels of activity, which caused the tadpoles to sink to the bottom. Tadpoles of various species of *Rana, Hyla,* and *Bufo* increase their use of refuge habitats in response to chemical cues from crayfish (fig. 14.20; Lefcourt 1996; Bridges and Gutzke 1997; Nyström and Åbjörnsson 2000). Tadpoles of *Rana temporaria* also increased their use of refuges when exposed to chemical cues from predatory fish (*Oncorhynchus mykiss*), but tadpoles of *Bufo bufo,* which are distasteful to fish, did not (Nyström and Åbjörnsson 2000). This type of response may be more common than currently recognized, because many laboratory studies have been designed to test the effects of predators on larval activity or spatial avoidance of predators, but have

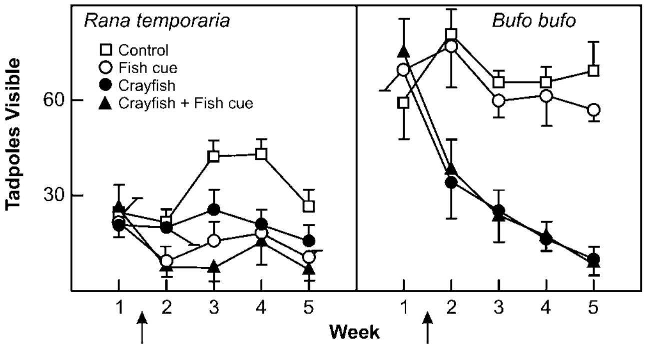

Fig. 14.20. Mean number of tadpoles of *Rana temporaria* and *Bufo bufo* visible (out of refugia) in experimental pools without predator cues (controls), with chemical cues from fish (*Oncorhynchus mykiss*), with free-ranging crayfish (*Pacifastacus leniusculus*), and with both fish cues and crayfish. *Rana temporaria* tadpoles actively avoided both fish and crayfish, whereas *Bufo bufo* tadpoles avoided only crayfish. After Nyström and Åbjörnsson (2000).

not included refuge habitats for the larvae (e.g., Mathis and Vincent 2000; Chivers and Mirza 2001; Chivers et al. 2001; Wildy and Blaustein 2001).

Probably the most common behavioral responses of amphibian larvae to the presence of predators are to move away from the predator, reduce foraging activity, and in some cases, become almost immobile. These types of predator avoidance behavior are phylogenetically widespread (Van Buskirk 2002a) and have been observed in tadpoles of *Ascaphus* (Feminella and Hawkins 1994), *Alytes* (Griffiths et al. 1998), *Bombina* (Van Buskirk 2002a), *Pseudacris* (Lawler 1989; Skelly 1995a; Kupferberg 1998; Puttlitz et al. 1999; Chivers et al. 2001), *Hyla* (Lawler 1989; Skelly 1992; Relyea 2001a, b), *Bufo* (Skelly and Werner 1990; Semlitsch and Gavasso 1992; Anholt, Skelly, and Werner 1996; Kiesecker, Chivers, and Blaustein 1996; Laurila, Kujasalo, and Ranta 1998; Lefcourt 1998; Petranka and Hayes 1998; Relyea 2001a, b), and *Rana* (Werner 1991; Stauffer and Semlitsch 1993; Horat and Semlitsch 1994; Werner and McPeek 1994; Anholt and Werner 1995; Manteifel 1995; Lefcourt 1996; Kiesecker and Blaustein 1997b, 1998; Laurila, Kujasalo, and Ranta 1997, 1998; Petranka and Hayes 1998; Van Buskirk and Yurewicz 1998; Relyea and Werner 1999; Eklöv 2000; Laurila 2000a; Nicieza 2000; Thiemann and Wassersug 2000; Babbitt 2001; Chivers and Mirza 2001; Relyea 2001a, b; Van Buskirk 2001). Some salamander larvae, including *Ambystoma* (Semlitsch 1987b; Figiel and Semlitsch 1990; Sih and Kats 1991, 1994; Storfer and Sih 1998; Storfer 1999; Wildy and Blaustein 2001), *Eurycea* (Petranka, Kats, and Sih 1987; Resetarits 1991), and *Notophthalmus* (Mathis and Vincent 2000), also reduce foraging activity or become immobile in response to predators. Larvae of *Hemidactylium scutatum* reduced activity in the presence of newts (*Notophthalmus viridescens*), but only after the first 12 days of development; activity of younger larvae already is very low (C. Wells and Harris 2001). In contrast, small larvae of *Ambystoma annulatum* were more likely to reduce activity in response to cues from newts than were larger individuals that were less susceptible to predation (Mathis, Murray, and Hickman 2003).

There is abundant evidence that movements associated with foraging activity make amphibian larvae especially vulnerable to predators that detect their prey visually or through tactile cues (Caldwell, Thorp, and Jervey 1980; Woodward 1983; Lawler 1989; S. Richards and Bull 1990a; Azevedo-Ramos et al. 1992; Chovanec 1992b; Skelly 1994; M. Moore and Townsend 1998). At the same time, actively foraging tadpoles can process food at a faster rate than less active foragers, and they achieve faster growth rates (Morin 1983a; Lawler 1989; Werner 1991, 1992; Werner and McPeek 1994; Skelly 1995a). A similar relationship between activity and early growth rate has been reported in salamander larvae, although in this case, the comparison was between distantly related species (*Ambystoma jeffersonianum* and *Hemidactylium scutatum;* C. Wells and Harris 2001). This means that reducing activity to escape predation carries a cost in reduced food intake and growth (fig. 14.21; Skelly and Werner 1990; Skelly 1992; Van Buskirk and Yurewicz 1998; Van Buskirk 2000), and these costs may be increased by simultaneous changes in tadpole morphology (Relyea 2002a). There can be other costs as well. Thiemann and Wassersug (2000) reported that tadpoles of *Rana clamitans* that were exposed to caged killifish (*Fundulus*) reduced levels of activity, but were more vulnerable to infection by parasitic trematodes. They attributed this to increased proximity to trematode cercariae in inactive tadpoles that spent more time on the substrate, but this was not tested experimentally.

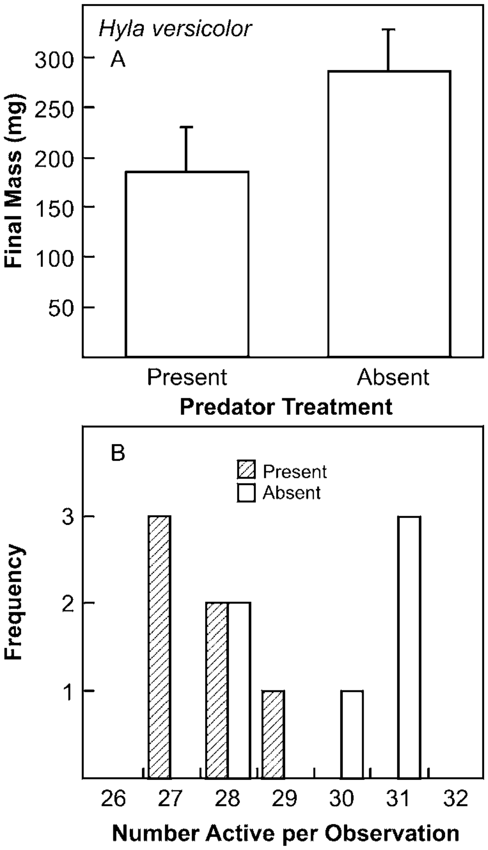

Fig. 14.21. Effect of exposure to a predator on growth and activity of *Hyla versicolor* tadpoles. (A) Final body mass of tadpoles growing in enclosures in a natural pond in the presence or absence of a tiger salamander larva (*Ambystoma tigrinum*) housed in a screen cage. (B) Number of active small and large tadpoles in the presence or absence of a tiger salamander larvae in a laboratory experiment. After Skelly (1992).

Because of the tradeoff between vulnerability to predators and foraging efficiency, tadpoles in permanent ponds, where predation is a major threat, often are relatively inactive foragers and tend to have slow growth rates. In contrast, tadpoles that live in temporary ponds, where rapid pond drying favors rapid growth, tend to be much more active, even if this exposes them to predators (Skelly 1995a). This relationship among level of activity, relative growth rate, and habitat appears to hold for several different families of anurans (J. Richardson 2001). One implication of this difference is that temporary pond species often are precluded from invading permanent ponds, especially those with fish, because of ineffective antipredator behavior, whereas permanent pond species are excluded from temporary ponds because of their slow development rates (Woodward 1983; Kats, Petranka, and Sih 1988; Azevedo-Ramos and Magnusson 1999).

A second implication of the tradeoff between feeding and predator avoidance is that amphibian larvae are expected to adjust their responses to predators according to their need for food or levels of food availability. Predators represent an immediate threat to foraging tadpoles, but tadpoles that fail to acquire sufficient food to reach metamorphosis are doomed as well. Tadpoles of *Rana lessonae* and *R. esculenta* reduced their activity and time devoted to foraging in the presence of predators, but hungry tadpoles were more active than well-fed tadpoles, even when predators were present (fig. 14.22; Horat and Semlitsch 1994). Tadpoles of *Rana sphenocephala* were more active when food was abundant than when it was scarce, but also showed a greater reduction in activity in response to predators when food was abundant (Babbitt 2001). Similar experiments with bullfrog (*Rana catesbeiana;* Anholt and Werner 1995) and wood frog (*R. sylvatica*) tadpoles (Anholt and Werner 1998) showed that tadpoles will reduce activity in the presence of predators when resource levels are high, but actually increase activity and suffer higher mortality when resources are low (fig. 14.23). The effectiveness of reduced activity as an antipredator defense also can be affected by the hunger level of the predator. Hungry dragonfly naiads, for example, are more likely to eat inactive tadpoles than are satiated ones (Altwegg 2003a).

In many aquatic environments, amphibian larvae are confronted with an array of predators that use different sensory modes to locate prey. This means that behavioral responses that provide protection against one predator may make them more vulnerable to other predators (Sih, Englund, and Wooster 1998). For example, reducing levels of activity of-

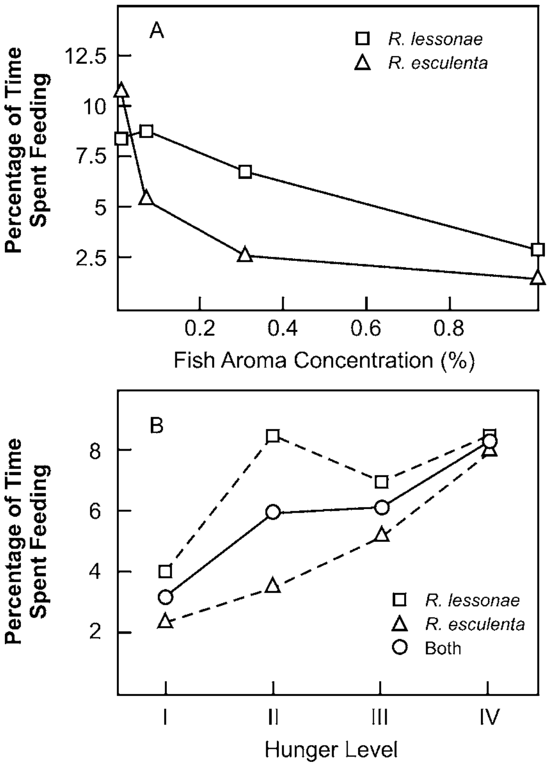

Fig. 14.22. Effect of hunger or resource level on feeding activity and mortality of tadpoles in the presence of predators. (A) Effect of fish aroma concentration on time spent feeding by tadpoles of *Rana esculenta* (triangles) and *R. lessonae* (squares). (B) Percentage of time spent feeding by tadpoles of these two species (same symbols) and the two species combined (circles) in the presence of predatory fish as a function of increasing hunger level. After Horat and Semlitsch (1994).

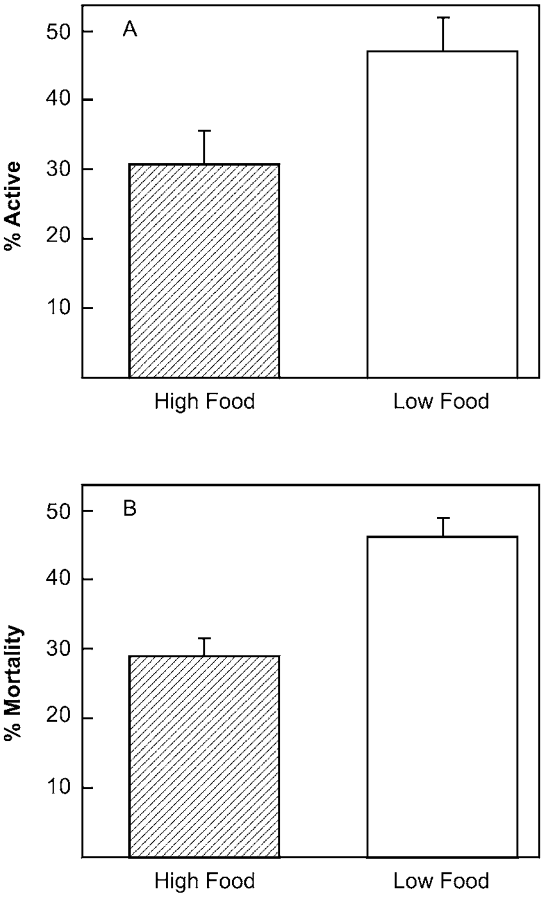

Fig. 14.23. (A) Percentage of bullfrog (*Rana catesbeiana*) tadpoles active in the presence of caged dragonfly naiads (*Tramea lacerata*) at high and low food levels. (B) Mortality of bullfrog tadpoles exposed to free-ranging dragonfly naiads at high and low food levels. After Anholt and Werner (1995).

ten is an effective defense against visually hunting predators, but not those that detect prey mainly by chemical cues rather than visual or tactile cues. Warkentin (1999a) found that tadpoles of *Agalychnis callidryas* could not escape detection by freshwater shrimp by remaining immobile, because these shrimp detect prey chemically. The only effective defense was to flee, a behavior that became more effective as the tadpoles grew, but this response tended to make the tadpoles more vulnerable to predators such as dragonfly naiads. In some cases, having several kinds of predators present in a pond can actually benefit a species in competition with other amphibians. For example, bullfrog tadpoles (*Rana catesbeiana*) are vulnerable to dragonfly naiads because of their foraging activities, but are relatively well protected from fish by noxious skin secretions. Because fish tend to eat dragonfly naiads, bullfrog tadpoles do better in ponds with fish than do green frog tadpoles (*R. clamitans*), which are vulnerable to both dragonflies and fish (Werner and McPeek 1994; see chapter 15 for further discussion). Similarly, tadpoles of *Hyla cinerea* were less vulnerable to some combinations of predators than to single species of predators alone, apparently because the various predators tend to eat each other (Gunzburger and Travis 2005).

Sensory Cues for Predator Detection and Recognition

The experiments described previously indicate that amphibian larvae are capable of detecting the presence of dangerous predators and responding with appropriate changes in behavior. A number of sensory cues could be used to detect predators, including tactile, visual, and chemical cues. Several experiments have shown that tactile and visual cues either are not necessary for predator detection, or are not effective. In most cases, chemical cues are used for predator detection and recognition. McCollum and Leimberger (1997) showed that chemical cues are both necessary and sufficient to induce morphological changes. Other experiments have used behavioral responses such as changes in activity and shifts in microhabitat use to determine the cues used by larvae to detect predators. Antipredator responses can be induced by exposing tadpoles (Semlitsch and Gavasso 1992; Semlitsch and Reyer 1992a; Lefcourt and Eiger 1993; Stauffer and Semlitsch 1993; Feminella and Hawkins 1994; Lefcourt and Blaustein 1995; Manteifel 1995; Kiesecker, Chivers, and Blaustein 1996; Lefcourt 1996, 1998; Eklöv 2000; Laurila 2000a) and salamander larvae (Petranka, Kats, and Sih 1987; Sih and Kats 1991) to water conditioned by predators, even when the predators themselves are not present.

In some cases, larvae discriminate between cues derived from dangerous and less dangerous predators (Manteifel 1995; Kiesecker, Chivers, and Blaustein 1996; Lefcourt 1996, 1998). For example, bullfrog (*Rana catesbeiana*) tadpoles exhibit a greater reduction in activity in response to cues from a dangerous predator (dragonfly naiads) than to those from a less dangerous predator (bluegill sunfish; Eklöv 2000). When cues from the two predators were presented together, tadpoles reduced activity to about the same level as they did with bluegills alone. One possible reason for this is that the presence of bluegills reduces activity of dragonfly naiads, which in turn may reduce the cues emanating from the dragonflies to which the tadpoles respond (Eklöv and Werner 2000). Tadpoles of another ranid frog, *Rana temporaria,* show reduced activity to both dragonfly naiads and fish, but show greater spatial avoidance of dragonflies (Laurila 2000a). Tadpoles of the western toad (*Bufo boreas*) avoided chemical cues from backswimmers (*Notonecta*), giant waterbugs (*Lethocerus americanus*), and garter snakes (*Thamnophis sirtalis*), all of which prey on toad tadpoles (Kiesecker, Chivers, and Blaustein 1996). They did not avoid chemical cues from newts (*Taricha granulosa*) or trout (*Oncorhynchus mykiss*), both of which find toad tadpoles distasteful (fig. 14.24). Six different species of anurans tested by Relyea (2001a) differed in their tendency to reduce activity or move away from five different types of predators. All species responded to dragonfly naiads (*Anax*), but they varied in their responses to newts (*Notophthalmus viridescens*), tiger salamander larvae (*Ambystoma tigrinum*), mudminnows (*Umbra limi*), and giant waterbugs (*Belostoma*). Across all anuran species, the decrease in activity in response to mudminnows was proportional to the risk posed by that predator, but this was not true for dragonfly naiads (Relyea 2001b). This may be because dragonflies are relatively dangerous predators for most anuran tadpoles.

Some amphibian larvae respond differently to chemical cues derived from predators that have fed on conspecific larvae compared to those that have fed on other types of food (Lefcourt and Blaustein 1995; Laurila, Kujasalo, and Ranta 1997, 1998; Chivers and Mirza 2001). In some cases, however, they respond equally strongly to predators that have not fed on conspecifics (Petranka and Hayes 1998). Tadpoles also may reduce their antipredator responses as they grow, because large tadpoles often are less vulnerable to certain predators than are small ones (Puttlitz et al. 1999; Eklöv 2000).

Often the ability to recognize predators appears to be genetically based, because previous experience with a predator is not required to elicit a response (Gallie, Mumme, and Wissinger 2001; Mathis, Murray, and Hickman 2003). Nevertheless, some populations of tadpoles can recognize predators from the local area, but not members of the same species from other regions (Griffiths et al. 1998). This suggests that there has been selection at the local level for recognition of dangerous predators. Populations of some species apparently lack the ability to recognize or avoid predators that

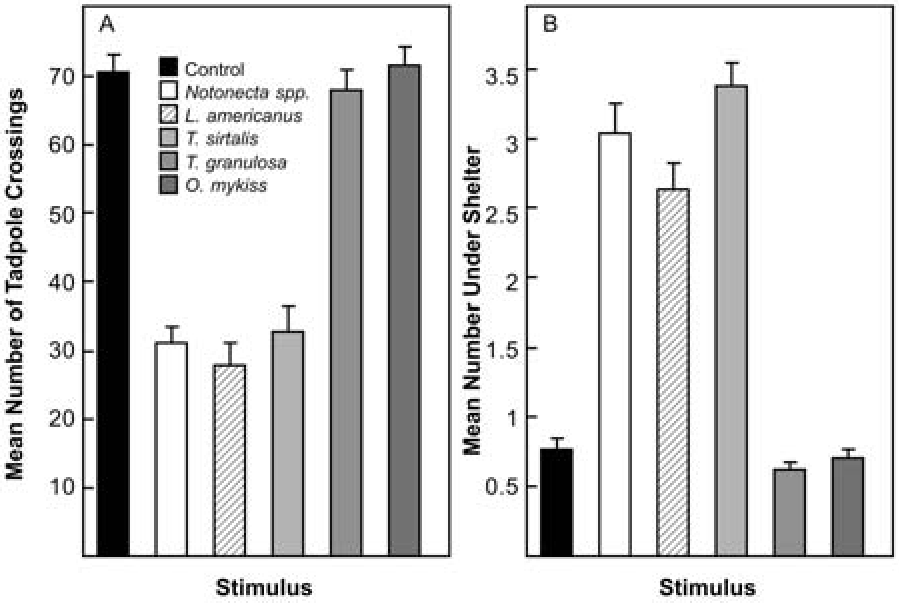

Fig. 14.24. Effect of chemical cues from potential predators on activity and use of refugia by tadpoles of *Bufo boreas.* (A) Activity of tadpoles, measured as the number seen crossing the midline of the experimental tank during a five-min trial. (B) Number of tadpoles under a shelter. Tadpoles were exposed to chemical cues from dangerous predators (*Notonecta, Lethocerus,* and *Thamnophis*) and predators that do not feed on toad tadpoles (*Taricha, Oncorhynchus*). The tadpoles exhibited antipredator behavior in response to the dangerous predators, but not to the others. After Kiesecker, Chivers, and Blaustein (1996).

have been introduced into the area very recently (Gamradt and Kats 1996). Similarly, amphibian larvae from temporary pools that lack fish typically do not show antipredator responses to chemical extracts from fish, whereas those from permanent ponds usually do (Kats, Petranka, and Sih 1988).

Antipredator behavior may evolve relatively rapidly, however, in response to strong selection imposed by introduced predators. For example, tadpoles of red-legged frogs (*Rana aurora*) from streams in Oregon inhabited by introduced bullfrogs (*Rana catesbeiana*) reduced their activity and increased their use of refuges when presented with chemical cues from either tadpoles or adult bullfrogs. Tadpoles from streams that lacked introduced bullfrogs did not show these responses, but they did respond to native predators (Kiesecker and Blaustein 1997). A similar difference has been reported in responses of terrestrial juveniles of *Pseudacris regilla* to introduced bullfrogs. Frogs from populations that co-occur with bullfrogs exhibited a much greater avoidance response than did those from populations where bullfrogs are absent (Chivers et al. 2001). In some cases, larvae may learn to avoid predators by responding to cues from injured conspecifics. For example, larvae of *Ambystoma macrodactylum* reduced their activity in response to cannibalistic conspecifics that had been on other larvae, but not those that had fed on *Tubifex* worms, and they responded even more strongly to injured conspecifics (Wildy and Blaustein 2001).

Alarm Responses

In addition to detecting predators directly, some amphibian larvae respond to cues emanating from injured conspecifics, and use these cues to avoid areas where predators are likely to be found (Hrbâçek 1950; Kulzer 1954; Pfeiffer 1966, 1974; Hews and Blaustein 1985; Hews 1988). Tadpoles of *Bufo americanus* can be induced to abandon a rich food patch if they are exposed to chemical extracts from injured conspecifics (Petranka 1989c). Alarm responses tend to induce behavior that is the opposite of the antipredator behavior discussed previously. Rather than reducing activity, tadpoles tend to increase activity in their attempts to escape from the vicinity of a potential predator. Although increased activity can make a tadpole more conspicuous to predators, this type of reaction can be beneficial when the tadpole already has been detected. Indeed, Hews (1988) showed that tadpoles of *Bufo boreas* that had been exposed to chemicals from an injured conspecific were less likely to be captured by dragonfly naiads. Whether the chemical substances released by injured tadpoles are pheromones that have evolved specifically as alarm signals, or are chemicals in the skin that have other functions, is the subject of some debate, which has yet to be resolved.

Some authors have suggested that alarm responses should be best developed in species of tadpoles that tend to aggregate with kin, because evolution of alarm signaling could be maintained by kin selection (see chapter 12). However, tadpoles of *Bufo boreas,* which forms large aggregations of mixed kin and nonkin, shows relatively strong alarm responses (Hews 1988), whereas tadpoles of *Rana cascadae,* which form small kin aggregations, do not (Hokit and Blaustein 1995). Although responses to alarm substances have been studied mostly in tadpoles that are social, sociality may not be a prerequisite for the evolution of alarm responses. Tadpoles of *Pseudacris regilla,* which are not highly social, will respond to extracts from injured conspecifics or heterospecific tadpoles (*Rana aurora;* M. Adams and Claeson 1998).

Changes in Growth and Development

For many amphibian larvae, rapid growth probably provides the best protection against predators. Travis (1983b) demonstrated genetic variation in larval growth rate, with high rates being correlated with higher survivorship. Most predators take prey over a limited size range, so some amphibian larvae eventually become too large to be eaten (Heyer, McDiarmid, and Weigmann 1975; Caldwell, Thorp, and Jervey 1980; Brodie and Formanowicz 1983; Crump 1984a; Travis, Keen, and Juilianna 1985b; Alford 1986; Cronin and Travis 1986; Formanowicz 1986; Semlitsch and Gibbons 1988; S. Richards and Bull 1990b; Kehr and Schnack 1991). Although the effect of tadpole size varies with the type of predator and predator size, tadpoles generally become less vulnerable as they grow (Alford 1999). This appears to result from a greater ability of large tadpoles to escape from predators. In general, tadpole sprint swimming speed increases with increasing size (Huey 1980; S. Richards and Bull 1990b), although locomotor performance may decline as a tadpole reaches metamorphosis (R. Brown and Taylor 1995). This means that predators may have to make more strikes at large prey to achieve a successful capture (Formanowicz 1986). Some predators are more adept than others at handling large tadpoles, and most species probably never reach a size that makes them completely invulnerable to attack. Some aquatic predators, and terrestrial predators such as birds, can actually be more successful at capturing large tadpoles than small ones (Crump and Vaira 1991; Tejedo 1993b). Nevertheless, predation probably is an important selective force acting on growth rates of larval amphibians (Travis 1983b; Travis, Keen, and Juilianna 1985a; Cronin and Travis 1986; Semlitsch and Gibbons 1988).

Exposure to predators also can alter rates of development and progress toward metamorphosis. For example, tadpoles of *Bufo boreas* that were exposed to predatory backswimmers (*Notonecta*) or cues from injured conspecifics reached metamorphosis more quickly than those raised with nonpredatory insects (Chivers et al. 1999). This was interpreted as an adaptive change in life history that enabled tadpoles to escape from dangerous conditions in the aquatic environment. Tadpoles of *Bufo boreas, Bufo americanus,* and *Pseudacris regilla* exposed to cues from predatory garter snakes (*Thamnophis sirtalis*) not only showed a tendency to form aggregations, but they also completed metamorphosis more synchronously than did those not exposed to a predator (DeVito et al. 1998, 1999; DeVito 2003). In contrast, larvae of *Ambystoma macrodactylum* that were exposed to cues from cannibalistic conspecifics took longer to metamorphose, presumably because they reduced foraging activity in response to the predator cues (Wildy, Chivers, and Blaustein 1999). A similar cost of antipredator behavior has been reported in several species of tadpoles, especially those from permanent ponds that tend to have long larval periods to begin with (e.g., Relyea and Werner 1999).

Chemical Defenses

Some amphibian larvae, particularly anuran tadpoles, are distasteful or even toxic to certain predators, but the phylogenetic distribution of distastefulness is poorly understood. Toad tadpoles (*Bufo*) often are assumed to be distasteful (e.g., Waldman 1982b), and the schooling behavior of many toad tadpoles has been interpreted as a behavior that could enhance the aposematic effect of conspicuous coloration in distasteful species (Wassersug 1973; Waldman 1982b; J. Peterson and Blaustein 1991; see chapter 12). However, only a few species have been tested for palatability, and these experiments have produced mixed results. Various *Bufo* tadpoles are distasteful to fishes (Voris and Bacon 1966; Glandt 1984; Kruse and Stone 1984; Kats, Petranka, and Sih 1988; Lawler 1989; Henrikson 1990; Lawler and Hero 1997), salamanders and newts (Cooke 1974; J. Peterson and Blaustein 1991), other tadpoles (Bragg 1960), and some invertebrates (Brodie, Formanowicz, and Brodie 1978). However, other studies have shown toad tadpoles to be palatable to a variety of vertebrate and invertebrate predators (Brockelman 1969; Heusser 1971a; Heyer, McDiarmid, and Weigmann 1975; Brodie, Formanowicz, and Brodie 1978; Morin 1983a; Leclair, Alarie, and Bourassa 1986; Banks and Beebee 1988; Hews 1988; Peterson and Blaustein 1992). Palatability of *Bufo* and other tadpoles to certain predators may depend on the hunger level of the predator and the availability of alternative prey, and it may vary with developmental stage (Brodie and Formanowicz 1987). Newly hatched tadpoles of *Bufo americanus* are distasteful to invertebrate predators, as are metamorphosing individuals, but they appear to be palatable at intermediate stages (Brodie, Formanowicz, and Brodie 1978). Palatable tadpoles may benefit from the distastefulness of newly hatched tadpoles because predators learn to avoid black tadpoles (Brodie and Formanowicz 1987). In contrast, the tadpoles of *Bufo marinus* were unpalatable at all developmental stages to predatory fish, but the later stages were the least palatable (Lawler and Hero 1997).

Closely related predators sometimes differ in their tendency to eat toad tadpoles. For example, adult *Triturus cristatus* readily eat *Bufo* tadpoles, but *T. vulgaris* and *T. helveticus* avoid them (Banks and Beebee 1988). Similarly, *Bufo americanus* tadpoles presented to aquatic beetle larva (*Dytiscus*) were eaten by one species (*D. verticalis*), but only occasionally by another species (*D. harrisii*) from the same pond (Leclair, Alarie, and Bourassa 1986). Failure to eat tadpoles does not necessarily indicate they are distasteful. Leclair, Alarie, and Bourassa (1986) demonstrated experimentally that *D. verticalis* from a pond containing toad tadpoles readily ate them, whereas larvae of the same species from a pond lacking toad tadpoles did not, suggesting that familiarity with the prey or availability of alternative prey may influence feeding preferences.

The relative palatability of tadpoles in other families has scarcely been explored in a systematic manner, although it is clear from the discussion earlier in this chapter that tadpoles are consumed by many kinds of predators. Wassersug (1971) tested leptodactylid, hylid, dendrobatid, and bufonid tadpoles from Costa Rica on human volunteers; only *Bufo marinus* was found to be highly distasteful. Tadpoles of a Neotropical treefrog, *Hyla semilineata,* which form dense schools in ponds and rivers, are black and distasteful to both natural predators (fish and free-ranging birds) and unnatural ones (domestic chickens; D'Heursel and Haddad 1999). Formanowicz and Brodie (1982) found that ranid, hylid, and bufonid tadpoles, as well as larval *Ambystoma maculatum* and *Notophthalmus viridescens,* were palatable to diving beetles (*Dytiscus*), but metamorphic stages of several species were distasteful. This suggests that distasteful skin secretions in some species do not develop until the larvae are about to leave the water. Tadpoles of *Pseudacris regilla* and *Rana cascadae* are highly palatable to both fish and aquatic insects (Peterson and Blaustein 1991, 1992). Liem (1961) found that tadpoles of the Asian ranid *Rana chalconota* had large granular glands and were highly distasteful to fishes, but tadpoles were examined only in late stages of development. Tadpoles of frogs that are highly toxic as adults, such as *Dendrobates, Phyllobates,* and *Atelopus,* have not been tested for palatability to natural predators, but some species of dendrobatid tadpoles readily consume conspecifics (see chapter 12).

Sometimes tadpoles of closely related species differ in their palatability to certain predators. For example, bullfrog (*Rana catesbeiana*) tadpoles are less palatable to fish than are green frog (*R. clamitans*) tadpoles (Werner 1991; Werner and McPeek 1994), although *R. clamitans* tadpoles are less palatable than are wood frog (*R. sylvatica*) tadpoles (Kats, Petranka, and Sih 1988). Tadpoles of the green tree frog (*Hyla cinerea*) are more frequently found in ponds with fish than are those of the barking tree frog (*H. gratiosa*). *Hyla cinerea* tadpoles were less palatable to fish when offered alone, but when the two species were offered in equal numbers, the fish did not discriminate between them (Blouin 1990).

Why has distastefulness or toxicity not evolved in nearly all amphibian larvae? Presumably the reason is that distasteful or toxic skin secretions can be expensive to produce. The cost of producing such compounds may be too great for many temporary pond tadpoles, which must channel most of their available energy into rapid growth to ensure that they leave the pond before it dries up. The cost of producing defensive chemicals probably is not as great for tadpoles that live in permanent ponds, many of which grow slowly anyway and may remain in ponds for months or even for several years. Because of their prolonged exposure to fish and other predators, the enhanced protection afforded by becoming distasteful probably more than repays the energetic cost of producing these defenses. The biochemical pathways leading to synthesis of noxious defensive compounds have not been investigated in tadpoles, but it is possible that this process requires chemical antecedents that cannot be readily obtained from the food available to tadpoles in ponds and other bodies of water. Some highly toxic adult frogs, for example, apparently sequester chemicals obtained by eating insects and use them to manufacture defensive compounds (see the following).

Defensive Adaptations of Adults

As in larval amphibians, adult amphibians can reduce the chances of being eaten by a predator either by reducing the likelihood of being detected and identified by the predator, or by reducing the chances of being consumed once an encounter takes place (Edmunds 1974; Endler 1986). This can be accomplished through passive defenses such as cryptic coloration, through behavioral avoidance of predators, or through active defenses such as flight, attack, or chemical defenses.

Cryptic Coloration

Cryptic coloration provides the first line of defense for many adult amphibians. Often this involves a general matching of dorsal coloration and pattern with that of the environment (Cott 1940; Edmunds 1974). Most amphibians tend to have ground colors that are various shades of green, yellow, red, brown, or gray. Terrestrial salamanders often are dark brown, gray, or black, with very low skin reflectance; this makes them very hard to see at night when they are most active (Norris and Lowe 1964). Many tropical frogs that rest on green vegetation during the day have bright green coloration (e.g., centrolenid frogs, *Agalychnis,* and many species of *Hyla, Litoria,* and *Hyperolius*). Some of these frogs reflect light not only in the visible spectrum, but in the near-infrared as well, perhaps rendering them thermally cryptic to predators such as boid snakes that use infrared radiation to detect prey (Schwalm, Starrett, and McDiarmid 1977; Emerson, Cooper, and Ehleringer 1990). Frogs that are found on dead vegetation near the ground often are colored various shades of yellow or brown (e.g., *Hyla microcephala, H. ebraccata;* Duellman 1970). Dark coloration and mottled patterns are characteristic of many frogs that escape from predators by diving into a pond or stream, where they blend in with algae-covered or muddy substrates (e.g., *Rana muscosa:* Norris and Lowe 1964; *R. septentrionalis:* Hedeen 1972; *R. pretiosa:* Licht 1986a). Frogs that escape by jumping onto land, such as *R. sylvatica, R. aurora,* and *R. pipiens,* often have lighter coloration, which provides a better match with terrestrial vegetation or dead leaves (Heatwole 1961; Hedeen 1972; Licht 1986a).

Some anurans exhibit preferences for certain types of substrates that render them cryptic to predators. For example, juvenile American toads (*Bufo americanus*) preferred visually complex substrates such as sand with holes, vegetation, or gravel to plain sand. The toads were better protected from hunting garter snakes (*Thamnophis sirtalis*) on those substrates than on plain sand (Heinen 1993b). Green and brown color morphs of the Pacific tree frog (*Pseudacris regilla*) exhibited preferences for substrates that best matched their colors, and again, this provided some protection against garter snakes (Morey 1990). Garter snakes probably locate prey largely by chemical cues, so these anurans might be even better protected by background matching from visually hunting predators such as spiders or birds. On the other hand, green and brown color morphs of *Rana pipiens* did not respond differently to green and brown backgrounds, but generally preferred brown to green substrates (Croshaw 2005).

Background matching with the environment can be enhanced by rapid color change. Although amphibians cannot equal the almost instantaneous color changes of flounders, squid, and octopus, some species can change color in a matter of minutes. The eyes probably are involved in the perception of background characteristics, but there is evidence that the skin of some species is sensitive to changes in illumination as well (Iga and Bagnara 1975). In general, frogs exhibit changes in reflectance that result in a lightening or darkening of the skin to approximate the brightness of the substrate, but they do not exhibit precise matching of hue or color purity with that of the background. For example, *Hyla cinerea* exhibits a range of coloration, from lemon yellow to nearly black, but frogs placed on a yellow background may be almost any hue from lemon yellow to green (Nielsen and Dyck 1978). Nevertheless, frogs placed on light substrates are consistently lighter than those on dark substrates. Color change in this species is affected by both background brightness and temperature (R. King, Hauff, and Phillips 1994). Similar results have been obtained with other species placed on colored or black and white backgrounds, including *Pachymedusa dacnicolor* (Iga and Bagnara 1975), *Hyla arborea* (Nielsen 1980), *Pseudacris crucifer* (Kats and Van Dragt 1986), *Rana esculenta* (Nielsen 1979) and a number of other species (references in R. King, Hauff, and Phillips 1994). Background matching may be particularly effective in reducing predation by animals that lack color vision, although it may reduce predation by those with color vision as well.

Some amphibians have evolved cryptic patterns that match particular environments rather precisely. For example, many tree frogs have dorsal patterns resembling lichen-covered tree bark, and others have complex mottled color patterns and dermal appendages that give the frogs the appearance of moss or lichen that grows on trees (fig. 14.25 A–C). Climbing salamanders may resemble lichen-covered rocks (e.g., *Aneides aeneus;* fig. 14.25 D), or bare granite (e.g., *Hydromantes platycephalus*). Mimicry of dead leaves is a particularly common theme among tropical forest frogs (fig. 14.26). In some of these species, the "dead leaf" effect is enhanced by dermal flaps on the eyes and nose that obscure the froglike features of the body, or by flaps along the sides that reduce shadows beneath the body (Cott 1940). *Bufo alatus* reacts to potential predators by freezing and flattening the body against the ground, further enhancing the appearance of a dead leaf (fig. 14.26 D). A more common form of cryptic coloration is a pattern that combines various elements of disruptive coloration (fig. 14.27). These include the light dorsal stripes found in many anurans, dark eye lines or masks that obscure the eyes, and patterns of irregular blotches or spots that break up the outline of the body and limbs. In some species, blotches that appear randomly placed when the animal is active form a contiguous pattern when the animal is at rest, thereby giving a sleeping animal an appearance unlike that of a frog. This type of coincident disruptive coloration is especially common on the limbs of anurans (Cott 1940).

Color Polymorphism

Many cryptically colored anurans are polymorphic for pattern and coloration (E. Hoffman and Blouin 2000). For example, some ranid frogs are polymorphic for background coloration (Corn 1981), the presence or absence of a light mid-dorsal stripe (Moriya 1952; Moriwaki 1953; Stugren 1966; Fishbeck and Underhill 1971; Ishchenko and Shchupek 1974; Schueler and Cook 1980), or the presence or absence of spots (Merrell 1965, 1973; L. E. Brown and Funk 1977). Cricket frogs (*Acris*) are polymorphic for vertebral stripe color, which may be gray, green, or reddish-brown

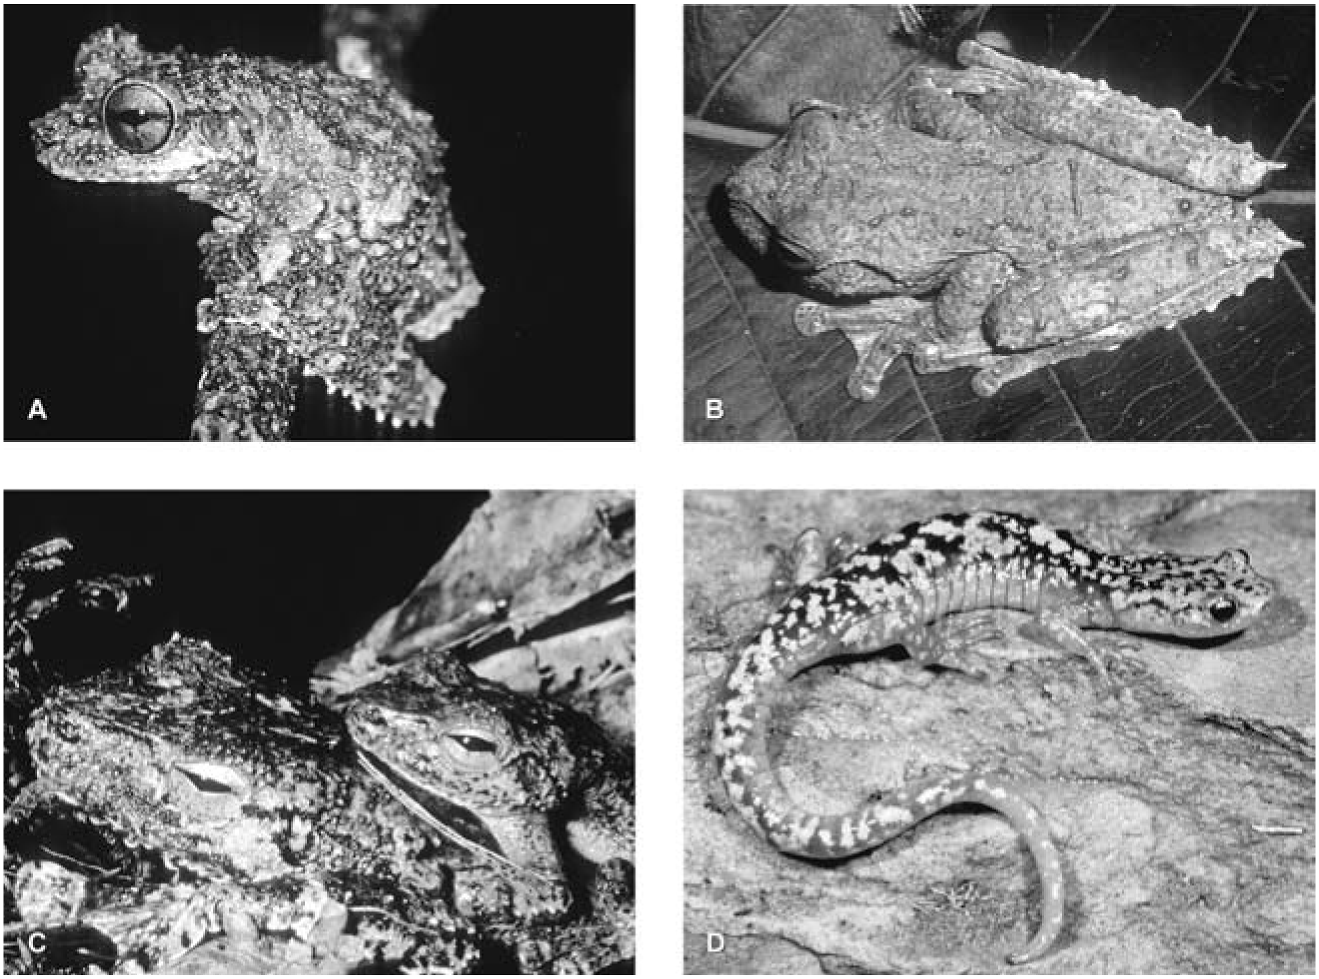

Fig. 14.25. A cryptic resemblance to moss or lichen is a common defensive adaptation among amphibians. (A) Mosslike pattern of a Neotropical treefrog, *Osteocephlus buckleyi* (Hylidae). (B) This treefrog from New Guinea, *Litoria genimaculata* (Hylidae) has a similar pattern, which is relatively conspicuous against a plain background. (C) Against a more complex background, this pair of *L. genimaculata* appears more cryptic. (D) The mottled pattern of *Aneides aeneus* (Plethodontidae) blends with the lichen-covered rocks typical of its habitat. Photos by Walter Hödl (A), David Bickford (B, C), and Wayne Van Devender (D).

(Pyburn 1961a, b; Nevo 1973; Milstead, Rand, and Stewart 1974; R. Gray 1983; Gorman 1986). Various species of *Pseudacris* are polymorphic for background coloration and dorsal pattern (Resnick and Jameson 1963; T. Matthews and Pettus 1966; Jameson and Pequegnat 1971; T. Matthews 1971; Tordoff, Pettus, and Matthews 1976; Tordoff and Pettus 1977; Tordoff 1980; Hoppe and Pettus 1984; Travis and Trexler 1984; S. R. Morey 1990). In *P. regilla,* there are both fixed green and brown morphs and a distinctive color-changing morph that can change between green and brown on a time scale of days or weeks (Wente and Phillips 2003). The slowness of color change in this morph would not enable a frog to assume cryptic coloration in response to an immediate predation threat, but would be adaptive in tracking seasonal changes in environmental background coloration. In fact, this species exhibits a seasonal shift in the proportion of brown and green morphs that tracks the availability of brown and green substrates. This shift probably is mediated by differential predation on the two color morphs, as well as the ability of some individuals to change color (Wente and Phillips 2005). Color change in this species is complex, however, and is affected not only by background color, but also by light intensity and temperature. Hence, color change in this species may serve other functions in addition to crypsis, such as thermoregulation (Stegen, Gienger, and Sun 2004).

Color polymorphism seems to be most pronounced in tropical anurans. M. Stewart (1974) estimated that at least 60% of the anuran species found in Malawi exhibit some degree of polymorphism. The most striking example is the genus *Hyperolius,* which exhibits so much variation in color within species that the group is a taxonomist's nightmare (Laurent 1965; Schiøtz 1971, 1999; Wieczorek, Channing, and Drewes 1998; Lötters et al. 2004). Small African frogs

Fig. 14.26. A general resemblance to dead leaves is common among terrestrial frogs that live in leaf litter, or those that breed in litter-filled ponds. (A) The Solomon Islands frog *Ceratobatrachus guentheri* (Ranidae) has a variable brown color pattern with skin flaps around the eyes, mouth, and legs that enhance its resemblance to dead leaves. (B) The Neotropical frog *Otophryne pyburni* (Microhylidae) has a leaflike color pattern and adopts an unusual upright, immobile posture to enhance the effect. (C) Another microhylid frog, *Chiasmocles shudicarensis,* has a middorsal line that enhances its resemblance to leaves while floating in a shallow pond. (D) The Panamanian toad *Bufo alatus* (Bufonidae) flattens itself on the ground when threatened, and flaps of skin on the side of the body eliminate shadows and enhance the dead-leaf effect. Photos by Wayne Van Devender (A), Walter Hödl (B, C), and Kentwood D. Wells (D).

of the genus *Phrynobatrachus,* which are rather similar to *Acris* ecologically, are highly polymorphic, with variation in background color, skin texture, and the size, shape, and color of vertebral stripes (Stewart 1974). Similar polymorphism occurs in Neotropical frogs of the genus *Eleutherodactylus,* which vary in background color, striping and spotting patterns, skin texture, and other pattern elements (fig. 14.28). Color patterns often vary in parallel among species in the same region, making species identification difficult (Goin 1947, 1950, 1954, 1960b; Lynch 1966; J. Savage and Emerson 1970; Crombie 1977, 1986; Lynch and Myers 1983; Heyer 1984; J. Savage 1987). Other polymorphic tropical frogs include *Polypedates leucomystax* (Church 1963), *Pleurodema bibroni* (Hellmich 1932; Cei and Capurro 1957; Cei 1958, 1962), *Rhinoderma darwinii* (Cei 1962), various hylid marsupial frogs (Duellman and Fritts 1971; Duellman 1973, 1983; Duellman and Ruiz-C. 1986), other hylid frogs such as *Hyla leucophyllata* and *H. ebraccata* (Duellman 1970), and toads in the *Bufo margaritifer* group (Hoogmoed 1990a; Hass et al. 1995).

Genetic control of color polymorphism has been well established for a number of species. It usually involves a rather simple Mendelian system (Goin 1950, 1954, 1960b; Moriya 1952; Moriwaki 1953; S. Anderson and Volpe 1958; Pyburn 1961a, b; Merrell 1965, 1973; Browder, Underhill, and Merrell 1966; Matthews and Pettus 1966; Fogleman, Corn, and Pettus 1980), although expression of color patterns also can be influenced by environmental conditions during tadpole development (Travis and Trexler 1984; Harkey and Semlitsch 1988) or ontogenetic changes (C. Richards 1976, 1982; Duellman and Ruiz-C. 1986). The selective forces that maintain color polymorphism in a population are not as well understood (see Dubois 1980b and E. Hoffman and Blouin 2000 for reviews). One possibility is that polymorphism is maintained by higher fitness in the heterozygotes (overdominance for fitness), but this is hard to test because heterozygotes generally cannot be identified in the field or laboratory (Merrell, 1969 1973).

Most explanations invoke some form of spatial or temporal variation in selective pressures, with predation often being the putative selective agent. Wood frogs (*Rana sylvatica*) with light vertebral stripes tend to increase from east to west in Minnesota. Fishbeck and Underhill (1971) suggested that striped morphs are more cryptic in areas where pine needles are common on the bottom of ponds, whereas unstriped morphs would be more cryptic in areas of hardwood forest. Schueler and Cook (1980) found a rough correlation between the amount of grass in breeding habitats and the frequency of striped morphs, again suggesting that linear patterns in the environment select for linear patterns on the frogs. However, even in grassy areas, the vast majority of wood frogs lack stripes, suggesting that other forces are important. J. Savage and Emerson (1970) attributed the high degree of polymorphism in *Eleutherodactylus* to the heterogeneous nature of the forest floor, arguing that the variety of colors, textures, and lighting conditions would result in continuously shifting selective advantages for different morphs. Again, predation was assumed to be the principal selective agent.

Other authors have argued that seasonal variation in selective pressures is the main force maintaining polymorphism in anuran populations. Several mechanisms have been proposed. One is that the survivorship of different color morphs changes with seasonal changes in background coloration (Merrell 1965; Matthews 1971; Jameson and Pequegnat 1971; Tordoff 1980). Another is that physiological differences give different morphs an advantage at different seasons (Merrell and Rodell 1968; Hoppe 1978). A third is that differences in rates of larval development favor faster-developing morphs in dry seasons (Merrell 1972; Bull 1977;

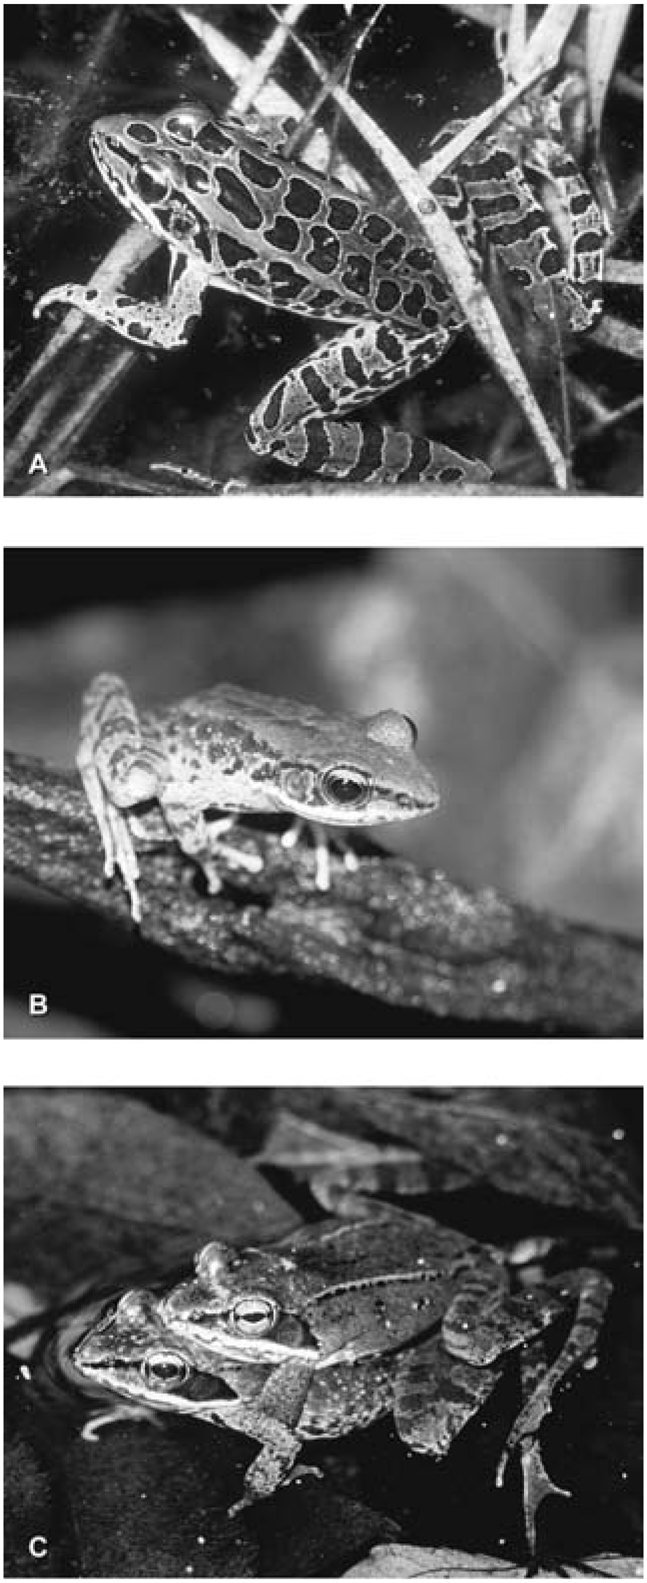

Fig. 14.27. Many frogs, such as these ranids, exhibit generalized cryptic color patterns that include several elements of disruptive coloration that serve to break up the outline of the body. (A) *Rana palustris* from North America, a species found in all sorts of terrestrial habitats near ponds. Elements of cryptic coloration include spots, transverse bars on the legs, and light dorsal lines. (B) *Rana swinhoana* from Taiwan, which lives among boulders in small streams. Elements of cryptic coloration include brown dorsal color with countershading, blotches on the sides of the body, transverse bars on the hind legs, and a dark line through the eye. (C) *Rana sylvatica* from North America, which breeds in leaf-filled ponds, but spends most of the year in leaf litter on the forest floor. This species exhibits some degree of background matching, adopting a dark color while in breeding ponds, but a lighter color while on land. Photos by Kentwood D. Wells.

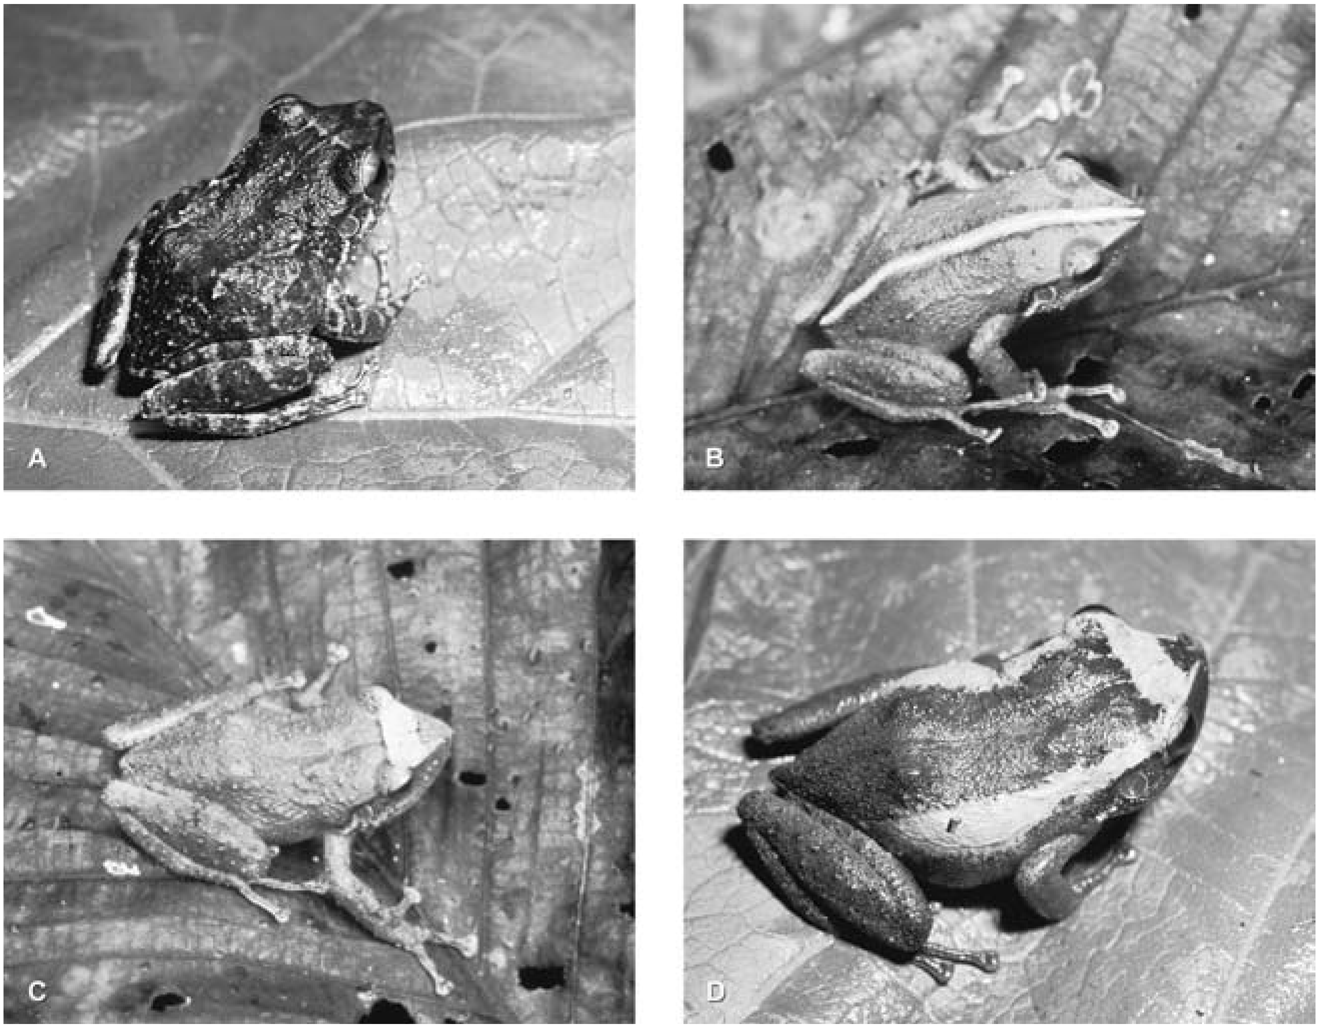

Fig. 14.28. Color pattern polymorphism in a Puerto Rican frog, *Eleutherodactylus coqui.* All of these color patterns can be found in individuals living in the same habitat. Photos by Margaret M. Stewart (A, D) and Daniel S. Townsend (B, C).

Corn 1981; Hoppe and Pettus 1984). Pyburn (1961a) observed a seasonal shift in color morph frequencies in cricket frogs (*Acris*) that he attributed to changes in substrate coloration. Nevo (1973) reported a correlation between substrate color and morph frequency over a wide geographic area, but he did not detect seasonal shifts in morph frequencies. He thought that both visual selection by predators and physiological differences among color morphs were responsible for the maintenance of color polymorphism. However, subsequent studies have found little evidence of seasonal variation in selection, differential predation, or physiological differences that would favor one morph over another (Isaacs 1971; R. Gray 1977, 1978, 1983; Gorman 1986).

Milstead, Rand, and Stewart (1974) suggested that color polymorphism in frogs is maintained by apostatic selection, a form of frequency-dependent selection (B. C. Clarke 1962; Ayala and Campbell 1974). Predators often form search images of their prey and are likely to focus on the most common prey types, taking them in frequencies greater than expected from their representation in the population, while rare forms are likely to be taken less frequently than expected (Murdoch and Oaten 1975). Switching between prey types as a function of relative abundance has been demonstrated in a number of species (B. C. Clark 1962; Ayala and Campbell 1974; Murdoch and Oaten 1975; Curio 1976; Sargent 1981). Pietrewicz and Kamil (1981) found that blue jays improved their ability to find cryptic prey when they had repeated experience with the same morph, but failed to improve their detection when presented with several morphs in random order. This supports the idea that polymorphism could reduce predation on highly variable frogs such as *Eleutherodactylus*.

Much of the thinking on color polymorphism in anurans has been somewhat simplistic, and many of the proposed modes of selection are at odds with conclusions drawn from theoretical population genetics. The idea that spatial or temporal variation in selective pressures can maintain polymorphism in populations is intuitively appealing, but population genetics models suggest that this will happen only under certain conditions. Fine-grained spatial variation, such as that proposed by J. Savage and Emerson (1970), is unlikely to lead to polymorphism in the absence of overdominance (specifically, unless the geometric mean fitness of the heterozygotes exceeds that of the homozygotes). This is because selective advantages enjoyed by different morphs are never perfectly balanced, and one eventually would become fixed in the population (Felsenstein 1976; Hedrick, Ginevan, and Ewing 1976; Hedrick 1986). Course-grained spatial variation is unlikely to maintain polymorphism unless there is differential choice of appropriate microhabitats by different morphs. Conditions under which polymorphism can be maintained by temporal variation in selective pressures are even more restrictive than for spatial variation, but in general, polymorphism will not be maintained in the absence of overdominance. This is particularly true when the generation time of the organism is a year or more, as it is in frogs (Felsenstein 1976; Hedrick, Ginevan, and Ewing 1976; Hedrick 1986).

At present, some form of frequency-dependent selection, such as the apostatic selection proposed by Milstead, Rand, and Stewart (1974), seems the most likely explanation for the maintenance of color polymorphism, but this has not been tested experimentally for any anuran species. Probably it is unrealistic to expect that a single evolutionary force will explain polymorphism in all anurans. In well-studied polymorphic species such as European banded snails (*Cepaea*), a variety of interacting evolutionary forces have been found to be important in determining morph frequencies in different populations. Heterozygote advantage, climatic selection, visual selection by predators, frequency-dependent selection, density-dependent selection, disruptive selection, stabilizing selection, and various random process all may be operating (J. S. Jones, Leith, and Rawlings 1977). The whole question of color polymorphism in anurans needs to be reexamined, with an eye toward rigorous testing of hypotheses derived from current ideas in population genetics.

Behavioral Avoidance of Predators

Juvenile or adult amphibians often have characteristic behavioral responses to predators. Perhaps the simplest defense is to avoid locations where predators are likely to be found. Until recently, most studies of antipredator behavior in juvenile or adult amphibians focused on responses to direct contact by predators. It has now become clear that some amphibians are capable of detecting and avoiding chemical cues from predators or injured conspecifics, even when the predator is not present. This is to be expected in aquatic amphibians, which tend to rely heavily on chemical senses for much of their behavior, but perhaps more surprising in terrestrial amphibians, especially anurans, which are not known for their chemosensory abilities. Newts (*Cynops* and *Notophthalmus*) avoided chemical extracts from the skin of conspecifics when these are presented on land (Marvin and Hutchison 1995) or in the water (Woody and Mathis 1997). Adult newts avoided chemical stimuli from predatory fish if these were associated with stimuli from injured conspecifics (newt skin extract), but not to fish stimuli alone (Woody and Mathis 1998). Once conditioned to avoid newt skin extract, the newts also avoided stimuli from an unfamiliar predator (*Siren*) if those stimuli were associated with newt skin extract. Experiments with another aquatic salamander, *Eurycea multiplicata griseogaster,* showed that salamanders could distinguish between predatory fish and nonpredatory tadpoles through chemical, but not visual, cues, and they also could distinguish predatory from nonpredatory fish species through chemical cues (Hickman, Stone, and Mathis 2004).

Several studies have shown that terrestrial and semiaquatic salamanders and anurans also respond to chemical stimuli from injured or stressed conspecifics (Lutterschmidt, Marvin, and Hutchison 1994; Chivers et al. 1996, 1997, 1999; Mathis and Lancaster 1998; B. Graves and Quinn 2000; Hucko and Cupp 2001; Watson et al. 2004), although not all species consistently show this type of response (Marvin et al. 2004). Some salamanders also respond to chemical cues from predatory snakes (Cupp 1994; Flowers and Graves 1997; DeVito et al. 1998; Schley and Griffiths 1998; R. Watson, Mathis, and Thompson 2004). Red-backed salamanders (*Plethodon cinereus*) gave a stronger response to odors from snakes that had fed on salamanders than to those that had fed on earthworms (Madison et al. 1999a, b; McDarby, Madison, and Maerz 1999; Murray and Jenkins 1999). In general, this species also responded more strongly to snakes that had fed on conspecifics than on heterospecific salamanders, although red-backed salamanders that were sympatric with *Eurycea bislineata* also avoided snakes that had fed on that species (A. Sullivan, Picard, and Madison 2005). Red-backed salamanders did not avoid chemical cues from snakes that had fed on *Desmognathus ocrophaeus,* a species that does not use the same microhabitats. *Eurycea bislineata* avoided cues only from snakes that had fed on conspecifics, whereas *D. ochrophaeus* did not avoid any predator cues (A. Sullivan, Madison, and Rohr 2004).

Several amphibians in the western United States showed variable responses to predator cues. Three species (*Rana lutiventris, Pseudacris regilla,* and *Ambystoma macrodactylum*), tested with garter snakes (*Thamnophis elegans*), did not distinguish between chemical cues from predators that had fed on conspecifics or on earthworms, although the two frog species did avoid chemical cues from injured conspecifics (Wirsing, Roth, and Murray 2005). *Rana luteiventris* adults did avoid chemical cues from garter snakes, as did *A. macrodactylum,* whereas *P. regilla* and *Taricha granulosa* did not (Murray, Roth, and Wirsing 2004). Only *R. luteiventris* showed avoidance of chemical cues from bullfrogs (*Rana catesbeiana*), predators that are not native to the region.

Behavioral Defenses against Predators

Once an amphibian actually encounters a predator, its behavioral responses depend on the morphology and ecology of the animal and the identity and proximity of the predator. In many cases, fleeing from a predator is the most effective defense. Many slender-bodied frogs are agile jumpers (see chapter 1) and rely on rapid flight to escape predators (Marchisin and Anderson 1978; Licht 1986a; Heinen and Hammond 1997). Plethodontid salamanders often exhibit flipping behavior, literally snapping themselves away from the predator with rapid jerks of the body (Brodie 1983; Brodie, Dowdey, and Anthony 1989; Hileman and Brodie 1994; Dowdey and Brodie 1989; Whiteman and Wissinger 1991; Azizi and Landberg 2002). One salamander that lives on rocky slopes, *Hydromantes platycephalus,* coils its body and escapes by rolling away from a predator (García-París and Deban 1995). Similar behavior has been seen in a toad (*Oryophrynella*) that also lives on hillsides (McDiarmid and Gorzula 1989). Alternatively, many amphibians become immobile and flatten themselves against the ground, especially if contacted by a predator such as a snake (Brodie, Johnson, and Dodd 1974; Dodd and Brodie 1976; Brodie 1977; Dodd 1977, 1989; Dodd and Cupp 1978; Dowdey and Brodie 1989; Hayes 1989; Heinen and Hammond 1997). This behavior is found both in species that are well protected by noxious chemicals and those that lack such defenses. Others flip themselves on their backs and remain immobile (fig. 14.29 B), a behavior sometimes called "death-feigning," although the functional significance of the behavior is poorly understood (Toledo 2004b; Vaz-Silva et al. 2004).

Amphibians in close proximity to predators such as snakes often must select an appropriate antipredator behavior very quickly, and choosing the wrong behavior can be fatal. When confronted by birds or mammals, two-lined salamanders (*Eurycea bislineata*) exhibit display postures that present noxious skin glands to the predator (Brodie 1977; Brodie, Nowak, and Harvey 1979; see "Chemical Defenses," following). This type of response is ineffective against garter snakes, which are not repelled by the salamanders' skin secretions. The usual response to snakes is either to remain immobile or to flee, but not to display (Ducey and Brodie 1983). The best response depends on how the snake contacts the salamander. If contacted by the snake's head or body, the most effective defense is to remain immobile, but if contacted by the snake's tongue, then fleeing is most effective. This species exhibits both individual and geographic variation in antipredator behavior. Individuals that fled from garter snakes were faster runners than were those that remained immobile, and salamanders from populations where snakes were common were more likely to flee than those from areas were snakes were scarce (Dowdey and Brodie 1989). Another salamander, *Desmognathus ocoee,* often is confronted by larger species such as *D. quadramaculatus* and *Gyrinophilus porphyriticus,* which are capable of eating it. *Gyrinophilus* is the more dangerous predator (Formanowicz and Brodie 1993), and *D. ocoee* is more likely to flee from that species than from *D. quadramaculatus* (Hileman and Brodie 1994).

Some frogs and salamanders give displays or vocalizations that may serve to startle the predator (Licht 1973; Sazima 1975; Veloso 1977; Brodie 1978; Weber 1978b; see chapter 7). A number of large frogs are capable of inflicting painful bites on attacking predators (Duellman and Trueb 1986), and even small salamanders such as *Desmognathus* can deter predators with persistent bites (Brodie 1978; Brodie, Dowdey, and Anthony 1989; Whiteman and Wissinger 1991). When actually grabbed by a predator, amphibians use a number of methods to reduce their chances of being swallowed. Many anurans inflate the body and stretch out their legs when confronted by predators (fig. 14.29 C), particularly snakes that swallow their prey whole (Hinsche 1928; Hanson and Vial 1956; Marchisin and Anderson 1978).

Tail displays are an important component of antipredator behavior in many salamanders (fig. 14.30), especially in the families Plethodontidae and Salamandridae (Brodie 1977; Brodie, Nussbaum, and DiGiovanni 1984; Brodie, Nussbaum, and Datong 1990). Plethodontids often display the tail to redirect attacks away from the head and body. In some species, the tail is readily autotomized (broken off) when the salamander is attacked (Wake and Dresner 1967). This often allows the salamander to escape while the predator consumes the tail (Arnold 1982; Ducey and Brodie 1983; Labanick 1984; Ducey et al. 1993). The disadvantage of this strategy is that valuable energy reserves may be lost, thereby reducing future growth and reproduction. Maiorana (1977) and Arntzen (1981) suggested that loss of tails in salamanders could result in females skipping a year of reproduction. They worked on two genera (*Batrachoseps* and *Chioglossa*) that have unusually long tails relative to body size. More recent work on two species with shorter tails, *Desmognathus ocoee* and *D. carolinensis,* indicated that even severely injured animals still could reproduce, but the magnitude of tail injury was negatively correlated with reproductive investment (Bernardo and Agosta 2005). Salamanders also use tail displays to direct attacks of predators

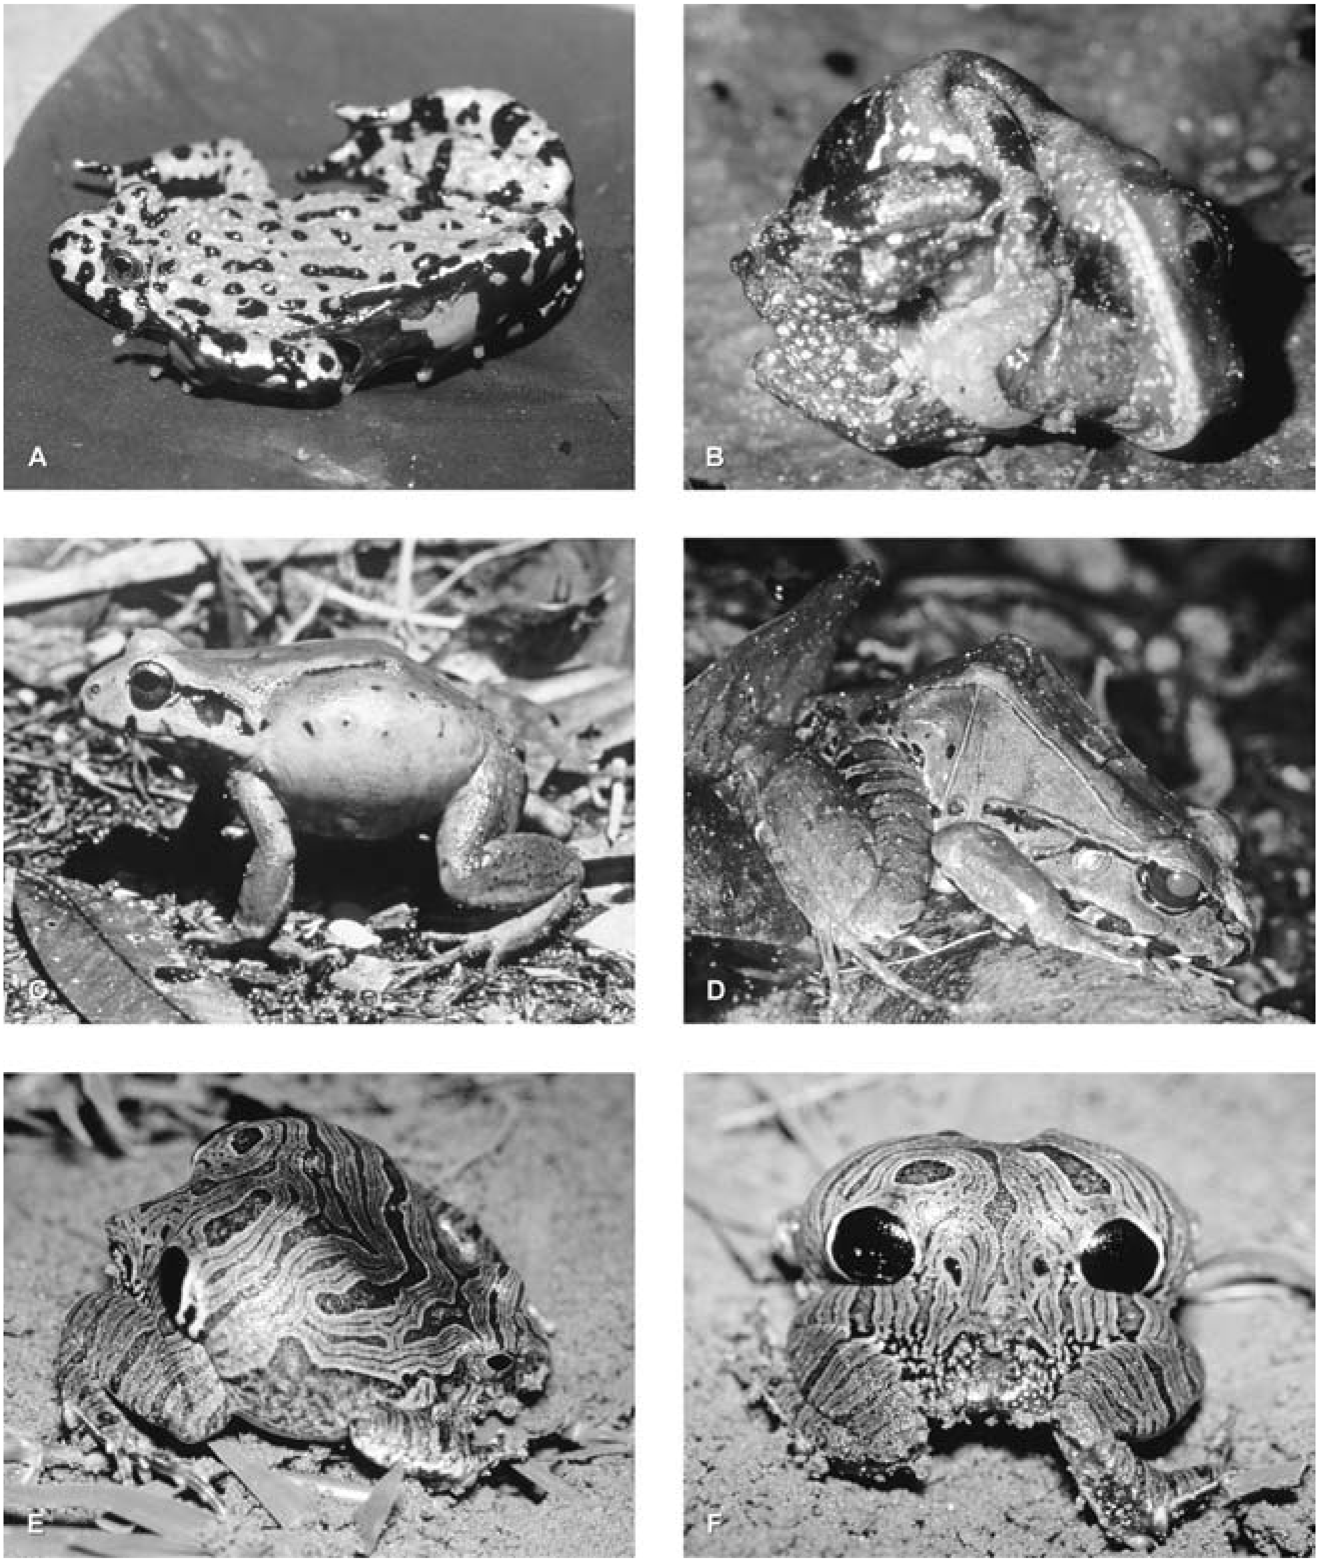

Fig. 14.29. Defensive postures of anurans. (A) *Bombina orientalis* (Bombinatoridae) has a green and black pattern on the back and bright red and black markings on the feet and belly, probably a means of displaying aposematic coloration to fish attacking from below. When disturbed on land, members of this genus adopt an "unken reflex" posture that reveals the bright coloration on the feet to potential predators. (B) Many anurans become immobile when threatened by predators, adopting a so-called "death feigning" posture, as in *Kassina lamottei* (Hyperoliidae) from the Ivory Coast. (C) Large anurans often repond to predators by elevating the body and infating themselves with air, thereby exaggerating the size of the body, as in *Leptodactylus stenodema* (Leptodactylidae) from South America. (D) Another common defensive posture is to lower the head and elevate the rear part of the body, as in *Leptodactylus pentadactylus.* This posture probably makes the head less vulnerable and often exposes dorsal poison glands to the predator. (E, F) *Physalaemus nattereri* (Leptodactylidae) from Brazil combines this head-down posture with fake eyespots, which are particularly conspicuous from the rear and may startle predators and advertise posterior poison glands. Photos by Martha L. Crump (A), Mark Oliver Rödel (B), Walter Hödl (C, D), and Celio F. B. Haddad (E, F).

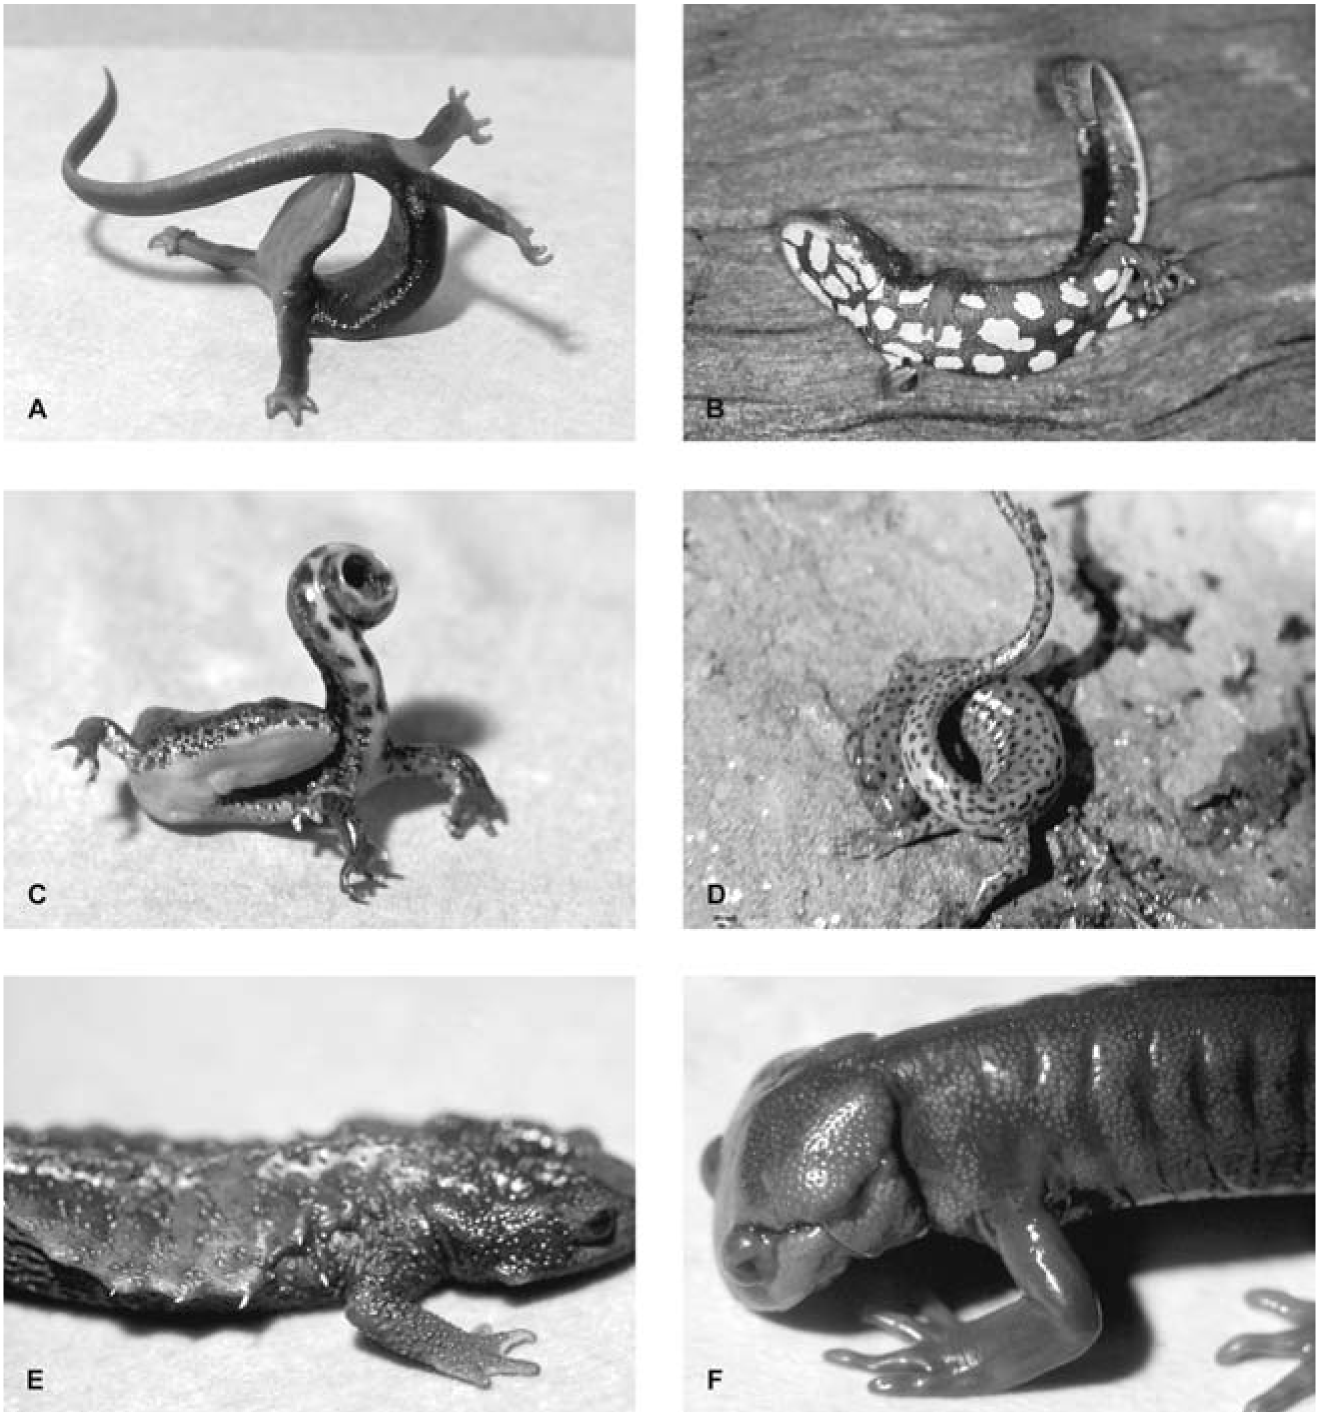

Fig. 14.30. Defensive postures of urodeles. (A) "Unken reflex" display of aposematic ventral coloration in a North American newt, *Taricha rivularis* (Salamandridae). (B) Display of aposematic ventral coloration by an Asian newt, *Paramesotriton deloustali* (Salamandridae). (C) Rigid posture of the alpine newt, *Triturus alpestris,* with bright orange ventral color on the tail directed toward the predator. (D) Elevated tail display of a North American cave salamander, *Eurycea lucifuga* (Plethodontidae). (E) The Asian newt *Echinotriton andersoni* (Salamandridae) has sharp ribs that protrude through the body wall. This not only injures a predator, but also delivers secretions from poison glands into the predator's mouth. (F) Head-butting posture of a North American salamander, *Ambystoma gracile* (Ambystomatidae), which exposes large parotoid glands to the predator. Photos by Edmund D. Brodie, Jr.

toward aggregations of poison glands on the tail; these displays are discussed in more detail under "Chemical Defenses," following. Some species wrap their tails around a predator and exude copious amounts of mucus, thereby partially immobilizing the predator (Arnold 1982; Brodie 1983).

Chemical Defenses

Amphibians have a highly glandular skin (see chapter 2) and have a greater array of chemical defenses than any other group of vertebrates. Defensive secretions are produced by granular glands in the skin, so called because of their granular appearance under the microscope. These glands are found in all amphibians and are rather similar in structure, regardless of the types of compounds produced. Lindemann and Voute (1976), Whitear (1977), and Toledo and Jared (1995) provide reviews of amphibian skin and gland structure, and I will not discuss the histology of glands in detail here. Granular glands appear to be an ancestral amphibian trait and originally may have produced compounds other than defensive secretions, with production of highly toxic compounds being a secondary adaptation that has evolved independently a number of times (Neuwirth et al. 1979). For example, many of the skin secretions of amphibians have antibacterial or antifungal properties (Preusser et al. 1975; Zasloff 1987; Barthalmus 1994; Toledo and Jared 1995; Bowie et al. 1999), and protection against these disease agents could have preceded the evolution of chemical defenses against predators.

Granular glands often are distributed throughout the skin, as in many dendrobatids, hylids, ranids, microhylids, pelobatids, leptodactylids, and salamandrids (Lutz 1971; Brodie 1977; Garton and Mushinsky 1979; Neuwirth et al. 1979; Duellman and Trueb 1986; Toledo and Jared 1995). They also may be concentrated in certain regions or aggregated into larger glands. These include the parotoid glands found behind the head in many bufonids and some other anurans. Some bufonids, ranids, pelobatids, leptodactylids, myobatrachids, and discoglossids have large glands, clusters of glandular warts, or glandular ridges on the legs, along the sides of the body, or on the dorsal surface (Toledo and Jared 1995). Parotoid glands are found in many salamandrids and some ambystomatids, hynobiids, and plethodontids (Brodie 1983). Salamanders in these families also have concentrations of granular glands on the dorsal surface of the tail, and salamandrids may have lateral glands as well. In the spiny newts (*Echinotriton*), sharp ribs penetrate the lateral warts (fig. 14.30 E) and serve to injure predators and to deliver poisonous secretions into the wounds (Brodie, Nussbaum, and DiGiovanni 1984). Sharp ribs also are found in *Pleurodeles* and serve a similar function. However, in this genus, poison glands are found all over the body, and are not concentrated around the rib tips (Nowak and Brodie 1978). The European fire salamander (*Salamandra salamandra*) has a double row of very large middorsal glands running from the back of the head to the tip of the tail. These are imbedded in specialized trunk muscles that can be contracted to spray the noxious secretions of the glands toward predators (Brodie and Smatresk 1990).

Defensive postures of amphibians are closely correlated with the distribution of granular glands. Anurans with parotoid glands, or concentrations of dorsal poison glands, respond to predators by bending the head downward and arching the back (fig. 14.29 D), exposing the glands to the attacker (fig. 14.29; Hinsche 1928; Hanson and Vial 1956; Brodie and Gibson 1969; Villa 1969; Altig 1972a; Toledo 2004a). In a number of unrelated species of frogs, conspicuous patches on the flanks or inguinal region are closely associated with concentrations of granular glands. These frogs respond to predators by elevating the rear of the body to expose these bright patches and to orient the glands toward the predator (fig. 14.29 E, F; see the following "Aposematic Coloration"). Anurans that have concentrations of granular glands and bright coloration on the ventral surface, such as *Bombina* and *Melanophryniscus,* respond to predators with the "unken reflex," with the back arched and the ventral surfaces of the feet and throat displayed (fig. 14.29 A).

Some newts have a similar defensive posture (fig. 14.30 A). Salamanders with concentrations of glands in the tail often display the tail, wave it at the predator, or lash it from side to side when attacked (fig. 14.30 B, C). This increases the likelihood that the predator will attack the tail and receive a dose of noxious secretions. It also exposes the least vital part of the animal's body to attack. Salamandrids with granular glands throughout the body often exhibit immobility responses to predators, or adopt postures that expose aposematic patterns to the attacker (Brodie, Johnson, and Dodd 1974; Brodie 1977, 1983). Salamanders that have granular glands concentrated in parotoid glands on the head adopt postures that direct these glands toward a predator (fig. 14.30 F).

Amphibian granular glands produce a wide array of compounds that serve a defensive function (Toledo and Jared 1995). There is an enormous literature on the biochemical structure and pharmacological properties of these secretions, mainly because of their potential application in the development of human drugs. Erspamer (1994) and Daly, Garraffo, and Spande (1999) provided exhaustive reviews of the subject, and I will not go into great detail here (for earlier reviews, see Daly and Witkop 1971; Erspamer 1971; Daly et al. 1978; Daly, Highet, and Myers 1984; Daly, Garraffo, and Spande 1993). Amphibian defensive secretions include two general categories of compounds (Daly and Witkop 1971; Daly, Highet, and Myers 1984). The first are widespread, naturally occurring compounds that may serve other biological functions, such as protection against microbes and fungi, but are effective as defensive secretions when produced in large quantities. These include various biogenic amines and peptides that are found in most of the major amphibian families. Some of these have irritant properties, while others are quite toxic. Other compounds seem to have evolved mainly for defensive purposes and often are very toxic. These include tetrodotoxins and related compounds, found in many species of salamandrids and some anurans (*Atelopus* and *Brachycephalus*); cardiotoxic steroids known as bufodienolides, found mainly in bufonids; and extremely toxic steroidal alkaloids, found in *Salamandra, Dendrobates, Epipedobates, Phyllobates,* and some bufonids (*Melanophryniscus*), myobatrachids (*Pseudophryne*), and *Mantella.* The diversity of compounds that serve much the same function is enormous. Several hundred alkaloids have been described from the Dendrobatidae alone, and altogether, some 400 alkaloids are known from amphibian skin (Daly et al. 1978; Daly, Highet, and Myers 1984; Daly, Garraffo, and Spande 1993). Nearly identical defensive compounds have evolved independently in different families of amphibians (Daly, Highet, and Myers 1984; Daly et al. 1996), yet populations of a single species may produce very different compounds (Daly and Myers 1967; Myers and Daly 1983; V. Clark et al. 2005). Even individuals within the same population often differ in alkaloid profiles (V. Clark et al. 2005).

The origin of many of the alkaloids found in the skin of dendrobatid frogs and other anurans was long a mystery (Daly 1995, 2003; Daly, Garraffo, and Myers 1997). Some of these compounds lack known counterparts in other plants or animals and are presumed to be synthesized by the frogs (B. P. Smith et al. 2002). These include bufadienolides, which are present in laboratory-reared animals raised on a diet of fruit flies (Daly, Garraffo and Myers 1997; Daly, Padgett et al. 1997). Others, however, are derived from chemicals obtained from the arthropods that these animals eat (Daly Garraffo et al. 1994). Many of the toxic dendrobatids feed mostly on ants (Toft 1995; Caldwell 1996b), as do poison frogs (*Mantella*) from Madagascar (Vences, Glaw, and Böhme 1997/98; V. Clark et al. 2005) and many bufonids. Among dendrobatids, the presence of distasteful and toxic alkaloids and aposematic coloration is correlated with the degree of dietary specialization on ants, and has evolved independently in several distantly related clades within the family (Santos, Coloma, and Cannatella 2003; Summers 2003; Darst et al. 2005). Several types of alkaloids found in the skin of these frogs are similar or identical to compounds found in ants (Daly 1998; Spande et al. 1999; T. Jones et al. 1999; Daly et al. 2000, 2002; Saporito et al. 2004). Other probable sources of toxic compounds include beetles and millipedes (Daly 1995; Saporito et al. 2003; V. Clark et al. 2005). When toxic frogs such as *Dendrobates, Atelopus,* and *Mantella* were fed on fruit flies in the laboratory, they lacked most alkaloid skin secretions, indicating that these compounds are derived from the diet. There has been remarkable convergent evolution in aposematic color pattern, the presence of toxic alkaloids, and the ability to acquire defensive chemicals from the diet in dendrobatid and mantellid frogs, two families that are quite distantly related (V. Clark et al. 2005).

When laboratory-reared dendrobatid frogs (*Dendrobates, Phyllobates,* and *Epipedobates*) were fed fruit flies dusted with alkaloids in the laboratory, the chemicals accumulated in the skin and remained active for months (Daly, Secunda et al. 1994). Some of these compounds apparently are sequestered unchanged, but for some species of *Dendrobates,* there is evidence of secondary metabolic enhancement of the toxic effects of ingested alkaloids (Daly et al. 2003). Nontoxic dendrobatids in the genus *Colostethus* do not accumulate alkaloids and apparently lack the biochemical machinery to do so.

The skin secretions of amphibians are noxious to a wide variety of predators, including birds (see references in discussion of aposematic coloration and mimicry), mammals (J. Anderson 1963; Brodie, Nowak, and Harvey 1979; Formanowicz and Brodie 1979; Brodie and Formanowicz 1981; Mason, Rabin, and Stevens 1982), turtles (Hurlbert 1970), snakes (Hurlbert 1970; Lüling 1971; Sazima 1974; C. Myers, Daly, and Malkin 1978; Zielinski and Barthalmus 1989; Barthalmus 1994), amphibians (Brodie 1968b; Hurlbert 1970), fishes (Hurlbert 1970), ants (Fritz, Rand, and de Phaniphilis 1981), and spiders (Szelistowski 1985). The secretions need not be toxic to be effective, but may simply repel predators by irritating mucus membranes of the mouth, causing regurgitation, impairing coordination, or affecting their chemical senses. Nevertheless, amphibians vary in their degree of toxicity to predators, and some have skin secretions that are capable of killing predators (Brodie, Ducey, and Baness 1991). Presumably, many predators that live in the same habitats with highly toxic amphibians learn to recognize them or exhibit innate avoidance of these animals and are seldom actually killed. When toxic prey, such as the toad *Bufo marinus,* are introduced into areas with naïve predators, however, the results can be fatal to the predators (Covacevich and Archer 1975; Burnett 1997; Catling et al. 1999; B. Phillips, Brown, and Shine 2003).

Why do some amphibians evolve extremely toxic skin secretions, while others have only noxious ones? One possible reason is the energetic cost of maintaining the biochemical machinery needed to either manufacture or sequester highly toxic compounds in the skin, but this cost has yet to be investigated. Another is that predators vary in their responses to skin secretions and may evolve resistance to the chemical defenses of amphibians. This in turn will select for increased toxicity in the skin secretions of the amphibian prey. Some tropical snakes, such as *Leimadophis epinephelus,* seem to be remarkably resistant to toxins produced by *Dendrobates, Phyllobates,* and *Atelopus,* and will eat dendrobatid frogs that are rejected by other tropical snakes (Myers, Daly, and Malkin 1978). Snakes such as *Heterodon* and *Xenodon* feed mostly on toads that are distasteful or even toxic to other predators (H. M. Smith and White 1955). Some garter snakes also feed on toads and exhibit enhanced resistance to toad poisons (Macartney and Gregory 1981).

The best-studied example of this type of evolutionary arms race between predators and prey involves garter snakes (*Thamnophis sirtalis*) preying on newts (*Taricha granulosa*), the most toxic of all salamanders (fig. 14.31). Garter snakes in Oregon regularly feed on newts. Snakes from populations that are sympatric with newts and are known to feed on them are more resistant to newt toxins (tetrodotoxin) than are snakes from populations where newts are not found. They also are more resistant than is another species of garter snake, *T. ordinoides,* which never feeds on newts (Brodie and Brodie 1990). On Vancouver Island, British Columbia, newts are much less toxic than are those on the mainland. Garter snakes on Vancouver Island readily feed on these newts, but the snakes are not resistant to the toxins of mainland newts (Brodie and Brodie 1991; Hanifin et al. 1999). Individual snakes appear to assess their own level of resistance and reject newts that are too toxic for them to consume (B. Williams, Brodie, and Brodie 2003).

Tetrodotoxin resistance is derived from evolutionary changes in sodium channels in muscle (Geffeney et al. 2002, 2005). Such resistance appears to carry a cost, because movement speed was negatively correlated with resistance, and this may affect a snake's ability to escape from predators (Brodie and Brodie 1999). Tetrodotoxin resistance has a genetic basis (Brodie and Brodie 1990), and the snakes do not acquire resistance from repeated exposure to the toxin (Ridenhour, Brodie, and Brodie 1999). There is considerable geographic variation in resistance among populations of garter snakes, even on small spatial scales (Brodie, Ridenhour, and Brodie 2002). Phylogenetic analysis of tetrodotoxin resistance across a wide range of colubrid snakes indicated that only *Thamnophis sirtalis* that are sympatric with *Taricha* are highly resistant. However, all species of garter snakes that were tested, and possibly all natricine snakes, exhibit somewhat higher resistance than do other clades of colubrid snakes (Motychak et al. 1999). Species of *Thamnophis* with low resistance exhibit some genetic variation for resistance, indicating that this genus may be predisposed to evolve resistance to toxic prey.

Aposematic Coloration

Many amphibians are brightly colored, and most either have noxious skin secretions or are Batesian mimics of noxious

Fig. 14.31. A garter snake (*Thamnophis sirtalis)* from the Pacific Northwest eating a highly poisonous newt (*Taricha granulosa*). Populations of garter snakes that eat newts have evolved heightened resistance to tetrodotoxin secreted by the newts. Photo by Edmund D. Brodie III.

species (fig. 14.32). Individuals benefit from this aposematic coloration because predators learn to associate certain colors with distastefulness of the prey. This requires that the color patterns of prey species contrast with the prevailing background coloration, making the animals conspicuous to potential predators (Siddiqi et al. 2004). Although most aposematically colored amphibians exhibit contrasting patterns of black, red, orange, or yellow, a variety of other colors, including bright blue and green, can be aposematic if these colors contrast with the background colors of the habitat. Indeed, some species, such as *Dendrobates pumilio,* exhibit extreme polymorphism in aposematic coloration (Summers, Cronin, and Kennedy 2003). Some of this polymorphism may be maintained by sexual selection. Females prefer to mate with males of the same color morph (Summers et al. 1999), even though individuals of different color morphs can successfully interbreed (Summers, Cronin, and Kennedy 2004).

Aposematic coloration has evolved independently many times in amphibians. The most striking examples are the Neotropical dart-poison frogs (*Dendrobates, Allobates, Epipedobates,* and *Phyllobates*), which display various combinations of bright red, orange, yellow, and blue coloration (Myers and Daly 1983). A phylogenetically based comparative analysis of the family Dendrobatidae indicated that level of toxicity, determined by injecting skin secretions into laboratory mice, is positively correlated with brightness of coloration, determined on a ranked scale by human observers (Summers and Clough 2001). Members of the genus *Phyllobates* are the most colorful and the most toxic, whereas members of the genus *Colostethus* are the least colorful and the least toxic. The genera *Allobates, Epipedobates,* and *Dendrobates* are intermediate in both respects. There also is a tendency within lineages for bright coloration to be correlated with large body size, suggesting that selection has favored increased body size in the most aposematically colored species (Hagman and Forsman 2003).

There are many other brightly colored frogs in various parts of the world, especially in the tropics. Frogs of the genus *Mantella* from Madagascar superficially resemble dendrobatid frogs in their morphology, chemical defenses, and coloration, and in their diurnal habits (Daly, Highet, and Myers 1984; V. Clark et al. 2005). Neotropical bufonids of the genus *Atelopus* (Fuhrman, Fuhrman, and Mosher 1969; Kim et al. 1975) often have red, yellow, orange, and black markings. The "golden frog" (*Atelopus zeteki*) of Central America, the Costa Rican "golden toad" (*Bufo periglenes;* J. Savage 1966), and the "gold frog" of southeastern Brazil (*Brachycephalus ephippium*) all are bright orange. The Australian myobatrachids *Notaten bennetti* and *Pseudophryne corroboree* have conspicuous yellow, red, and black markings (Habermehl 1965; Daly, Highet, and Myers 1984; Barker, Grigg, and Tyler 1995). The South American frog *Leptodactylus laticeps* has large red spots on a yellowish-white background (Cei 1980). The African frogs *Kassina senegalensis* (Hyperoliidae) and *Phrynomantis bifasciatus* (Microhylidae) both have patterns combining black with yellow, red, or pink markings (Cott 1940; Jaeger 1971c; Passmore and Carruthers 1995).

The most conspicuously aposematic urodeles are salamandrids such as yellow and black European fire salamanders (*Salamandra*) and the terrestrial red eft stage of the newt *Notophthalmus viridescens* (Cott 1940; Brodie 1968b; Steward 1969). The bright red plethodontid salamander *Pseudotriton ruber* also is distasteful to some predators (Brandon, Labanick, and Huheey 1979b; Brodie, Nowak, and Harvey 1979). The yellow and orange spots of *Ambystoma maculatum* appear to serve an aposematic function (Barach 1951; R. R. Howard 1971; Brodie, Nowak, and Harvey 1979). The same probably is true of the conspicuous black-and-yellow and black-and-white patterns of other ambystomatids such as *A. tigrinum, A. macrodactylum, A. annulatum,* and *A. opacum,* all of which are distasteful to predators (J. Anderson 1963; Brodie 1977; DiGiovanni and Brodie 1981; Mason, Rabin, and Stevens 1982). A number of Neotropical bolitoglossine salamanders have bright red, orange, or yellow markings on a dark background and are quite distasteful to predators (Dodd and Brodie 1976).

Some distasteful species are not brightly colored all over, but have patches of bright coloration that probably serve as aposematic signals. For example, salamanders such as *Plethodon jordani, Bolitoglossa subpalmata,* and *B. flavimembris* have dark dorsal coloration with bright red, orange, or yellow markings on the legs or cheeks; all produce noxious skin secretions (Dodd and Brodie 1976; Hensel and Brodie 1976). A somewhat similar pattern is found in the Asian salamandrid *Tylototriton taliangensis,* which has a dull black dorsum with orange patches on the parotoid glands and toes (C. Liu 1950). Examples among anurans include the Australian myobatrachid *Pseudophryne australis* and the South American leptodactylid *Telmatobufo bullocki,* both of which have red or yellow patches on the head (Cei 1962; Barker, Grigg, and Tyler 1995). Australian myobatrachids such as *Limnodynastes* and *Uperoleia,* several South American leptodactylids (*Pleurodema, Physalaemus*), and African microhylids (*Phrynomantis*) have bright red, yellow, and orange patches on the flanks, groin, and inguinal region (Cei 1980; M. Davies and Littlejohn 1986; M. Davies, McDonald, and Corben 1986; Herrmann 1988a, 1989; Barker, Grigg, and Tyler 1995; Brodie, Williams, and Tyler 1998). All of these species are well endowed with skin glands, which often are closely associated with the color patches (Erspamer, de Caro, and Endean 1966; Erspamer et al. 1975; Cei, Erspamer, and Roseghini 1967; Roseghini, Erspamer, and Endean 1976; Cei 1980).

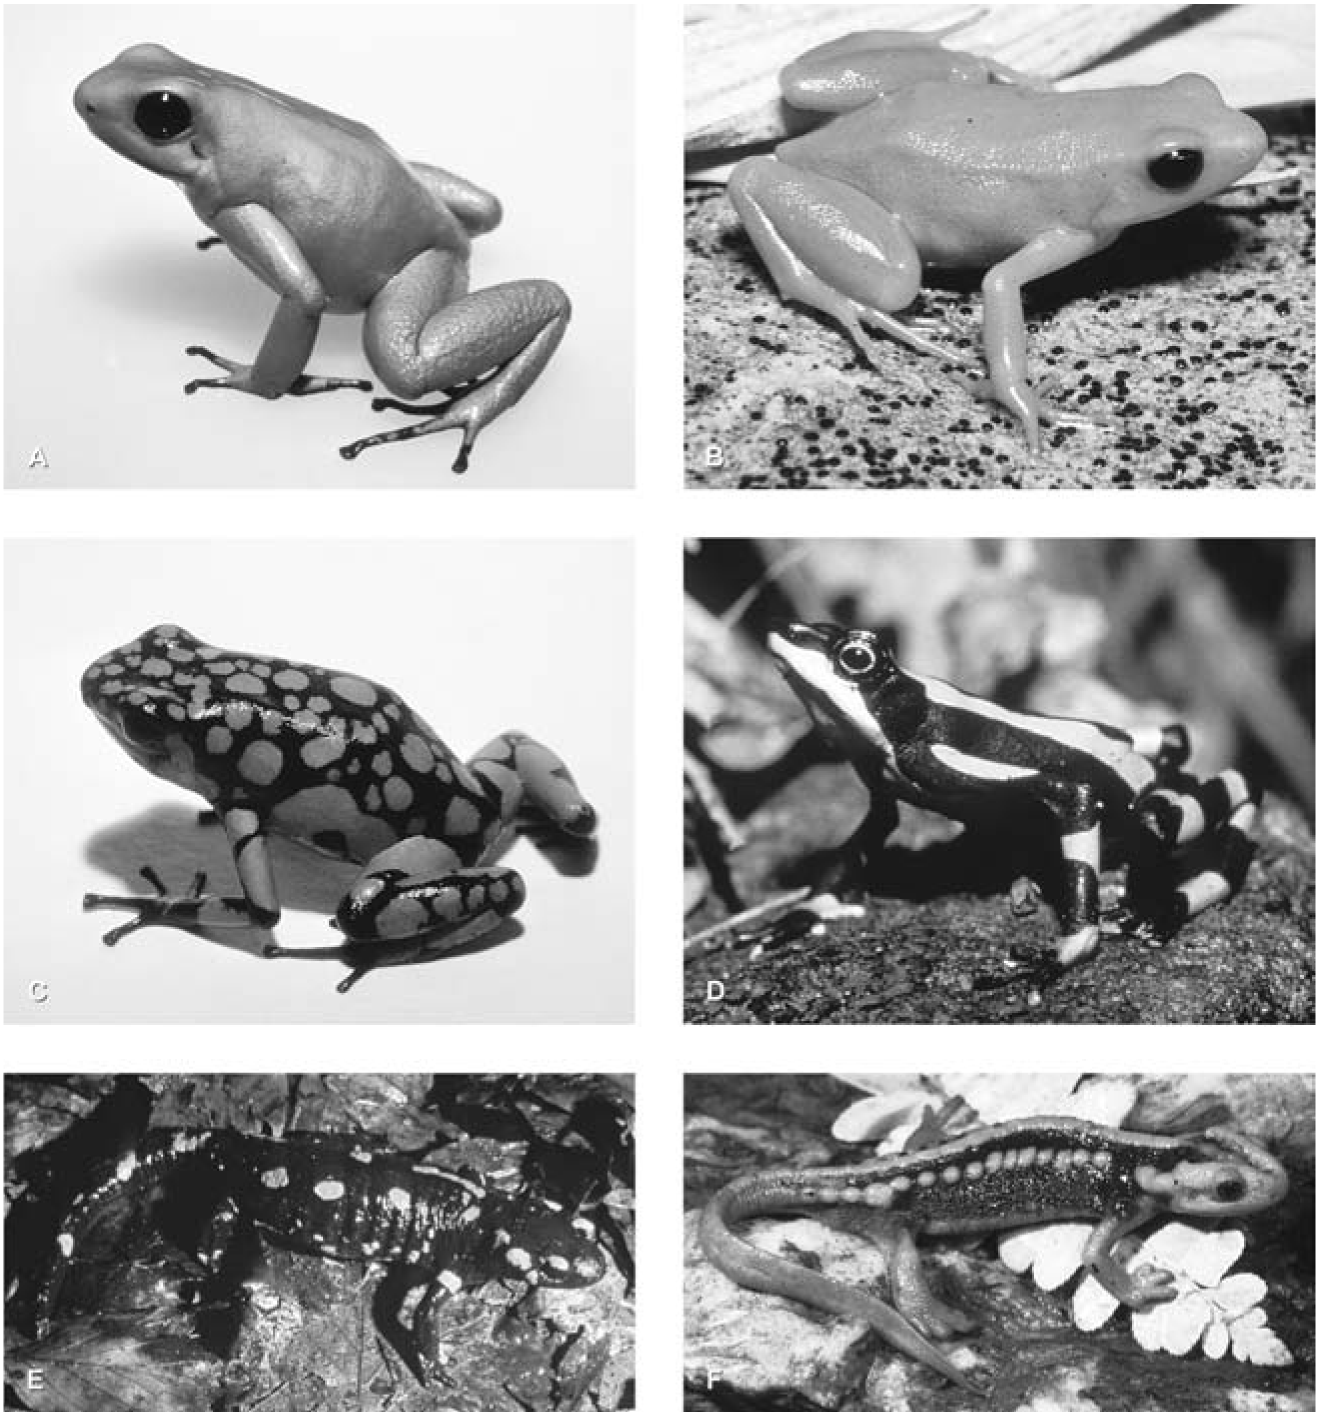

Fig. 14.32. Aposematic coloration in amphibians advertises the presence of toxic or distasteful skin secretions. Most aposematic color patterns consist of either solid red, yellow, or orange, or contrasting patterns of red, yellow, orange, and black. (A) *Phyllobates terribilis* (Dendrobatidae) from Colombia, a lemon-yellow frog with some of the most toxic skin secretions of any anuran. (B) *Mantella aurantiaca* (Mantellidae) from Madagascar, a bright orange frog that exhibits remarkable convergence with dendrobatids in morphology, behavior, and toxic skin secretions. (C) *Dendrobates histrionicus* (Dendrobatidae) from Colombia, a bright red frog with black reticulations, one of many different aposematic patterns found in this species. (D) *Atelopus varius* (Bufonidae) from Ecuador, a highly toxic frog with a contrasting pattern of bright yellow and black markings, one of several aposematic color patterns in this species. (E) *Salamandra salamandra* (Salamandridae) from Europe, a highly toxic salamander with bright yellow or orange markings on a black background. (F) *Tylototriton shanjing* (Salamandridae) from China, a terrestrial salamander with brown-black background coloration with bright orange markings, some of which highlight parotoid glands on the head and rows of poison glands along the body. Photos by Charles W. Myers (A, C), Wayne Van Devender (B, F), Martha L. Crump (D), and Walter Hödl (E).

Some amphibians have aposematic patterns primarily on the ventral surface. When confronted by predators, they often adopt postures that expose these colors to the attacker. A well-known example is the "unken reflex" of *Bombina* (Hinsche 1926; Bajger 1980). These frogs arch the back and raise the legs into the air, exposing the brightly colored ventral surfaces to the predator (fig. 14.28). Nearly identical behavior occurs in the South American bufonid *Melanophryniscus stelzneri* (Fernández 1926; Cei 1980; Herrmann 1988b). Many salamandrids display ventral colors by elevating the anterior part of the body into a vertical position, coiling the body into a circle so the ventral surface is exposed, or displaying the tail in a coil above the body (fig. 14.29; Brodie 1977; Brodie, Nussbaum, and DiGiovanni 1984). In the Asian species *Paramesotriton chinensis,* the display is carried a step further, with the animal turning on its back to reveal a ventral pattern of orange blotches on a black background (Brodie, Nussbaum, and DiGiovanni 1984).

Many anurans have relatively cryptic dorsal coloration, but have bright patches of red, orange, yellow, or blue on the flanks, legs, and feet. These generally are described as "flash colors" that are hidden when the frog is at rest, but serve to startle predators when the frog jumps (Noble 1931; Cott 1940; Duellman 1970; Lutz 1973; Edmunds 1974; Duellman and Trueb 1986; Mattison 1987). However, many of these frogs produce noxious skin secretions, and the "flash colors" may serve primarily as aposematic signals. For example, phyllomedusine tree frogs are noted for their noxious secretions and strong odors when handled, and many species seem to be distasteful to predators (Budgett 1899; Cei and Erspamer 1966; Lutz 1966; Sazima 1974; Cei 1980). Their flank colors often are striking combinations of yellow, orange, and black markings characteristic of many aposematic animals. The Brazilian treefrog *Hyla anceps* has a pattern of dark bands on a coral red background on the flanks and legs. Lutz (1973) suggested that these frogs are Batesian mimics of coral snakes. However, she also stated that they release a sticky secretion and have a strong odor when handled, so the pattern could be aposematic. The same probably is true of the orange "flash colors" of *Hyla versicolor* and *Rana palustris,* both of which are distasteful to some predators (Formanowicz and Brodie 1979; Brodie and Formanowicz 1981). The striking inguinal "eye spots" found in some species of *Physalaemus, Phrynomantis,* and *Pleurodema* (fig. 14.28) probably are aposematic as well as deimatic (startling) signals. The South American hylid *Phrynohyas coriacea* has black spots on the flanks that are revealed during antipredator displays, and this species also has noxious skin secretions (de la Riva 1994). Cott (1940) cited the bright vermilion patches on the thighs and axillae of the African frog *Kassina maculata* as an example of "flash coloration," but this species is a slow-moving frog that does not make sudden leaps to escape from predators (Passmore and Carruthers 1995). It seems more likely that the pattern is aposematic.

Aposematic coloration is advantageous only when predators have color vision; birds generally are assumed to be the principal selective agent favoring aposematic patterns. Birds readily learn to avoid both the bright red efts of *Notophthalmus v. viridescens* (R. R. Howard and Brodie 1971, 1973) and the brown efts of *N. v. louisianensis,* but learning may be more rapid with the brighter color (Brandon, Labanick, and Huheey 1979a). J. Johnson and Brodie (1975) demonstrated that birds learned to avoid *Taricha granulosa* more rapidly when the newts displayed their bright ventral colors, compared to presentations where only the dorsum was visible to the predator. Other experiments have shown that wild-caught passerine birds quickly learn to avoid the red-cheeked and red-legged morphs of *Plethodon jordani,* but are less likely to avoid all-black morphs, even though these also are distasteful (Hensel and Brodie 1976). They also learned to avoid red-cheeked morphs with the red cheeks painted black, suggesting that the red color enhances avoidance learning, but is not essential for the birds to learn the salamanders are distasteful.

Not every species of amphibian that is equipped with chemical defenses is aposematically colored. For example, all species of *Bufo* probably are noxious to predators, but most are cryptically colored. The same is true of large tree frogs such as *Hyla vasta* from Hispaniola and various species of *Phrynohyas* from South and Central America (Duellman 1970; Lutz 1971). Some anurans that are both noxious and cryptically colored probably are too large to be taken by birds, and therefore may not have undergone strong selection for aposematic coloration. Many also are nocturnal and therefore would derive little benefit from conspicuous coloration, but do benefit from chemical defenses against nocturnal predators such as mammals and snakes.

Mimicry

If predators learn to avoid the aposematic patterns of distasteful species, then edible species can benefit by evolving a pseudoaposematic pattern resembling that of the distasteful model, a form of mimicry known as Batesian mimicry (Cott 1940; Wickler 1968; Edmunds 1974; Huheey 1988; Pough 1988). The occurrence of Batesian mimicry in amphibians was first suggested by Dunn (1927), who pointed out the similarity between the red-cheeked *Plethodon jordani* and red-cheeked *Desmognathus* found together in the mountains of North Carolina, which he called *D. fuscus imitator.* Electrophoretic studies have shown that there actually are two very similar *Desmognathus* with red cheeks in this region (Tilley et al. 1978). The first, *D. imitator,* is endemic to the Great Smoky Mountains, and red-cheeked individuals

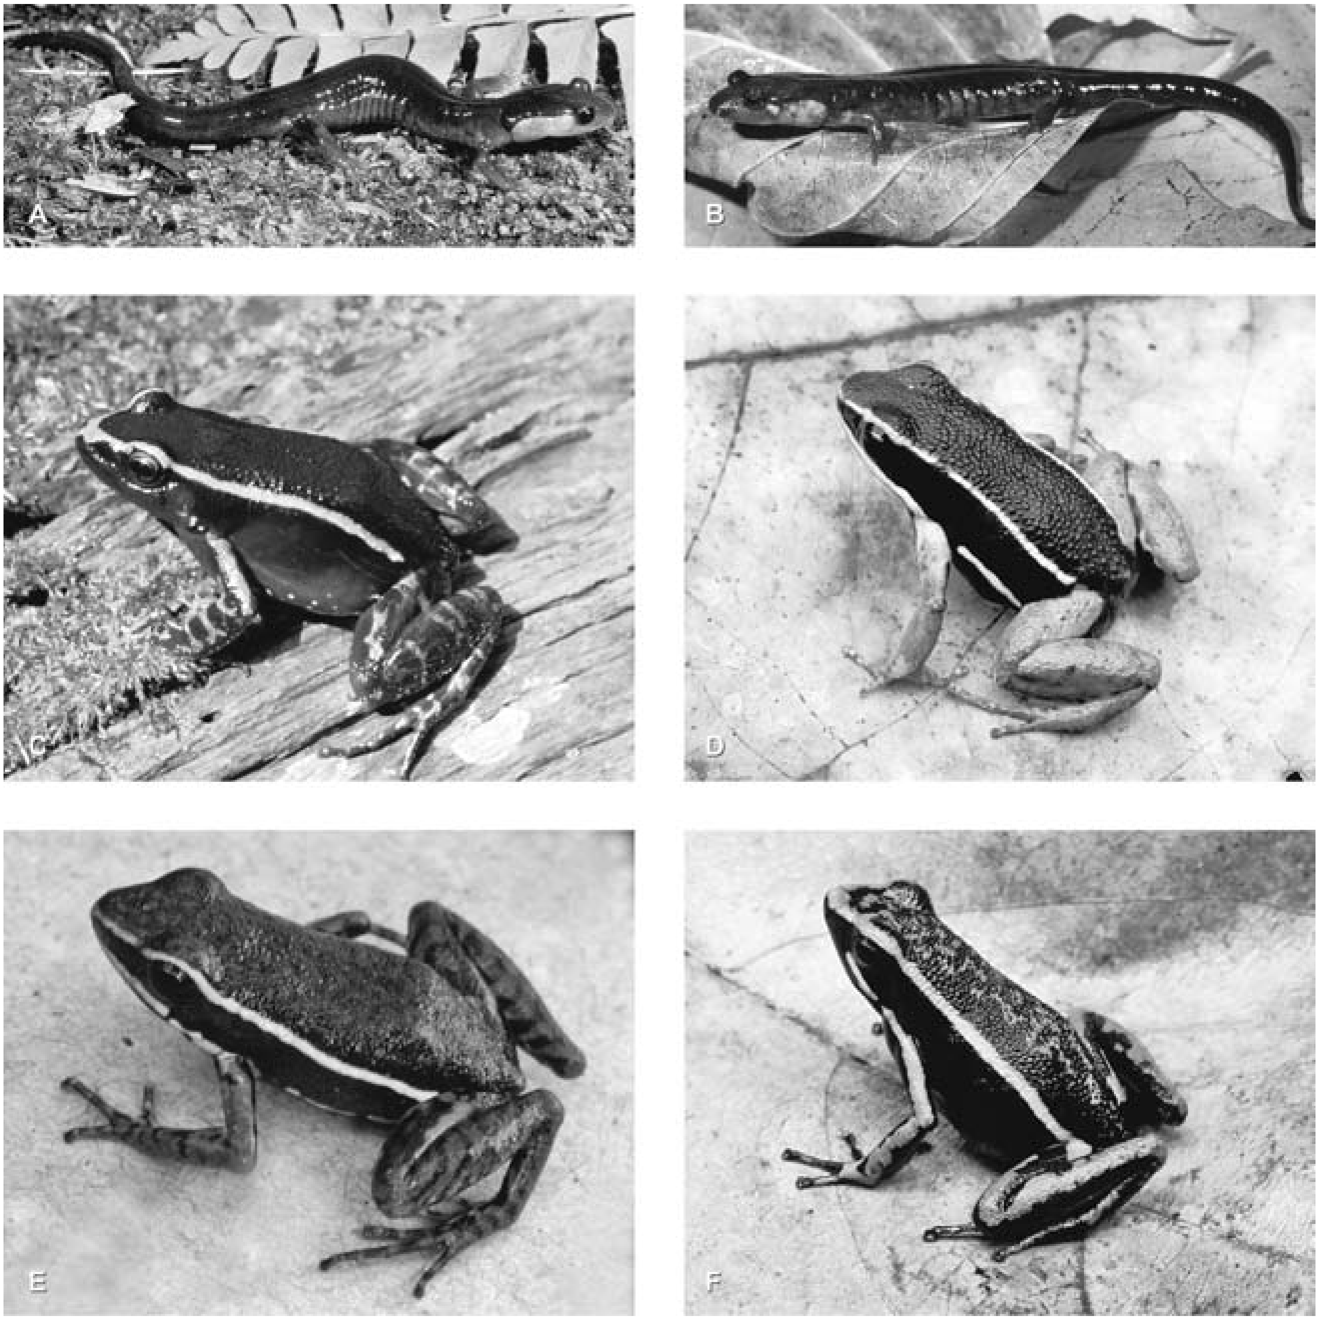

Fig. 14.33. Examples of mimicry in amphibians. (A) *Plethodon jordani* from Great Smoky Mountains National Park, a distasteful black salamander with reddish-orange cheek markings. (B) *Desmognathus ocoee,* a nondistasteful salamander with a dark body and similar orange cheek markings, a Batesian mimic of *P. jordani.* (C) *Lithodytes lineatus,* a nontoxic leptodactylid frog from the Amazon Basin that may be a Batesian mimic of several toxic dendrobatid frogs, including *Allobates femoralis* (D), *Epipedobates pictus* (E), and *E. trivittatus* (F). These toxic, aposematically colored dendrobatid frogs may form a Müllerian mimicry complex. Photos by Wayne Van Devender (A, B) and Janalee P. Caldwell (C–F).

are found only in sympatry with red-cheeked *P. jordani* (fig. 14.33 A, B). However, red-cheeked morphs of the second species, *D. ocoee,* occur outside of the Smoky Mountains in areas that lack an appropriate Batesian model (these populations are referred to as *D. ochrophaeus* in most of the published literature on mimicry). Some *D. ocoee* have red legs and are found only in sympatry with red-legged *P. shermani* in the Nantahala Mountains, but there are populations of *D. ocoee* with a combination of red cheeks and red legs in areas where appropriate distasteful models are absent (Labanick 1988). Experiments with both domestic chickens and wild-caught passerines have shown that predators conditioned to avoid distasteful *P. jordani* or *P. shermani* also learn to avoid the red-cheeked (*D. imitator*) or red-legged (*D. ocoee*) mimics found in the same area (Brodie and Howard 1973; Labanick and Brandon 1981). However, it is not clear why conspicuous red-cheeked and red-leg/red-cheek morphs of *D. ocoee* are maintained in populations outside the range of appropriate Batesian models, since all *Desmognathus* seem to be palatable to predators (Huheey 1966; Labanick 1988).

Two other examples of mimicry in salamanders both involve red efts of *Notophthalmus viridescens* and plethodontid salamanders. *Plethodon cinereus* lacks chemical defenses and is readily eaten by a variety of predators, including birds. This species has three color morphs: a uniformly slate-gray "lead-backed" morph, a "red-backed" morph with a dull red middorsal stripe, and an "erythristic" morph that is a uniform bright reddish orange. The erythristic morph is found only in the northeastern United States, where red efts are common (Lotter and Scott 1977; Tilley, Lundrigan, and Brower 1982). Experiments with both free-ranging and captive passerines have shown that birds tend to avoid erythristic *P. cinereus* more than the normal red-backed phase, although survival was lower than that of the highly distasteful red efts (Brodie and Brodie 1980; Tilley, Lundrigan, and Brower 1982). This suggests the red *P. cinereus* are mimics of the efts.

The plethodontid salamander *Pseudotriton ruber* also resembles red efts in color and has an overlapping distribution (Huheey and Brandon 1974; Pough 1974a). This species originally was considered a Batesian mimic of red efts because domestic chickens readily ate *Pseudotriton* before being exposed to red efts, but avoided them after experience with the distasteful efts (R. R. Howard and Brodie 1971; Brodie and Howard 1972). Similar results were obtained with wild-caught passerines and naive, hand-reared chicks (R. R. Howard and Brodie 1973). However, Brandon, Labanick, and Huheey (1979b) found that both *P. ruber* and *P. montanus,* another reddish species, were less palatable to chicks than were *Desmognathus,* but more palatable than red efts. Furthermore, these salamanders produce toxic skin secretions (Brandon and Huheey 1981), suggesting that *Pseudotriton* and red efts are part of a Müllerian mimicry system, in which several distasteful species mutually benefit from a similar color pattern. In this case, one species is considerably more noxious than the other. Huheey (1976, 1980, 1988) has argued that a spectrum can exist between pure Batesian and pure Müllerian mimicry, corresponding to a spectrum of relative prey palatability, but this has been disputed by other workers (Benson 1977; Sheppard and Turner 1977; J. Turner 1984a, b).

Another example of apparent mimicry in salamanders is found in California, where the plethodontid salamander *Ensatina eschscholtzii xanthoptica* closely resembles the color pattern of the highly toxic newts of the genus *Taricha.* Experiments with clay models of *Ensatina* painted with aposematic and nonaposematic colors showed that attacks by predators, presumably birds, were more common on the nonaposematically colored models. These results support the hypothesis that *Ensatina* derives some benefit from its resemblance to *Taricha,* although it has not yet been established whether this species is itself distasteful and therefore a Müllerian rather than a Batesian mimic of *Taricha* (Kuchta 2005).

Several examples of mimicry in anurans have been proposed. *Lithodytes lineatus,* a leptodactylid frog of the Amazon Basin, has a pattern of yellow dorsolateral stripes and orange "flash colors" resembling those of *Allobates femoralis* and several species of *Epipedobates* (fig. 14.33 C–F; Nelson and Miller 1971; Duellman 1978; Regös and Schlüter 1984). This resemblance suggests the possibility of Batesian mimicry, while the similarity of patterns in *Allobates femoralis* and *Epipedobates pictus* led Silverstone (1976) to speculate that these species are Müllerian mimics of each other. Although adult *Lithodytes* are largely nocturnal, juveniles are active both day and night, and it is the juvenile pattern that most closely resembles that of the diurnal *Epipedobates* (Duellman 1978; Regös and Schlüter 1984). However, it is not known whether this species also is distasteful and therefore might represent a case of Müllerian mimicry. Adults are associated with leaf-cutter ant nests (Schlüter and Regös 1981; Hoogmoed 1986) and conceivably could produce ant-repelling secretions, like those of *Gastrophryne* (Garton and Mushinsky 1979), which also might be distasteful to vertebrate predators.

Recent work has shown that a species from Amazonian Ecuador that is closely related to *Allobates femoralis, A. zaparo,* is a Batesian mimic of two other species of dendrobatids with very similar aposematic color patterns, *Epipedobates bilinguis* and E. *parvulus.* These two species differ in toxicity, with *E. parvulus* being the more toxic. Where only one model species occurs, *A. zaparo* has a color pattern that mimics that model, but in areas where the two model species overlap, *A. zaparo* actually has a pattern closer to the less toxic model species. The proposed explanation for this counterintuitive result is that birds that have experienced the less toxic model species will avoid only mimics that look very much like that species, whereas an experience with the more toxic species is so distasteful that only a general resemblance to the model is required. Consequently, where the two models overlap, mimics are better off looking like the less toxic species, because they will be protected regardless of which model a predator has encountered (Darst and Cummings 2006; Darst, Cummings, and Cannatella 2006).

Another possible example involves mimicry of one or more species of *Phyllobates* by *Eleutherodactylus gaigeae* in

Panama and Colombia. This species also has light dorsolateral stripes and overlaps the ranges of two dendrobatids with similar patterns, *P. aurotaenia* and *P. lugubris* (Myers and Daly 1983; Lynch 1985). Finally, Symula, Schulte, and Summers (2001) showed that the highly polymorphic species *Dendrobates imitator* has evolved distinct color patterns that closely resemble three other species of dendrobatid frogs in different parts of its range. Because all of the species involved are assumed to be toxic, this is most likely a case of Müllerian mimicry, although as in the case of the interaction between *Allobates zaparo* and the two species of *Epipedobates,* these species could differ considerably in distastefulness and toxicity. This type of mimicry may be relatively common in areas where several dendrobatid frogs are sympatric, but the details of these possible mimicry systems have yet to be explored in detail (Summers 2003).

A highly speculative proposed case of mimicry in another tropical amphibian is the possible mimicry of either banded millipedes or coral snakes by caecilians with banded patterns, such as *Siphonops paulensis* (Vitt 1992). Unfortunately, we have no information on either the efficacy of aposematic coloration in any caecilian or on possible distasteful skin secretions produced by the caecilians themselves, so the nature of this putative mimicry remains unknown.

Summary and Conclusions

Amphibians are subject to predation by a vast array of invertebrates and vertebrates. Invertebrate predators include leeches, both larval and adult insects, and a variety of other arthropods such as crabs and spiders. Predation by invertebrates falls most heavily on egg and larval stages, and can be the most important source of mortality at these stages for both aquatic and terrestrial breeders. Most invertebrates are generalist predators that take amphibian eggs and larvae along with other types of prey. The only invertebrate predators that seem to specialize on amphibians are a number of genera of dipteran larvae that are obligate associates of amphibian egg masses and various helminth and arthropod parasites of adult amphibians. With few exceptions, the demographic impact of these predators is poorly understood.

Vertebrate predators include many freshwater fishes, both larval and adult amphibians, snakes, turtles, a few lizards and crocodilians, many passerine and nonpasserine birds, and mammals ranging from carnivores and insectivores to bats, rodents, armadillos, monkeys, and humans. The best quantitative data on the importance of amphibians in the diets of predatory vertebrates are for snakes and some kinds of water birds. Relatively few vertebrates are specialists on amphibians. In the temperate zone, the seasonal activity patterns of amphibians probably preclude specialization on amphibian prey by most endothermic predators, although some birds and mammals may concentrate for brief periods on amphibian prey when the latter are aggregated at breeding sites (e.g., hawks, owls, herons, ducks, otters, badgers, raccoons). In the tropics, there are a few hawks, and at least one bat, *Trachops cirrhosus,* which seem to specialize on amphibians, although *Trachops* eats lizards and other vertebrate prey as well as frogs. Only the snakes include large numbers of species that feed exclusively on amphibians. Frog-eating snakes are found in both the temperate zone and the tropics and are most diverse in regions where the diversity of frog species is high. A few snakes, such as the North American water snake *Farancia,* also specialize on salamanders. The fact that both snakes and amphibians are ectothermic, with similar seasonal activity patterns, probably has facilitated the evolution of amphibian eating as a dietary specialization.

While data are available on the importance of amphibians in the diets of certain predators, there are few data on the impact of specific predators or sets of predators on the demography of amphibian populations. In fact, with very few exceptions, it is not possible to identify any particular predator as the major source of mortality in an amphibian population. In part this is due to the rarity of predation events. Field workers seldom observe acts of predation, particularly on adult amphibians. One solution to this problem is for investigators to study the predators rather than the prey. An observer is much more likely to see a water snake eating a frog if he follows the snake while it searches for food rather than sitting and waiting for individual frogs to be eaten. With the help of radio transmitters, predators such as snakes can be located at frequent intervals or followed as they forage. Estimates of food intake by the predators in a relatively restricted area such as a pond, coupled with measurements of amphibian densities, would allow some estimate of the number of prey animals consumed by the predators and hence the demographic impact of predation on the prey population.

One difficulty in estimating the impact of predation on amphibian populations is that methods used to estimate survivorship and mortality in amphibian populations often have not been very sophisticated. Many workers have calculated survivorship from recaptures of marked individuals without adjusting the data for the probability of recapturing marked animals. This provides a rough estimate of "minimum survivorship" in the population, but almost certainly leads to an overestimate of actual rates of mortality. This problem is compounded by the short-term nature of most demographic studies of amphibians. F. Turner (1962) issued a call for more detailed, long-term demographic studies of amphibians, but only a handful of such studies have been conducted in the last 25–30 years, most on North American species.

Even when rates of mortality have been estimated accurately, evidence that predation is a major source of mortality usually consists of occasional observations of predators eating amphibians and sightings of potential predators in the area. Truly integrated studies of predator-prey interactions involving simultaneous long-term observations of amphibian populations and their principal predators are needed if further progress is to be made in this field. Although technically difficult because of the problems involved in accurately censusing amphibian populations, such studies should be possible if species and study sites are chosen carefully.

The means by which amphibians protect themselves from predators are many and varied. Embryos are protected by noxious chemicals, by mechanical properties of the egg capsule or jelly surrounding the egg mass, and by choice of protected oviposition sites by the parents. Some larvae also have distasteful defensive secretions, while others rely on crypsis, choice of protected microhabitats, behavioral avoidance of predators, or rapid growth to escape predation. Primary defensive adaptations of adults include cryptic and aposematic coloration and mimicry. Secondary defensive adaptations decrease the chances of an individual being consumed once it is encountered by a predator. Such adaptations include chemical defenses, defensive postures that expose poison glands or expendable parts of the body to the predator, rapid escape behavior, threatening or startling displays, physical attacks on the predator, immobility responses, inflation of the body, and tail autotomy. Many of these defensive adaptations, such as noxious chemical secretions, aposematic coloration, and defensive postures, have coevolved to provide an integrated system of defense against a variety of predators.

Much of the literature on amphibian defensive adaptations is descriptive. Nevertheless, there have been experimental studies of the effects of aposematic coloration on prey choice by predators (e.g., R. R. Howard and Brodie 1973; Hensel and Brodie 1976), the role of defensive postures in reducing predator attacks (e.g., Johnson and Brodie 1975), the effectiveness of Batesian mimicry in reducing the chances of being eaten (e.g., Brodie and Howard 1973; Labanick and Brandon 1981; Tilley, Lundrigan, and Brower 1982), and the effect of tail autotomy and other types of defensive behavior on salamander survivorship (e.g., Arnold 1982; Ducey and Brodie 1983; Labanick 1984). A number of issues remain unresolved. For example, the presumed Batesian mimicry of dendrobatid frogs by leptodactylids has never been investigated experimentally. In fact, there is only anecdotal evidence that the aposematic coloration of dendrobatid frogs is an effective deterrent to predators, although it is a reasonable assumption. The supposed deimatic function of "flash colors" in many anurans also has not been investigated in any detail. The possibility that such colors actually serve as aposematic signals has been mentioned briefly by a number of authors (e.g., Cott 1940; Formanowicz and Brodie 1979; Brodie and Formanowicz 1981), but this hypothesis has been ignored by most authors and has not been rigorously tested.

Another issue that has seldom been explicitly addressed is the relationship between toxicity and the distastefulness of amphibian defensive secretions, as well as the relationship between these variables and conspicuous coloration. Levels of toxicity generally have been determined by injecting skin extracts into mice or other animals (e.g., Daly and Myers 1967; Brodie 1968a, b; Brodie, Johnson, and Dodd 1974; Myers, Daly, and Malkin 1978; Garton and Mushinsky 1979; Brandon and Huheey 1981). Some animals, such as garter snakes, may be killed by injection of skin extracts, but can eat the same species without permanent damage (Brodie 1968a). Hence, the relationship between level of toxicity and the effectiveness of skin secretions as predator deterrents is not clear. Populations of *Dendrobates pumilio* vary widely in toxicity and coloration, but there is not a clear correlation between conspicuousness and toxicity (Daly and Myers 1967). However, they did not test responses of natural predators to different populations, and it may be that frogs with relatively low levels of toxicity have skin secretions distasteful enough to deter predators. Indeed, it is not clear what selective pressures have favored the evolution of extraordinarily toxic skin secretions in some amphibians, while distasteful chemicals are sufficient to protect other species. In some cases, the evolution of highly toxic skin secretions may be driven by an "arms race" between predators and prey, with predators evolving resistance to amphibian skin secretions and amphibians in turn evolving more potent defenses against these predators.

Chapter 15 The Ecology of Amphibian Communities

Brazil is the land of frogs, and almost half the species of the order live here. The naturalist meets with something surprising at every step; every creature is unlike the creatures he knows at home, and he is filled with reverence before such an inexhaustible wealth of forms. But he cannot be content with mere amazement; he longs to understand something of the wealth of species offered by the world about him. No Brazilian animal lives entirely to itself. . . . We shall understand the individual animal only if we consider it in relation to others.
—Konrad Guenther, A Naturalist in Brazil (1931)

Since the days of the earliest explorer naturalists, European and North American biologists have been impressed by the diversity of tropical life. My first experience with tropical amphibians came on a trip to the summit of El Yunque, Puerto Rico, a mountain topped with a bizarre elfin forest of stunted trees draped with mosses, lichens, and a host of other epiphytes. After a drive up the narrow road to the summit, I emerged from the car on a rainy night and seemed to be surrounded by frogs calling from moss-covered trees, logs, or damp leaves on the forest floor. Nearly a dozen species of frogs are found on El Yunque, most in the genus *Eleutherodactylus* (Joglar 1998; Rivero 1998). Some live in holes and crevices in the gnarled trunks of forest trees; others prefer tree limbs, leaves, forest litter, boulders in mountain streams, or roadside ditches. At night, the sound of calling frogs is almost deafening, and the overall impression is of a forest teeming with amphibians, all sharing the same habitat, but each using the habitat in a slightly different way.

Such diversity of amphibian species in a single locality is not unique to Puerto Rico; indeed, many parts of the tropics have even larger assemblages. More than 30 species of frogs have been observed in a single rain forest pond in Peru (Schlüter 1984), and the area around the village of Santa Cecilia in Amazonian Ecuador once supported more than 80 species (Duellman 1978), approximately the number found in all of the United States. Even in the temperate zone, it is possible to find a number of amphibian species sharing the same habitat. Ponds in the southeastern United States can support up to 17 species of amphibians (Wilbur 1997), all of which contribute larvae to a complex aquatic community, and an equivalent diversity of terrestrial salamanders can be found in some moist forests of the southern Appalachian Mountains.

The occurrence of so many species sharing the same habitat raises a number of questions of interest to community ecologists. What determines the distribution and abundance of species in nature? Why are some species common and others rare, some widespread and others restricted in range, some generalized and others specialized? Do assemblages of species exhibit regular patterns of organization, or are they simply random groupings of species? If some degree of organization is apparent, is this the result of biological interactions among species, or independent adaptations to the environment? Except for chapter 14, which dealt with interactions between amphibians and their predators, most of this book has focused on the ecology and behavior of individual species of amphibians. In this chapter, the emphasis shifts to interactions among species, with an eye toward understanding the structure and organization of amphibian communities.

A Conceptual Framework for Studies of Amphibian Communities

Studies of the structure and organization of amphibian communities are part of a larger field of community ecology that has undergone gradual evolution over the last 40 years or so. It is not possible to review the complete development of community ecology in this book, but a brief overview of key ideas and approaches will help to provide a framework for understanding the work that has been done on amphibians.

Defining a Spatial Scale for Community Analysis

Community ecologists traditionally have concerned themselves with local assemblages of species, such as the tadpoles inhabiting a single pond or the salamanders occurring along a mountain stream. Larger-scale patterns of distribution and abundance have fallen mostly within the purview of systematists and biogeographers rather than ecologists (e.g., Duellman 1999a). Nevertheless, community ecologists have recently become interested in species interactions at larger spatial scales, and there have been attempts to unify biogeography and community ecology into a new field of macroecology (Ricklefs and Schluter 1993a; J. Brown 1995). Local species interactions can be affected by processes that occur at larger spatial scales and over long (evolutionary) time spans. These include speciation events, barriers to dispersal, and species-specific responses to features of the environment, such as rainfall patterns, landscape topography, and habitat productivity (Ricklefs 1987; Holt 1993; Ricklefs and Schluter 1993b; Rosenzweig and Abramsky 1993). Macroecological approaches enable ecologists to address questions about regional patterns of species diversity and abundance in relation to environmental variables, the relationship of local abundance to the size of geographic ranges, and the relationship between geographic range and body size. This approach has not been widely used in studies of amphibians, although some studies have addressed ecological determinants of species distribution and abundance at large and intermediate spatial scales (e.g., J. Lee 1980, 1993; Inger and Voris 1993; Murray, Fonseca, and Westoby 1998; Parris and McCarthy 1999; Eterovick and Fernandes 2001; Barr and Babbitt 2002; Eterovick 2003; Poynton 2003). This approach is particularly important for making informed decisions about the conservation of key habitats for amphibians (e.g., García, 2006). Some studies have incorporated phylogenetic information into analyses of speciation and geographic distribution. For example, Graham, Stacy, and Sih (2004) found that closely related species of dendrobatid frogs in the Andes tend to be well separated ecologically along basic habitat axes such as temperature, rainfall, and altitude. If applied to a number of different clades of amphibians with overlapping ranges, this approach has the potential to provide information on how current assemblages of species have come to coexist in particular localities.

Defining the Species Composition of Communities

Most studies of community structure have focused on only a fraction of the organisms present, with the community being delimited either along taxonomic lines (e.g., the plethodontid salamander community) or by subsets of ecologically similar species that appear to form a unified guild (the forest litter frog community). It is important to keep in mind, however, that such assemblages of species are artificial constructs, because any limited assemblage of species is imbedded within a larger community of organisms that interact with one another as competitors, predators, parasites, or mutualists. For example, the assemblage of frogs (*Eleutherodactylus*) in the El Verde rainforest of Puerto Rico is part of a much larger community composed of a wide variety of invertebrates and vertebrates and the plants on which they feed (fig. 15.1). Interactions among different species of frogs are likely to be influenced, at least in part, by how the frogs interact with all of the other organisms in the forest (Beard et al. 2003).

Many ecologists have assumed that competition is most intense among closely related species. Nevertheless, significant competition can occur among animals as distantly related as ants and rodents (J. Brown and Davidson 1977; J. Brown, Davidson, and Reichman 1979; Davidson, Samson, and Inouye 1985), nectar-feeding birds and insects (F. Carpenter 1979; Kodric-Brown and Brown 1979), insectivorous lizards and spiders (Spiller and Schoener 1988, 1990), and lizards and birds (S. Wright 1979, 1981; Adolph and Roughgarden 1983; Moermond 1983). Interactions among distantly related taxa can be especially complex, because they may interact as both predators and competitors (e.g., Spiller and Schoener 1990).

Insectivorous vertebrates such as birds and lizards are potential competitors of terrestrial amphibians (Barbault 1974a; Duellman and Pianka 1990; Vitt and Caldwell 1994; Caldwell and Vitt 1999), and spiders are potential predators, prey, and competitors (Reagan, Camilo, and Waide 1996; Stewart and Woolbright 1996). A number of investigators have analyzed the distribution, abundance, and resource use of terrestrial amphibians and reptiles living in the same habitats (Lloyd, Inger, and King 1968; Crump 1971; Heyer and Berven 1973; Barbault 1974b, c, 1976a, b, 1977; N. Scott 1976, 1982; Inger and Colwell 1977; Duellman 1978, 1989b, 1990; Inger 1980; Inger et al. 1987; Duellman and Pianka 1990; Vitt and Caldwell 1994; Caldwell and Vitt 1999; Lima, Magnusson, and Williams 2000). While some overlap in resource use is common, especially between insectivorous lizards and frogs, we still know relatively little about how these

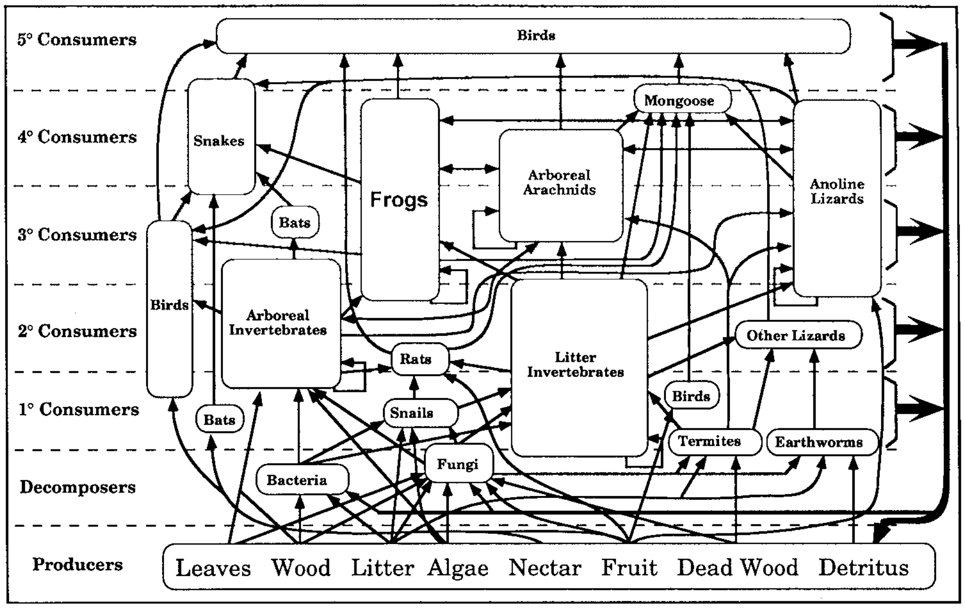

Fig. 15.1. The food web of the El Verde Rainforest community in Puerto Rico. Frogs of the genus *Eleutherodactylus* are part of a complex web of trophic interactions among vertebrates, invertebrates, plants, and decomposers. After Waide and Reagan (1996).

animals actually affect one another. The interactions between amphibians and spiders have not been studied, except for the possibility that spiders prey on amphibians (Rubbo et al. 2003). Fishes are both predators (see chapter 14) and potential competitors of amphibian larvae or aquatic adults (Antonelli, Nussbaum, and Smith 1972; Olenick and Gee 1981; Resetarits 1991, 1997; P. Harris 1995). Tadpoles potentially are in competition with other aquatic organisms that feed on algal mats or phytoplankton, such as zooplankton (Alford 1989c), aquatic insects (L. Blaustein and Margalit 1994; L. Blaustein, Friedman, and Fahima 1996; Kuperferberg 1997a; Mokany and Shine 2002, 2003a, b), and snails (Brönmark, Rundle, and Erlandsson 1991). Experimental studies of aquatic communities have provided evidence for competition between amphibians and both aquatic invertebrates (Morin, Lawler, and Johnson 1988; Alford 1989c; Brönmark, Rundle, and Erlandsson 1991; Mokany and Shine 2003a, b) and fishes (Bristow 1991; Resetarits 1991). Some of these studies are discussed in more detail in later sections.

Defining the Processes That Structure Local Communities

Since the 1950s, most ecologists have assumed that animal communities are not simply random assemblages of species, but rather are organized products of biological interactions among species. Many biological processes may be involved, but it is interspecific competition that has been the principal focus of much of the community ecology literature. This emphasis on competition originated in pre-Darwinian natural history and was central to Darwin's own interpretation of ecological processes (Worster 1977). It was brought to maturity under the influence of G. F. Gause, David Lack, G. Evelyn Hutchinson, Nelson Hairston, Sr., Robert MacArthur, and a host of later workers (Kingsland 1985). The work of the "competition school" of community ecology is based on a number of premises about how natural communities are organized (Schoener 1982). The most important is that communities are resource-limited, with competition for limiting resources being the major determinant of the distribution and abundance of species in the community. Under most circumstances, species using identical resources cannot permanently coexist, so species must exhibit differences in their use of resources sufficient to allow them to live together. These differences, in turn, may be products of interspecific competition, with natural selection favoring divergence among coexisting species when this reduces competition. When species are very similar ecologically, then they may displace one another geographically, so the ranges of some species may be limited, at least in part, by competitive interactions.

In the 1970s and early 1980s, the primacy of interspecific competition as an organizing force in natural communities was challenged on a number of fronts. One criticism was that competition had been overemphasized at the expense of other biological interactions, such as predation, parasitism, or mutualism. Several authors, particularly Connell (1975, 1983), argued that many species do not reach population densities high enough to permit interspecific competition for resources, being limited instead by predation. It is well established that both predation and competition influence the distribution and abundance of species in some systems. In the rocky intertidal, for example, predation on a superior competitor can prevent that species from excluding another from the same habitat (Connell 1971, 1975; Paine 1974). In other cases, predation can actually reverse the outcome of interspecific competition (Morin 1981), so it is important to examine the interactions among a variety of biological processes when studying community structure (see also Quinn and Dunham 1983).

A second criticism was derived from empirical studies that failed to demonstrate interspecific competition among ecologically similar species. One well-known example is work on grassland bird communities, which revealed a broad overlap in resource use by coexisting species, but produced little evidence of competitive interactions (Wiens 1973; Wiens and Rotenberry 1979, 1980; Rotenberry 1980). These results led Wiens (1977, 1984) to question the importance of competition in structuring animal communities. He argued that in a variable environment, populations often are limited by abiotic, density-independent factors, such as weather conditions, resulting in communities that are not at equilibrium. In such communities, resources may become limited during "ecological crunches" brought about by harsh conditions such as droughts, leading to brief episodes of intense interspecific competition. During more benign periods, however, interspecific competition will be relaxed, and the responses of different species to environmental variations should be largely independent of one another. Hence, one would not expect to see the type of tightly structured community predicted by traditional competition theory. These interpretations were strengthened by studies on a variety of other animals, suggesting that interspecific competition is not always an important determinant of community structure (e.g., coral reef fishes: Sale 1977, 1984; insects: Strong 1984; Lawton 1984; Seifert 1984; spiders: Wise 1984).

The most persistent challenge to the "competition school" came from a group of workers centered at Florida State University. These workers questioned not only the importance of interspecific competition in structuring communities, but also the existence of the structural patterns themselves (Connor and Simberloff 1979, 1986; Simberloff 1983; Strong 1983; see also various contributions in Strong et al. 1984). They argued that perceived regularities in patterns of species diversity and abundance, or morphological differences among coexisting species, are more apparent than real. They suggested that many community ecology studies involve circular reasoning: the importance of competition in structuring a community is assumed, differences among species in local distribution, morphology, and resource use are documented, and the results are taken as confirmation that competition has been an important force in community evolution. They advocated a rigorous testing of observed patterns against suitable null hypotheses that assume that biological interactions among species are not important. Such interactions should then be invoked only if the observed patterns differ significantly from those expected under the null hypothesis. Unfortunately, it often is not clear how appropriate null hypotheses should be constructed, or even whether such hypotheses really are "null" models (Harvey et al. 1983; Quinn and Dunham 1983; Roughgarden 1983; Colwell and Winkler 1984; May 1984; other chapters in Strong et al. 1984). Consequently, these criticisms generated much heated debate (Simberloff 1983; Strong 1983; Strong et al. 1984; Connor and Simberloff 1986).

Although the relative merits of various positions can be debated, one useful result of these controversies was to shift the emphasis in community ecology from purely descriptive analyses of community patterns to experimental investigations of the processes that generate these patterns. This shift is readily apparent when one compares the contributions in Strong et al. (1984) with those in an earlier symposium on community ecology (Cody and Diamond 1975). Experimental approaches have come to dominate community ecology since the 1980s (e.g., Hairston 1989a; Resetarits and Bernardo 1998), but it is critical that experimental studies be anchored in solid natural history (Werner 1998). In part, these experimental studies have confirmed earlier views about the nature of community structure. There is now abundant evidence that interspecific competition is an important force in many animal communities (Schoener 1982, 1983; Connell 1983; Sih et al. 1985). This is not always true, however, and its importance cannot simply be assumed. The intensity of competition detected in experimental studies can be influenced by the venue in which the studies are conducted (e.g., Skelly and Kiesecker 2001; Skelly 2002). Furthermore, the way in which competition operates in a community often is mediated by physical factors in the environment or by biological factors such as predation.

Both descriptive and experimental methods have been used in studies of amphibian communities. Many investigators have examined patterns of resource use among species living in the same habitat (e.g., Toft 1985; Kuzmin 1995; Parmelee 1999; Eterovick and Barros 2003). Such studies often include detailed measurements of microhabitat use, activity times, and the sizes and types of prey eaten by different species. These studies often reveal a potential for competitive interactions among species, but do not, in themselves, demonstrate that such interactions are important in determining the relative abundance or patterns of resource use by individual species.

One way to investigate the role or competition or predation in structuring a community is to conduct field experiments in which the abundance of potential competitors or predators is manipulated and the responses of one or more species in the community are observed (Sih et al. 1985; Hairston 1987, 1989a). Field experiments have the advantage of maintaining a degree of realism in the experimental system because the animals are studied in their natural environments (Hairston, 1989b). The disadvantage of field experiments is that many variables than can affect the interactions between species cannot be controlled with great precision, and adequate replication of experimental treatments often is difficult (Morin 1998).

An alternative approach is to perform laboratory experiments that allow the investigator to precisely control all environmental variables except those that are specifically being manipulated. Laboratory experiments afford a high degree of precision in control of variables, but at some cost in realism (Morin 1998). A compromise between laboratory and field experiments is the use of mesocosms, such as cattle tanks used to mimic conditions in temporary ponds (Resetarits and Fauth 1998), or large-scale field enclosures (D. Scott 1990). This maintains some of the precision of control over variables that is possible with laboratory experiments, but also provides a higher degree of realism in the system. The relative merits of these approaches have been hotly debated, particularly with reference to studies of amphibians (e.g., Hairston 1989a, b; Jaeger and Walls 1989; Morin 1989, 1998; Petranka 1989a; Resetarits and Fauth 1998; Wilbur 1989; Skelly and Kiesecker 2001; Skelly 2002). All have advantages and disadvantages, and a research program that integrates information from a variety of approaches is most likely to yield insights into community structure (Werner 1998).

Global and Regional Patterns of Amphibian Distribution and Abundance

On a global and regional scale, the distribution and abundance of amphibians probably has little to do with biological interactions among species and a great deal to do with historical events and major features of landscape and climate (Duellman 1999a). The global distribution and diversity of amphibian species is strongly affected by latitude. In both the Old and New Worlds, amphibians are far more diverse in the tropics than in temperate latitudes (Duellman 1999b). This is not surprising, since the relatively constant temperatures and wet environments of tropical habitats are ideal for amphibians, especially those that lay eggs out of water. The diversity of amphibians is much higher in the Neotropics than in the Old World tropics. South America, for example, has nearly three times as many species of amphibians as does Africa, which is a much larger continent. In part this reflects the larger expanses of tropical forests in South America compared to tropical Africa, which has extensive grassland habitats. It also reflects the extensive radiation of several large families of anurans in tropical South America, including the Hylidae, Leptodactylidae, Centrolenidae, and Dendrobatidae. Islands tend to have a much lower diversity of amphibians than do mainland habitats, even in the tropics, but species diversity increases with island size. Large tropical islands such as New Guinea, Borneo, Sri Lanka, and Madagascar have high amphibian species diversity, whereas small tropical islands in the Caribbean have much smaller numbers of species.

In both the tropics and temperate zone, amphibian diversity is strongly affected by rainfall. In North America, for example, amphibians are most diverse in the southern Appalachians and the southeastern Coastal Plain, both areas of high rainfall (Duellman and Sweet 1999). A strong positive correlation between amphibian species diversity and rainfall is seen in other regions as well, including Middle America (J. Lee 1980; J. Campbell 1999), South America (Duellman 1999c), and tropical Australia (M. Tyler 1999). Amphibian species diversity also is strongly affected by altitude. In North America, salamanders are more diverse in montane habitats than in lowland habitats, but anurans are not. In South America, the wet slopes of the Andes harbor the highest diversity of anuran species in the world (Duellman 1999c). Montane regions of Africa generally have fewer species of amphibians than do New World mountains, but nevertheless these areas often are rich in endemic species with limited altitudinal distributions (Poynton 1999, 2003).

Certain lineages of amphibians have been particularly successful in montane regions, which often lack permanent or temporary ponds that can be used by amphibians for breeding. In the Neotropics, amphibian clades that deposit eggs out of water are particularly successful in the mountains. These include plethodontid salamanders in Middle America (all tropical plethodontids have direct development) and frogs of the genus *Eleutherodactylus* in South America, as well as dendrobatids (Campbell 1999; Duellman 1999c). Stream-breeding frogs, mostly hylids, centrolenids, and dendrobatids (*Colostethus*), also are very diverse in the mountains. In New Guinea, a very mountainous tropical island, the amphibian fauna is dominated by microhylids with direct development.

Global and regional patterns of amphibian diversity are due largely to independent responses of different lineages to physical factors such as landscape topography and rainfall, as well as historical factors such as speciation and dispersal (Graham et al. 2004). Similar habitats in relatively close proximity to one another often have slightly different assemblages of species present. Some species are distributed across a wide geographic area and live in a variety of habitats. Others have much more restricted ranges or more specialized habitat requirements. The resulting patterns of species diversity set the stage for ecological interactions among species in particular localities (Inger and Voris 1993; Zimmerman and Simberloff 1996; Murray, Fonseca, and Westoby 1998; Bunnell and Zampella 1999; Eterovick 2003; Eterovick and Barros 2003). Such interactions are likely to be more complex in areas with large numbers of species than in communities composed of only a few species. In any given area of tropical rainforest in South America, for example, the number of species in a given locality is likely to be much larger than in areas of similar size in North America. In part this is due to the much greater diversity of reproductive modes in the tropics, where anurans make use of all sorts of microhabitats for laying eggs that are not found in temperate habitats (see chapter 10). Trophic niches may be more diverse or more specialized in the tropics as well, and these are discussed in more detail in the next section. Within North America, assemblages of streamside salamanders, particularly those in the genus *Desmognathus,* are very diverse in the southern Appalachians, with five or six species present in some areas. In more northern habitats, there may be no more than two or three species living in the same type of habitat (Hairston 1987). Ecological interactions may be similar in these two types of assemblages, but clearly the number of possible interspecific interactions is larger in the more diverse assemblage.

Community Ecology of Adult Anurans

Anurans are diverse both morphologically and ecologically, and many species often can be found sharing the same habitat. This diversity would seem to make these animals ideal subjects for studies of community structure. Unfortunately, the cryptic habits of many species, coupled with relatively high mobility, makes assessment of local densities of anurans difficult, and manipulation of relative abundance even harder. Probably for this reason, studies of terrestrial anuran community ecology have been almost entirely descriptive. Some studies are broad-spectrum analyses of community structure, providing information on species abundance, diet, morphological differences, microhabitat use, activity times, and breeding habits for all of the species in a local assemblage (Crump 1971, 1974; Barbault 1974b, c, 1976b, 1977; Inger and Colwell 1977; Duellman 1978, 1989b, 1990; Toft and Duellman 1979; Pefaur and Duellman 1980; Schlüter 1984; Zimmerman and Simberloff 1996; Eterovick and Sazima 2000; Neckel-Oliveira et al. 2000). The diversity of reproductive modes is discussed in chapter 10, so I will focus on differences in activity time, microhabitat use, and diet.

There have been many descriptive studies of microhabitat use and feeding habits of frogs in local assemblages (Inger and Marx 1961; Inger 1969; Cintron 1970; Pengilley 1971b; Barbault 1974a; Toft 1980a, b, 1981, 1982; Lieberman 1986; Lizana Avia, Ciudad Pizarro, and Pérez-Mellado 1986; Lizana, Perez-Mellado, and Ciudad 1990; Das 1996a, c; A. Lima 1998; A. M. Anderson et al. 1999a; Parmelee 1999; Bellocq, Kloosterman, and Smith 2000; Eniang et al. 2003; Gillespie et al. 2004). There also are more limited studies that describe ecological differences between two or more species, often closely related, that comprise only part of a local community (Heatwole 1963; Inger and Greenberg 1966; Lescure 1971; M. Stewart and Sandison 1972; Heyer and Bellin 1973; V. Brown 1974; M. Stewart 1979; Loman 1978; Stewart and Martin 1980; K. Jones 1982; Mac Nally 1983; Miyamoto 1982; Diaz and Valencia 1985; Licht 1986b; McAlpine and Dilworth 1989; A. K. Howard et al. 1997; Guidali, Scali, and Carettoni 2000; Duré and Kehr 2001; Isacch and Barg 2002; França, Facure, and Giaretta 2004; Lötters et al. 2004). Most studies have shown that nearly all the anurans in multispecies assemblages are generalist predators on insects and other small animals, with broad overlap in diet among species. There may be minor ecological differences among co-occurring species along one or more resource axes, and such differences sometimes have been interpreted as the result of interspecific competition. In most cases, however, the processes underlying patterns of organization in these communities remain largely unknown. I will not review each study in detail, but instead will focus on a few assemblages that exhibit interesting patterns of community organization or are promising subjects for additional investigation.

Anurans of Tropical Forests

The anurans of most tropical forests can be divided into two distinct assemblages of species. The first are arboreal frogs, which find their food in understory vegetation or even high in the forest canopy (Duellman 1978, 1989b, 1990; Vitt and Caldwell 1994; Parmelee 1999). These frogs tend to be strictly nocturnal, and spend the day in sheltered retreats or adopt water-conserving postures on exposed leaves (see chapter 2). Most species are sit-and-wait predators that eat relatively large prey, such as orthopterans, beetles, and roaches. A few species exhibit unusual feeding modes, however. For example, the Neotropical hylid genus *Sphaenorhynchus* is almost unique among members of that family, and among arboreal frogs in general, in being an ant specialist (Parmelee 1999). These frogs also are unusual in having very narrow mouths, a trait that is more typical of terrestrial ant-eating microhylids than of hylids, which usually have generalized diets.

The second assemblage is one that is virtually unknown in temperate habitats—frogs that spend most of their lives in the leaf litter of the forest floor. Many of these species are active during the day, or both during the day and at night.

Use of this terrestrial microhabitat during the day is made possible by high moisture levels in the litter, and therefore is characteristic only of relatively humid forests. In contrast, dry tropical forests and highly seasonal tropical environments often have terrestrial species, but all are nocturnal (Inger and Colwell 1977; Das 1996c). Use of forest litter habitat is especially prevalent among species with some form of terrestrial reproduction, but it is not restricted to them. In the Neotropics, litter communities are composed mainly of bufonids, dendrobatids, and leptodactylids. The genus *Eleutherodactylus* often is especially common, but other leptodactylids, such as *Physalaemus, Edalorhina, Adenomera, Leptodactylus,* and *Ceratophrys,* may be present as well, and terrestrial or burrowing microhylids are found in some communities. Two of these groups are partially (dendrobatids) or completely (*Eleutherodactylus*) independent of water for reproduction. Diurnal forest floor communities in the Old World are composed mainly of bufonids and ranids, sometimes with microhylids and rhacophorids as well (e.g., Watanabe, Nakanishi, and Izawa 2005). Forest floor communities usually have fewer species in the Old World than in the New World, but the reasons for this are not fully understood (Heyer and Berven 1973; N. Scott 1976, 1982; Voris 1977; Toft 1982). This could be related to local environmental differences, such as the severity of the dry season, or to historical factors, such as the phylogenetic origin of the species in each community. Nevertheless, some Old World tropical forests have high densities of individuals, even when species diversity is low (Watanabe, Nakanishi, and Izawa 2005).

The number of anuran species in Neotropical litter communities is positively correlated with both the number of wet months in a year (fig. 15.2 A) and mean annual rainfall (fig. 15.2 B), with the former being a slightly better predictor of species richness. Similar trends have been found in

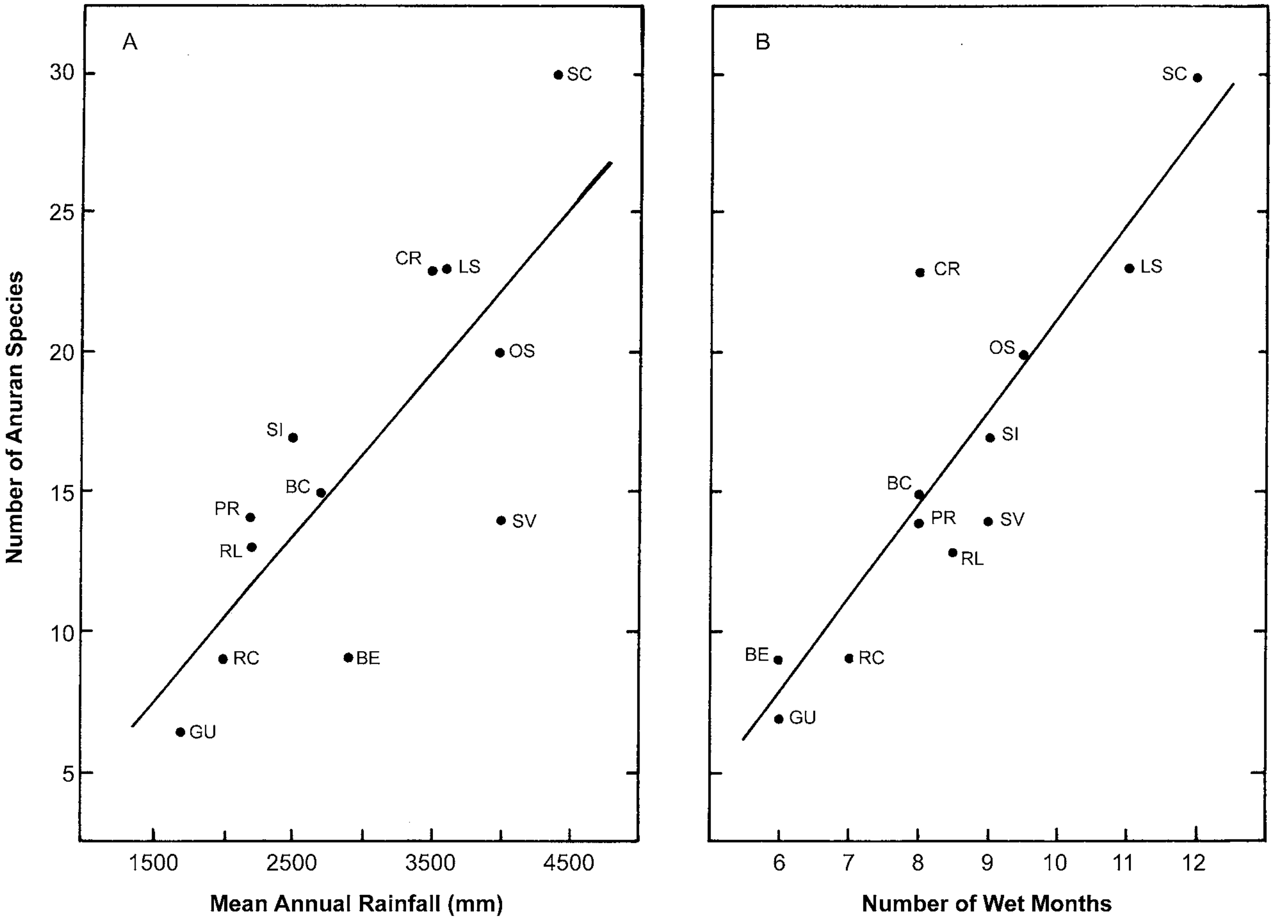

Fig. 15.2. Relationship of number of species of litter anurans to mean annual rainfall (A) and number of wet months per year (B) at several sites in South and Central America. Only diurnally active inhabitants of leaf litter are included. Regression equation for (A): $y = -1.42 + 0.006x$, $R^2 = 0.62$, $p < 0.002$; (B): $y = -12.2 + 3.34x$, $R^2 = 0.78$, $p < 0.0001$. Sites: BC = Barro Colorado Island, Panama; BE = Belem, Brazil; CR = Carti Road, Panama; GU = Guanacaste, Costa Rica; LS = La Selva, Costa Rica; OS = Osa Peninsula, Costa Rica; PR = Pipeline Road, Panama; RC = Rio Canclon, Panama; RL = Rio Llullapichis, Peru; SC = Santa Cecilia, Ecuador; SI = Silugandi, Panama; SV = San Vito, Costa Rica. Plotted from data in Heatwole and Sexton (1966), Crump (1971), Scott (1976), Duellman (1978), Toft and Duellman (1979), and Toft (1980a, b, 1981).

comparisons of total amphibian species diversity at several Neotropical localities (Crump 1971; Duellman 1978; J. Lee 1980; Pefaur and Duellman 1980; Duellman 1988; Duellman and Thomas 1996). Although population densities also are higher at wetter sites (N. Scott 1976; Toft 1980a, b), there is little consistency in seasonal patterns of abundance. In some areas, frogs are more abundant in the leaf litter during the wet season (Allmon 1991), but in others they are more abundant in the dry season (Lieberman 1986). These differences probably reflect both seasonal differences in recruitment of new individuals into the population (Toft, Rand, and Clark 1982; Watling and Donnelly 2002) and seasonal shifts in microhabitat preference (Toft 1980b). The numerical distribution of species in the forest litter is very uneven, with a few species usually predominating and others being comparatively rare (N. Scott 1976, 1982; Toft 1980a, b; Heatwole 1982; Toft, Rand, and Clark 1982; Lieberman 1986; Allmon 1991; Watling and Donnelly 2002).

Feeding Ecology

Neotropical leaf litter anurans differ in the timing of their foraging activity. Some dendrobatids, for example, are relatively inactive at midday, doing most of their foraging in the early morning or late afternoon, whereas other anurans are active throughout the day (Jaeger, Hailman, and Jaeger 1976; Jaeger and Hailman 1981). There also are species of *Eleutherodactylus* that hide in the leaf litter during the day, but usually forage on vegetation above the forest floor at night (Miyamoto 1982; M. Stewart 1985; Woolbright 1985b; Duellman 1990; Parmelee 1999). Each anuran species has a visual system adapted to function best under a specific light regime, and this in turn is reflected in the timing of foraging behavior (Jaeger and Hailman 1973; Hailman and Jaeger 1976). Temporal differences in activity could influence the types of prey available to each species and therefore could be an important component of resource partitioning in the community (Jaeger 1977, 1981c; Jaeger and Hailman 1981). However, at present there is little evidence that differences in diet among sympatric species are due to differences in foraging time, especially among those active mainly during the day (Parmelee 1999).

Although many forest litter anurans have generalized diets, some exhibit a greater degree of taxonomic specialization. Toft (1980a, b, 1981) compared the relative abundance of prey in frog stomachs and leaf litter for Neotropical communities and classified the frogs into three general categories: (1) ant specialists, (2) ant avoiders (= "non-ant specialists"), and (3) generalists. Parmelee (1999) adopted a somewhat similar classification, dividing anurans in Amazonian Peru into an ant/termite guild and a large prey guild. Because ant specialists eat relatively few types of prey other than ants (some eat small mites as well), they tend to have narrow calculated niche breadths. Both the ant avoiders and generalists, on the other hand, tend to eat a wide variety of prey taxa and therefore have much wider niche breadths. Indeed, Toft (1980a) found a strong negative correlation between niche breadth and electivity for ants (a measure of dietary preference). A few species of litter frogs are termite specialists, including *Physalaemus petersi* in Peru. Some ant-eating microhylids take termites as secondary prey (Parmelee 1999), and termites made up the largest volume of prey for the small Brazilian leptodactylid frog *Zachaenus parvulus* (Van Sluys, Rocha, and Souza 2001). Some very tiny forest floor frogs have become even more specialized for feeding on extremely small prey such as mites and collembolans (Simon and Toft 1991). Indeed, the abundance of such tiny prey may have contributed to the independent evolution of miniaturized body size in forest litter frogs in several different families (Clarke 1996; see also chapter 1).

In Panama, Costa Rica, and Peru, bufonids, microhylids, and dendrobatids tend to be ant specialists, whereas most *Eleutherodactylus* avoid ants and feed mainly on large prey, including orthopterans and beetles (Toft 1980a, b, 1981; Lieberman 1986; Parmelee 1999). The dendrobatids are particularly interesting because they exhibit a range of strategies, from active foraging (characteristic of ant specialists) to sit-and-wait predation (characteristic of ant-avoiders; Toft 1995; Caldwell 1996b). This variation is correlated with differences in activity metabolism (Taigen and Pough 1983, 1985), a subject that is discussed in more detail in chapter 5.

Prey size in litter anurans is correlated with body size and mouth width, but ant avoiders tend to take larger prey for a given mouth width than ant specialists (fig. 15.3), while generalists are intermediate. At larger body sizes, ant specialists also have smaller head widths than do ant avoiders of the same size (Toft 1980a; Parmelee 1999). Both generalists and ant specialists exhibit some ontogenetic changes in diet, taking progressively larger prey as they grow. This can result in some shift in types of prey eaten, since different prey taxa typically fall into different size categories (Lima and Moreira 1993; Lima 1998; Van Sluys, Rocha, and Souza 2001). There may be sexual differences as well, with the larger sex (usually females) taking somewhat larger prey than the smaller sex (Bonilla and La Marca 1996).

The feeding ecology of tropical anurans from other parts of the world is poorly known, but the limited data available suggest that general patterns are similar to those of the South and Central American species. In some cases, this similarity may be due to phylogenetic history. For example, bufonids eat large numbers of ants in both tropical and temperate communities. R. Clarke (1974b) reviewed 28 studies of the diets of 14 species of *Bufo* from around the world. In 13 cases, ants were the most important prey items, and in 14 others they ranked second. Many other studies

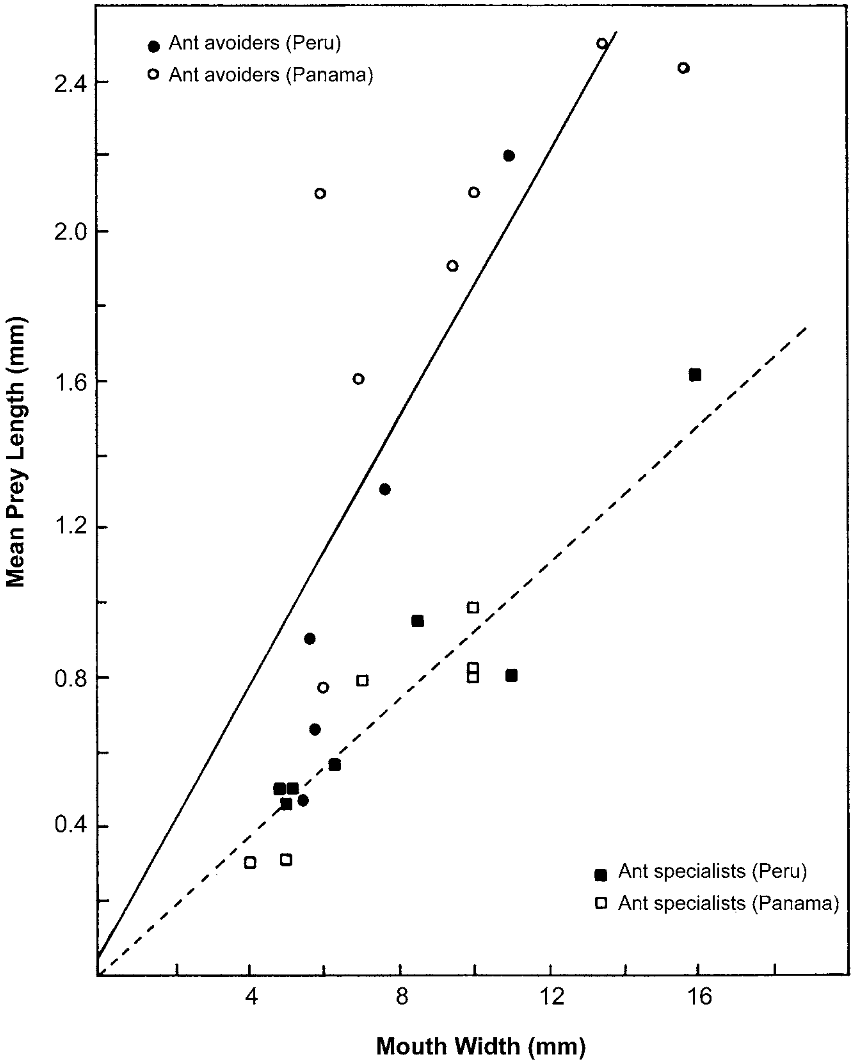

Fig. 15.3. Relationship of mean prey size to predator mouth width for litter anurans from Peru (solid symbols) and Panama (open symbols). Circles and solid line are for ant avoiders; squares and dashed line are for ant specialists. Regression equation for ant avoiders: $y = 0.05 + 0.18x$, $R^2 = 0.63$, $p < 0.001$; ant specialists: $y = -0.0008 + 0.09x$, $R^2 = 0.82$, $p < 0.0001$. Plotted from data in Toft 1980a, 1981.

have shown the same pattern (Paulian and Vilardebo 1946; Inger and Marx 1961; P. Berry and Bullock 1962; Lescure 1964, 1971; P. Berry 1970; Forge and Barbault 1978; Toft 1982; Strüssman et al. 1984; Wheater 1986; Vitt and Caldwell 1994; Lajmanovich 1995; F. Meyer, Kutzscher, and Grosse 1999; Parmelee 1999; Isacch and Barg 2002; Vaz-Silva, Silva, and da Silva 2003a, b; Moseley et al. 2005). Ants are important for both diurnal and nocturnal toads, and are heavily used not only by small species, but also by large species such as *Bufo marinus* (N. Weber 1938; Zug and Zug 1979; Strüssman et al. 1984). Terrestrial and burrowing microhylids also tend to be ant or termite specialists in both the Old and New World (Das 1996c; Parmelee 1999). In contrast, other anurans vary considerably in their feeding ecology. For example, while most species of *Eleutherodactylus* are sit-and-wait predators that eat large prey, a few species, such as *E. vocator* in Panama (Toft 1981) and *E. lentus* in the Virgin Islands (K. Jones 1982) are more active foragers and may eat smaller prey, especially ants. Other species of *Eleutherodactylus* include ants in a varied diet of insects, and take them roughly in proportion to their occurrence in the leaf litter (Lieberman 1986).

In several families of anurans, there is an association between specialized feeding on ants and the use of noxious skin secretions as a defense against predators (Toft 1995; Caldwell 1996b; Vences et al. 1997/98; Caldwell and Vitt 1999). For example, most dendrobatids, bufonids, and microhylids are well protected by skin secretions. Among the dendrobatids, the derived, highly toxic species of *Dendrobates* and *Phyllobates* are the most specialized ant predators

(Darst et al. 2005). Species of *Colostethus* (including *Nephelobates;* Bonilla and La Marca 1996) and some species of *Epipedobates* have more generalized diets, although they still eat large numbers of ants (Lima and Moreira 1993; Biavati, Wiederhecker, and Colli 2004). The association between ant-eating and toxic skin secretions derives from the ability of some frogs to sequester chemical compounds acquired from ants in the diet for use in their own defense (see chapter 14 for further details). A specialized diet of ants seems to have resulted in convergent evolution in a number of behavioral and morphological traits in poisonous frogs, especially members of the genus *Mantella* from Madagascar and the Neotropical dendrobatids. In addition to conspicuous aposematic coloration, these frogs share behavioral traits such as diurnal activity, an active foraging mode, and a preference for prey loaded with noxious chemicals (V. Clark et al. 2005). They also share certain morphological features that seem to be associated with feeding on very small prey, including reduction in gape, reduction in teeth, changes in tongue shape, and changes in features of the skull related to the jaw-opening mechanism (Vences, Glaw, and Böhme 1997/98).

Niche Overlap and Interspecific Competition

With the exception of the specialized diets discussed previously, litter anurans in the same guild show considerable overlap in prey taxa, as do arboreal frogs in the same communities (Parmelee 1999). In Peru, for example, the ant-avoiding species of *Eleutherodactylus* did not differ significantly in the proportion of different prey taxa in their diets. This is not surprising, since they all take prey taxa other than ants roughly in proportion to their abundance in the litter (Toft 1980a). Similar patterns were found in Panama (Toft 1980b) and in studies of African species (Inger and Marx 1961; Toft 1982). The Neotropical frogs differed considerably in body size, and prey size is correlated with body size (fig. 15.3). Therefore, calculated indices of niche overlap decrease when information on prey size is included, but they are still relatively high for many species pairs (Toft 1980a, b). In a four-species community in Gabon, on the other hand, diets are so similar that inclusion of prey size has little effect on calculations of niche overlap (Toft 1982). In this community, all but one species feed very heavily on termites, and therefore have diets similar in both prey size and prey type. Unfortunately, data for this assemblage are available for only part of one year, so the amount of seasonal variation in diet overlap is unknown.

The importance of competition for food in the organization of leaf litter anuran communities is not at all clear. Experiments with one very abundant species, *Eleutherodactylus coqui,* in Puerto Rico, showed that removal of frogs from small enclosures or from large plots significantly increased the density of herbviorous insects on foliage, but had little or no effect on the abundance of leaf litter insects (Beard et al. 2003). This suggests that leaf litter insects probably are not limiting, even at very high frog population densities.

Specialization on particular types of prey, such as ants, probably is part of a suite of characters resulting from independent feeding adaptations, but interspecific competition may have been more important in the evolution of food size and microhabitat partitioning (Toft 1985). The evidence for this is indirect. In Peru, interspecific overlap in food size was reduced during the dry season, when food was least abundant (Toft 1980a). This is consistent with competition theory, which predicts that niche overlap should decrease as resources become scarce (e.g., Schoener 1982), and with empirical data on other groups (e.g., Boag and Grant 1984). However, the changes in food size also could reflect seasonal shifts in microhabitats. In Panama, food was least abundant late in the wet season. At one site, overlap in prey size decreased in the wet season, but at another site, there was no change (Toft 1980b). Species of *Eleutherodactylus* often differ in their use of microhabitats and in altitudinal distribution, but virtually nothing is known about how biological interactions among species affect habitat use and distribution (e.g., Lynch and Duellman 1997).

Anurans of Tropical Savannas

Although there is a tendency to think of the tropics as an unbroken expanse of rainforest, there are extensive grasslands in the tropics as well, and many of these support diverse communities of anurans (Rödel 1996, 2000; Neckel-Oliveira et al. 2000). Extensive work on anuran communities in West African savannas provides some interesting parallels with tropical forest litter communities. Most of the studies were carried out in the Ivory Coast, in the Lamto Savanna (Barbault 1972, 1974b, c, 1977) and Comoé National Park (Rödel 1996, 2000). The region is characterized by a three-to-six month dry season and a six-to-nine month wet season, depending on the precise location of the savanna. These savannas exhibit a substantial amount of topographic and habitat complexity, with a relatively dry grassland plateaus, wetter lowlands, woodlands, and stretches of gallery forest.

About 50 species of anurans inhabit the West African savannas (Rödel 2000), with about 40 of these being found in the Lamto Savanna, where most of the detailed ecological work has been done (Lamotte 1967). Some of these are arboreal, but detailed community studies have focused on the terrestrial species, mainly ranids, bufonids, and hyperoliids. In contrast to the Neotropical litter anurans, these anurans are mainly nocturnal, and most depend on standing water for reproduction (a species of *Arthroleptis* is an exception; Barbault and Trefaut Rodrigues 1979a). The density of anurans in the savanna is closely tied to the number of months in which tem-

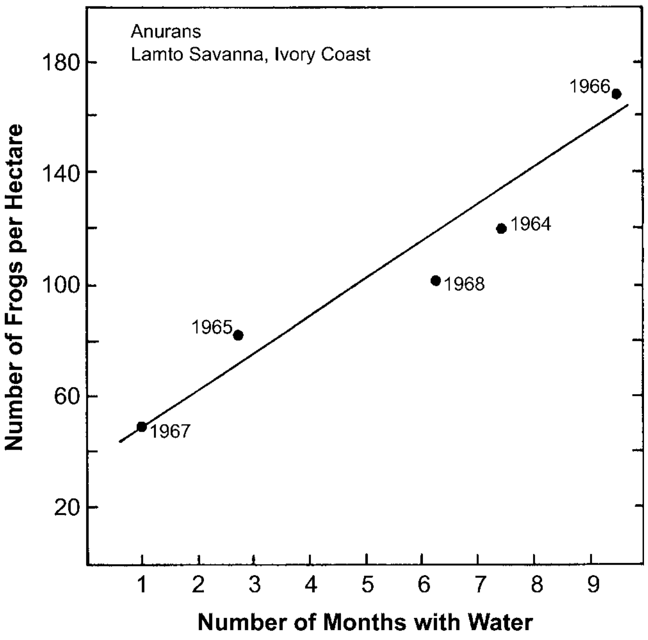

Fig. 15.4. Relationship of anuran density to number of months in which temporary ponds were available for breeding in the Lamto Savannah, Ivory Coast. Regression equation: $y = 36.14 + 12.47x$, $R^2 = 0.90$, $p < 0.008$. Plotted from data in Barbault (1972).

porary ponds are available for reproduction (fig. 15.4), and both seasonal and annual fluctuations in population density exceed those observed in humid forested habitats (Barbault 1972, 1974b, c, 1977). As expected, lowland areas with abundant temporary ponds have much higher population densities than drier upland areas (Barbault 1972). In comparisons between two different savannas, the wetter site had both higher species diversity (Barbault 1976b) and higher population densities (Barbault 1976a) than the drier site.

The feeding ecology of these savanna anurans is similar in many respects to that of the forest litter species. Most of the species feed on a variety of insects. However, one arboreal species apparently is an ant specialist, and a burrowing species (*Hemisus marmoratus*) feeds entirely on ants and termites. The bufonids eat mostly ants and beetles, and several ranids also show moderate specialization on ants (Barbault 1974a). As in the forest litter species, dietary diversity in the savanna anurans decreases as the importance of ants in the diet increases (fig. 15.5 A). Although dietary overlap between species is considerable, there is some separation by prey size, which again is strongly correlated with body size of the predator (fig. 15.5 B). As in the other communities discussed earlier, the role of interspecific competition in producing these patterns of resource partitioning is unclear. Barbault (1974a, c) suggested that food probably is not a limiting resource in most years, because population size is controlled mainly by the availability of water for reproduction, not by the abundance of insects. Predation may play an important role as well, by maintaining populations of anurans below levels at which competition for food is likely to occur (Barbault 1987, 1991). Barbault (1991) also speculated that interactions of amphibians with their predators indirectly affect other components of the community, especially insectivorous

Dietary diversity is expressed in bits calculated from the Shannon-Weaver diversity index. (B) Relationship of prey length to predator body size for six species. Prey do not include ants and termites. Regression equation for (A): $y = 3.17 + 0.025x$, $R^2 = 0.85$, $p < 0.0001$; (B): $y = -7.18 + 0.53x$, $R^2 = 0.96$, $p < 0.000$. Plotted from data in Barbault (1974c).

lizards. During dry periods, when amphibians are scarce, their predators may switch to feeding on lizards, which remain abundant during the dry season.

Tropical Riparian Communities

Although aquatic-breeding frogs are most commonly associated with temporary or permanent ponds, some tropical and subtropical species are found mainly along forested streams (K. Parris and McCarthy 1999). In a relatively dry evergreen forest in Thailand, several species of ranids inhabit riparian habitats. They exhibit minor habitat differences along a horizontal gradient, differing in their affinity for permanent streams and in their tendency to remain in the water. Otherwise, they appear to be rather similar ecologically (Inger and Colwell 1977). In riparian communities of up to 25 anuran species along forest streams in Borneo, there is some separation of microhabitats along both vertical and horizontal axes, with some species being more arboreal or more terrestrial than others (Inger 1969; Inger and Voris 1993; Das 1996a). A similar pattern was seen in a less diverse assemblage in Sulawesi, where stream-breeding frogs differed mostly in the types of perches they occupied along the streams (Gillespie et al. 2004). Most species in these assemblages are generalist predators on small invertebrates. However, bufonids specialize on ants, and two of the largest ranid species feed on crabs not available to the smaller frogs. Closely related species tend to be most similar ecologically, suggesting that phylogenetic history is a more important determinant of resource use than ecological interactions between species (Inger 1969).

An experimental study of three common ranids in these communities provides some evidence of current interspecific competition, although the resource being contested is not known (Inger and Greenberg 1966). There are minor differences among species in microhabitat and prey choice, but all are rather similar ecologically. Inger and Greenberg proposed that the relative abundance of species in the community is regulated by interspecific competition. *Limnonectes leporinus* (formerly *L. blythii*) was very common on all streams, whereas *L. ingeri* (formerly *L. macrodon*) was relatively rare and *L. ibanorum* was intermediate in abundance. When *L. ibanorum* was removed from one stream, the number of *L. leporinus* on the stream doubled over a period of several months. When *L. leporinus* was removed from another stream, *L. ibanorum* showed a small initial increase and then declined slightly, while *L. ingeri* initially showed no change and then increased slightly. These experiments suggest that interspecific competition does limit the numbers of some species on these streams. However, these conclusions are only tentative, because the experiment lacked proper replication and controls, with different streams being used as experimental and control sites. Changes in population size along these streams could have been due to differences between streams that were independent of the experimental treatments. Nevertheless, this study remains, after 40 years, the only attempt to examine competitive interactions among adult anurans experimentally.

Anuran Communities in the Temperate Zone

Temperate zone anuran communities lack both the structural complexity and high species diversity of tropical assemblages. Although a few species of treefrogs probably do much of their feeding in trees, most temperate zone anurans can be considered either terrestrial or semiaquatic. Indeed, several studies of local assemblages have shown that differences in microhabitat use can account for most of the ecological differences among species. In North America, for example, some ranid frogs, such as *Rana septentrionalis, R. catesbeiana,* and *R. pretiosa,* are more fully aquatic than are species such as *R. clamitans, R. pipiens,* and *R. aurora.* In general, all of these species are generalist predators on arthropods and other invertebrates, but the more aquatic species tend to take larger numbers of aquatic prey than do the species that live along pond shores (Stewart and Sandison 1972; Licht 1986b; McAlpine and Dilworth 1989; Werner, Wellborn, and McPeek 1995). Wood frogs (*Rana sylvatica*) and toads (*Bufo*) tend to be strictly terrestrial outside the breeding season, and can be expected to take mostly terrestrial prey species. Similar patterns are seen in Europe, where anuran communities are largely divided into semiaquatic and terrestrial components (Lizana, Perez-Mellado, and Ciudad 1990). Again, the more aquatic species, such as *Rana ridibunda, R. perezi,* and *Rana iberica,* tend to take more aquatic prey than do the more terrestrial species, such as *R. temporaria, R. dalmatina, R. arvalis,* and various bufonids and discoglossids (Lizana Avia, Ciudad Pizarro, and Pérez-Mellado 1986; Kuzmin 1999; Guidali, Scali, and Carettoni 2000). There have been many studies of the diets of individual species of temperate zone anurans, and these have revealed little evidence of diet specialization, except for the tendency of toads (*Bufo*) to eat large numbers of ants. Nearly all other species are generalist or opportunistic predators that take prey roughly in proportion to their abundance in the habitat, although many species exhibit at least limited aversion to ants (Jenssen and Klimstra 1966; Houston 1973; Blackith and Speight 1974; Labanick 1976; Cogălniceanu et al. 1998; A. M. Anderson, Haukos, and Anderson 1999a; Hirai and Matsui 1999, 2000, 2001; Kuzmin 1999; F. Meyer, Kutzscher, and Grosse 1999; Bellocq, Kloosterman, and Smith 2000).

Community Ecology of Terrestrial Salamanders

Assemblages of terrestrial plethodontid salamanders are among the most intensively studied of amphibian communities, with the greatest attention having been focused on forest litter species of *Plethodon* or streamside species of *Desmognathus* in the southern Appalachians (Hairston 1987, 1996). Nevertheless, the role of salamanders in terrestrial ecosystems tends to be underappreciated by ecologists in general. The classic study of salamanders at Hubbard Brook in New Hampshire by Burton and Likens (1975a, b) demonstrated that terrestrial salamanders not only can be numerically dominant members of forest ecosystems, but also can account for a large proportion of vertebrate biomass, despite their relatively small size. Subsequent studies, reviewed by Davic and Welsh (2004), have revealed even higher densities and greater biomass of salamanders than those found at Hubbard Brook. Furthermore, there is considerable evidence that salamanders can be dominant predators in a variety of habitats, including the forest floor litter community, and can affect ecosystem dynamics and the population dynamics of leaf-litter invertebrates.

Salamanders tend to be morphologically conservative, with closely related species often being very similar in both appearance and ecology. In some communities, similarity in resource requirements seems to have resulted in competitive exclusion of one species by another from apparently suitable habitat; in others, there is evidence of limited resource partitioning among coexisting species (Toft 1985). Several case studies will be discussed in detail in the following. First, however, I will review the foraging strategies of terrestrial salamanders and the evidence for potential interspecific competition for food, since food is the most commonly measured resource in studies of competition and resource partitioning among vertebrates.

Foraging Strategies

Most terrestrial plethodontids feed on a variety of small invertebrates, including earthworms, centipedes, millipedes, snails, isopods, pseudoscorpions, spiders, mites, and many types of adult and larval insects (Hairston 1949; Altig and Brodie 1971; Whitaker and Rubin 1971; Donavan and Folkerts 1972; Jaeger 1972; Bury and Martin 1973; Powders and Tietjen 1974; Burton 1976; Fraser 1976a, b; Maiorana 1978a; Sites 1978; Keen 1979; Kryzsik 1979; Lynch 1985; Hairston, Nishikawa, and Stenhouse 1987; Davic and Welsh 2004). Large semiaquatic plethodontids such as *Gyrinophilus* are important predators on smaller salamanders, but eat invertebrates as well (Hairston 1949, 1980c; Martof and Scott 1957; Bruce 1972a; Burton 1976; Kryzsik 1979). Some terrestrial plethodontids also eat smaller conspecific or heterospecific salamanders on occasion, but this appears to be uncommon (Heatwole and Test 1961; Altig and Brodie 1971; Donavan and Folkerts 1972; Powders 1973; Powders and Tietjen 1974).

Although all salamanders are carnivorous or insectivorous, there is no evidence that any species of salamander specializes on particular prey taxa within these broad categories. Only a few workers have compared prey abundance in salamander stomachs and the environment (Martof and Scott 1957; Altig and Brodie 1971; Maiorana 1978a; Sites 1978). Most have simply assumed that salamanders take prey in proportion to their relative abundance, although prey availability also may be affected by the size, mobility, and microhabitat choice of both the predator and the prey (Maiorana 1978a; Jaeger 1980b). Salamanders appear to be more selective in choosing prey sizes than prey taxa. For example, *Desmognathus fuscus* take large prey in higher proportions than their frequency in the environment (Sites 1978). In *Batrachoseps,* diet choice largely reflects prey availability, but some individuals preferentially select larger prey items if they are present (Maiorana 1978a).

Within species, there is a tendency for larger individuals to take larger prey. For example, Whitaker and Rubin (1971) found the same prey taxa represented in all size classes of *Plethodon metcalfi*. However, the relative importance of large prey such as earthworms, millipedes, and centipedes increased with increasing body size, while the importance of small prey such as ants, collembolans, and mites decreased (fig. 15.6). Lynch (1985) also found an ontogenetic decrease in the importance of collembolans and mites with increasing body size in *Aneides flavipunctatus,* and average prey size was positively correlated with salamander body size. Similar relationships (fig. 15.7) have been reported for other species (Fraser 1976a, b; Maiorana 1978a; Sites 1978; Kryzsik

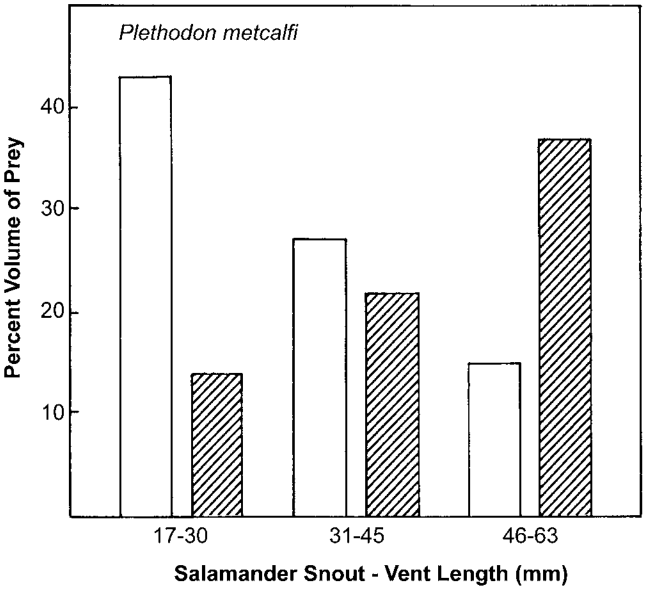

Fig. 15.6. Frequency of small prey (open bars) and large prey (striped bars) taken by *Plethodon metcalfi* as a function of salamander body size. Large prey include pooled percentages of spiders, earthworms, millipedes, centipedes, and craneflies; small prey include ants, collembolans, and mites. Plotted from data in Whitaker and Rubin (1971).

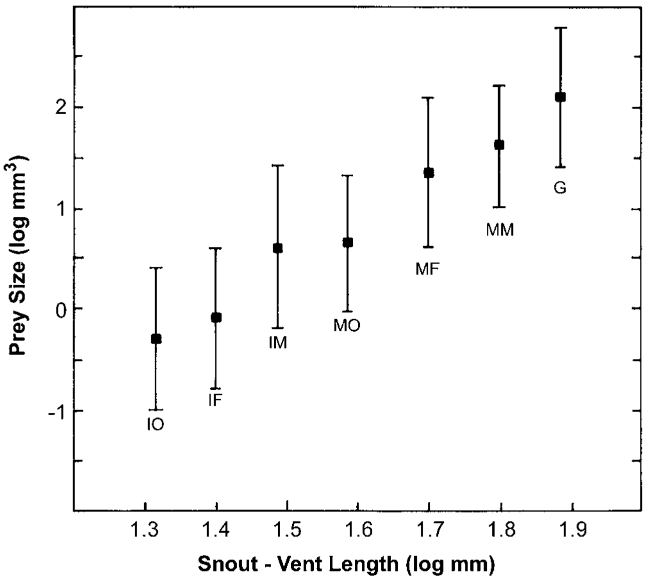

Fig. 15.7. Relationship of prey size to salamander body size for adults and juveniles of four species of streamside salamanders in Pennsylvania. Graph shows means ± standard deviations on a log scale. Species abbreviations: IO = immature *D. ochrophaeus,* IF = immature *D. fuscus,* IM = immature *D. monticola,* MO = mature *D. ochrophaeus,* MF = mature *D. fuscus,* MM = mature *D. monticola,* G = *Gyrinophilus porphyriticus.* Plotted from data in Krzysik (1979).

1979). Feeding experiments with *Aneides* showed that maximum prey size probably is determined by physical constraints imposed by the size of the salamander's mouth, while minimum prey size is determined by behavioral avoidance of small prey (Lynch 1985). However, in most species, large individuals eat some small prey (Kryzsik 1979; Lynch 1985), and prey utilization curves for large salamanders may completely encompass those of smaller individuals (fig. 15.8).

There is evidence that salamanders can assess prey profitability and adjust their foraging behavior to concentrate on the most profitable prey when conditions are favorable. A common prediction of optimal foraging models is that animals should become increasingly specialized in their choice of prey as food abundance increases, because a predator can afford to pass up less profitable prey in the expectation that better prey will be available (Krebs 1978). In laboratory experiments, Jaeger and Barnard (1981) presented *Plethodon cinereus* with a choice of large and small flies in equal numbers, but at different total prey densities. Large flies are more profitable because they have proportionately less indigestible exoskeleton. The salamanders specialized on large flies when total prey density was high, but ate large and small flies indiscriminately at low prey densities (fig. 15.9). At high prey densities, salamanders also were more persistent in attacking large flies that were initially missed. They continued to take some small prey if they could do so with relatively little energy expenditure (i.e., by using sit-and-wait foraging tactics), but were less likely to actively pursue small prey than large prey at all but the lowest prey density.

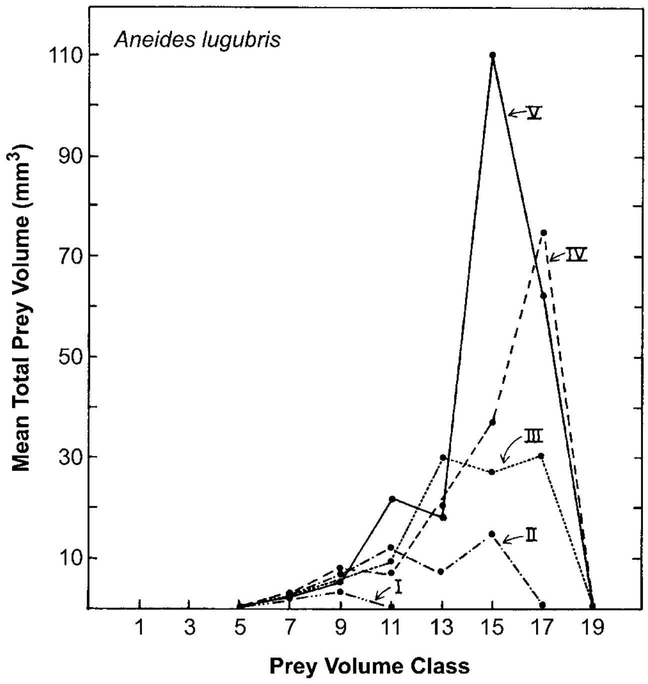

Fig. 15.8. Prey utilization curves for different size classes of *Aneides lugubris.* The curves for larger-size classes tend to enclose those for smaller classes. Roman numerals give salamander size classes in increasing order. Prey size classes give relative sizes on a log scale. After Lynch (1985).

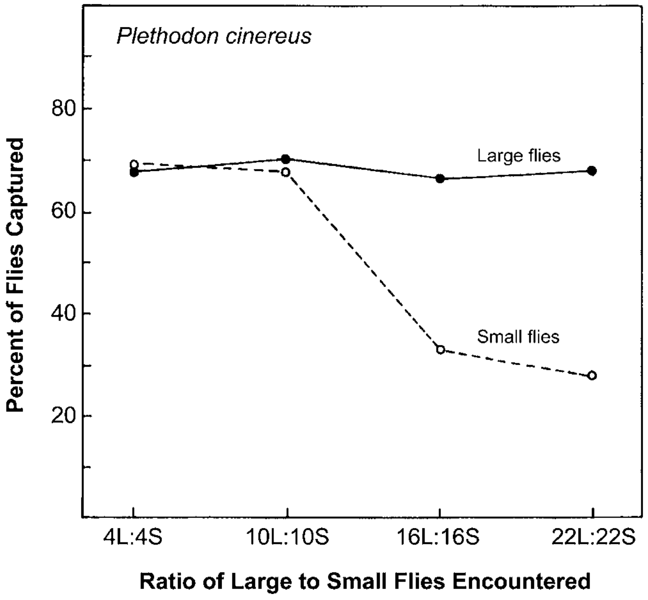

Fig. 15.9. Percentage of large and small flies ingested by *Plethodon cinereus* as a function of total prey density. As density increases, the salamanders tend to ignore smaller prey. Plotted from data in Jaeger and Barnard (1981).

Although the foraging behavior of salamanders is difficult to observe in the field, there is some evidence that they use similar "optimal foraging" tactics in nature. Prey availability for terrestrial salamanders is determined mainly by rainfall (Jaeger 1972, 1980b; Fraser 1976a; Keen 1979).

Even when prey abundance remains largely unchanged, the ability of salamanders to leave moist retreat sites to search for food may be severely limited by fluctuations in leaf litter moisture (see also chapter 2). Several authors have reported a tendency for salamanders to specialize on large prey items during relatively wet weather or when feeding in wet microhabitats, but to feed indiscriminately on large and small prey during dry periods or in drier areas (Burton 1976; Sites 1978; Keen 1979; Lynch 1985). Although these results suggest that salamanders are more selective feeders when prey is abundant, it also is possible that salamanders are able to exploit a wider range of microhabitats during wet weather and therefore are exposed to a wider diversity of prey (Jaeger 1978).

Interspecific Competition for Food

The extent to which food is a limiting resource for salamanders is not clear. Although salamanders may experience periodic food shortages (Jaeger 1972, 1980b; Fraser 1976a), food availability per se may not be the major determinant of population size. Unfortunately, there have been few long-term studies of salamander population dynamics, so the extent and causes of fluctuations in population size are not well understood. Such studies are particularly difficult with salamanders because their cryptic nature makes it difficult for investigators to obtain reliable estimates of fluctuations in population size (Dodd and Dorazio 2004), a necessary prerequisite for determining the causes of such fluctuations. Nevertheless, there is experimental evidence that dense populations of salamanders can have a significant impact on invertebrate populations. For example, Wyman (1998) removed red-backed salamanders (*Plethodon cinereus*) from forest-floor enclosures and found a significant increase in leaf-litter invertebrates. Rooney, Antolik, and Moran (2000) performed a similar set of experiments and found that the presence of *P. cinereus* actually enhanced the abundance of collembolans, which they do not eat, by reducing the abundance of their predators. Although these experiments were designed to investigate the effects of salamanders on invertebrates, rather than the effect of prey abundance on salamanders, they suggest at least the potential for prey to become limiting for some terrestrial salamanders.

In favorable habitats such as the southern Appalachians, salamander populations can be very dense (Hairston 1987; Petranka, Eldridge, and Haley 1993; Petranka and Murray 2001; Davic and Welsh 2004) and may be near the carrying capacity of the environment most of the time (Hairston 1980b). In harsher environments, density-independent factors may maintain populations well below carrying capacity (Dumas 1956). Even when populations are near carrying capacity, the resources that limit population size are not always obvious. Several authors have suggested that space, rather than food per se is the proximate limiting resource for some species. Individuals may compete for access to nesting sites or moist retreat sites that also provide access to food (Jaeger 1974; Fraser 1976a, b; Maiorana 1978b; Hairston 1981). A number of plethodontid salamanders defend territories centered on moist retreat sites against both conspecifics and heterospecifics (see chapter 9). Such retreats may enhance the foraging opportunities of territory holders, even though food is not the direct object of competition.

Descriptive Studies

Published studies of the diets of sympatric salamanders (Hairston 1949; Dumas 1956; Altig and Brodie 1971; Jaeger 1972; Bury and Martin 1973; Powders and Tietjen 1974; Burton 1976; Fraser 1976a, b; Krzysik 1979; Holomuzki 1980; Lynch 1985; Hairston, Nishikawa, and Stenhouse 1987) suggest several general conclusions about resource partitioning. Most sympatric species exhibit broad overlap in prey taxa, in some cases reaching levels of similarity of 80–90%. Differences in prey taxa generally reflect differences in microhabitat rather than differences in selectivity within shared microhabitats. For example, in communities of *Desmognathus,* differences in prey taxa generally reflect the proximity of each species to water, with more aquatic salamanders taking more aquatic prey (Hairston 1949; Krzysik 1979).

Differences in prey taxa also reflect morphological differences among salamander species. For example, salamander communities in northern California are composed of several morphologically distinct genera, including one or more species of *Aneides,* which have large bodies and relatively wide heads, *Ensatina,* a generalized terrestrial salamander, and *Batrachoseps,* a specialized burrowing salamander with a very narrow head. Differences in diets among these species are somewhat greater than in communities of salamanders composed of morphologically similar species (Bury and Martin 1973; Lynch 1985). However, differences in prey taxa may be a byproduct of differences in prey size, and may not reflect discrimination among types of prey. Prey size tends to be positively correlated with salamander body size; overlap in prey size is greatest between species with similar body sizes. Even when adults of different species exhibit significant differences in prey size, juveniles of large species often overlap completely with adults of smaller species (Krzysik 1979). Furthermore, as is the case within species, large species often eat both large and small prey, while small species eat only small prey. Although differences in prey size have been interpreted as evidence of resource partitioning among different size classes of salamanders (Fraser 1976a; Krzysik 1979; Toft 1985), there is little direct evidence that prey selection is influenced by the presence of other species. Maiorana (1978b) found that overlap in prey size between sympatric *Aneides* and *Batrachoseps* was positively correlated with overlap in space. This violates the principle of niche complementarity derived from competition theory, which predicts that species that overlap greatly on one resource axis should exhibit reduced overlap on another axis (Schoener 1974, 1982).

Fraser (1976a, b) suggested that both intraspecific and interspecific competition for food might be reduced by individuals having different activity periods, but there is little evidence of major differences in the timing of foraging among sympatric species. Most plethodontids tend to be active on the surface mainly at night, although they may forage under logs, rocks, or litter during the day; all are most active during wet weather. In the genus *Desmognathus,* larger, more aquatic species are reported to be slightly less nocturnal than smaller, more terrestrial species (Hairston 1949; Shealy 1975). Nevertheless, peaks of surface activity usually are similar for sympatric species (Shealy 1975; Holomuzki 1980), and temporal partitioning of resources probably is of little significance in most salamander communities (Toft 1985).

Experimental Studies

Exploitative competition for food can be demonstrated experimentally if the presence of one species significantly reduces the feeding rate, growth rate, energy reserves, or reproduction of a sympatric species, or the presence of one species leads to a shift in the food niche of another species. Only a few such studies have been performed, and most do not strongly support the hypothesis that competition for food is an important determinant of salamander community structure.

Perhaps the best places to look for interspecific competition among plethodontid salamanders are areas in which one species replaces another geographically, often with only a relatively narrow zone of overlap between them. Several small species of *Plethodon* exhibit this type of parapatric or near-parapatric distribution (Highton 1971). For example, the widespread species *Plethodon cinereus* is largely absent from the Valley and Ridge physiographic province of central Pennsylvania, where it is replaced by a very similar species, *Plethodon hoffmani.* Fraser (1976b) placed *P. cinereus* and *P. hoffmani* in laboratory enclosures at different densities in both single-species and mixed-species groups. He found that salamanders of both species lost mass as density increased, but there was no difference in the effects of conspecifics and congenerics (fig. 15.10). Since the highest densities in this experiment were considerably higher than were those in the field, it does not directly test for competition under natural conditions. However, it does show that under intense competition, neither species greatly exceeds the other in its ability to acquire food.

A study of morphological variation and resource use by these two species in sympatric and allopatric populations along a transect in Pennsylvania provides some of the strongest evidence for interspecific competition for food (Adams and Rohlf 2000). Allopatric populations of the two species exhibit few morphological differences in characters of the skull associated with food capture and consumption, but sympatric populations do differ morphologically. Furthermore, sympatric populations exhibited partitioning of prey that was absent in allopatric populations, with *P. cinereus* tending to eat smaller prey items and *P. hoffmani* eating larger prey. Individuals of both species had less food in their stomachs in sympatry than in allopatry, indicating significant competition for food. The morphological differences in sympatric populations involved biomechanical differences in jaw closure that were related to the size of prey that could be most efficiently consumed by each species. Exploitative competition is not the only type of interaction between these species, however. *Plethodon cinereus* tends to be more aggressive toward both conspecifics and heterospecifics than is *P. hoffmani,* suggesting that aggressive interference competition limits the distribution of *P. hoffmani* (Jaeger, Prosen, and Adams 2002).

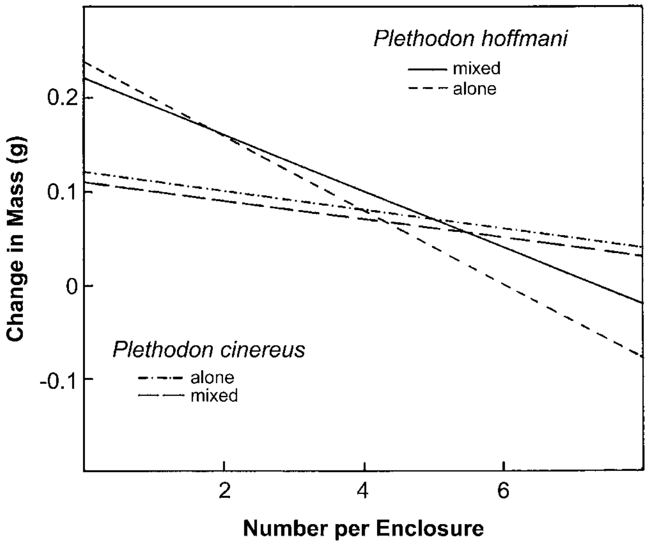

Fig. 15.10. Change in mass as a function of density for the salamanders *Plethodon hoffmani* and *P. cinereus* housed in single-species and mixed-species groups in the laboratory. After Fraser (1976b).

In studies of another pair of small *Plethodon* species, Jaeger (1971a, 1972) found that *P. cinereus* was competitively superior to *P. shenandoah* in a natural environment, and hypothesized that the former was more effective in finding and capturing prey. However, in mixed-species tests in the laboratory, *P. shenandoah* actually captured more prey than *P. cinereus* (D. Kaplan 1977), the opposite of the result predicted from the field data. Hence, exploitative competition for food does not appear to explain the relative success of the two species in nature. Subsequent experiments by Wrobel, Gergits, and Jaeger (1980) showed that the two species interact aggressively when housed together in the laboratory, but neither species consistently won these encounters, and there was no difference between them in the amount of mass lost during the experiment.

The only field experiment that has specifically tested the hypothesis of food competition is Kleeberger's (1984) work with *Desmognathus*. He added *D. monticola* to unfenced field plots containing both that species and *D. quadramaculatus*. The lipid reserves of *D. monticola* on the plots decreased, but *D. quadramaculatus* was not affected. However, when both *D. monticola* and rocks were added to experimental plots, the lipid reserves of *D. monticola* increased, suggesting that abundance of cover influences the abundance of prey. The addition of *D. quadramaculatus* had no effect on the lipid reserves of either species. These results reveal that food is potentially limiting for *D. monticola* in this area, and intraspecific competition may affect the distribution and abundance of that species, but there was no evidence of interspecific competition for food.

Interspecific Competition for Space

Although the evidence for exploitative competition among salamanders is relatively weak, it is becoming clear that interference competition is important in many salamander communities. Such competition is mediated by interspecific aggressive encounters (see chapter 9), with the object of competition most likely being suitable sites for feeding, sheltering, or oviposition. In some communities, interspecific competition may result in partitioning of available macro- or microhabitats among species. However, one cannot assume that such partitioning is always the result of interspecific competition, since salamanders might exhibit species-specific habitat preferences regardless of the presence or absence of other species.

Altitudinal Separation in Large *Plethodon*

The distribution of large species of *Plethodon* in the southern Appalachians has become a classic example of the role of interspecific competition in determining the limits of species' ranges. In several mountain ranges in the southern Appalachians, relatively large, white-spotted black salamanders tend to co-occur with smaller, unspotted black salamanders with varying degrees of altitudinal overlap and hybridization (Highton and Peabody 2000). The white-spotted species often are placed in the *P. glutinosus* group, a widespread complex with a number of species that occur outside of the southern Appalachians (fig. 15.11). Species in this region include *P. aureolus, P. chattahoochee, P. chlorobryonis, P. cylindraceus, P. glutinosus, P. kentucki,* and *P. teyahalee* (this species has been called *P. oconaluftee* by some authors; e.g., Hairston 1993, 1996; Petranka 1998). The unspotted species, some of which have bright orange markings on their

Fig. 15.11. Large plethodontid salamanders of the *Plethodon jordani* and *P. glutinosus* complexes. (A) *P. jordani* from Great Smoky Mountains National Park, North Carolina. cheeks or legs, often are placed in the *P. jordani* group (*P. amplus, P. cheoah, P. jordani, P. meridianus, P. metcalfi, P. montanus,* and *P. shermani*), which is found only in the southern Appalachians. Genetic studies suggest, however, that these two groups may not be monophyletic. For example, *P. teyahalee,* a member of the *P. glutinosus* group, may be more closely related to *P. shermani,* a member of the *P. jordani* group, than to other members of the *P. glutinosus* group, possibly having been derived from hybridization between *P. shermani* and *P. cylindraceus* (Highton and Peabody 2000).

In his pioneering study of salamander ecology, Hairston (1949) reported that *Plethodon metcalfi* in the Black Mountains of North Carolina exhibit a remarkable degree of altitudinal separation from populations of *P. cylindraceus* (Hairston 1996). The former is confined to high elevations, whereas the latter is widely distributed from low to mid-elevations. Later work revealed similar altitudinal separation between spotted and unspotted salamanders in several other mountain ranges (Hairston 1951, 1973, 1980b; Highton and Henry 1970; Highton and Peabody 2000). The unspotted species always are confined to higher elevations, but the precise boundary varies among mountain ranges and with slope exposure. Since the boundaries between these species are not related to obvious changes in climate or vegetation, Hairston (1951, 1973) proposed that competition with unspotted (*P. jordani* complex) species limits the vertical distribution of the spotted (*P. glutinosus* complex) species. On mountains where unspotted salamanders are absent, the local spotted species can be found up to the highest peaks.

This hypothesis was tested by a long-term field experiment in which individuals of the two species complexes were repeatedly removed from experimental plots in zones of sympatry (Hairston 1980b, 1987, 1996; Hairston, Nishikawa, and Stenhouse 1987). Experiments were conducted in both the Balsam Mountains, where species overlap by about 1,200 m, and the Great Smoky Mountains, where the overlap is only about 120 m (fig. 15.12). When these experiments were performed, the lower elevation populations were considered to be *P. glutinosus,* whereas the higher elevation populations were classified as two different color morphs of *P. jordani.* The proper taxonomy of these two salamander complexes has been much debated, but current taxonomy treats all of the lower elevation spotted salamanders used in the experiments as *P. teyahalee.* The two higher elevation experimental populations are *P. jordani* in the Smoky Mountains and *P. metcalfi* in the Balsam Mountains. Despite the confusing changes in taxonomy and some complex genetic interactions among these species (Highton and Peabody 2000), there is no doubt that all of these salamanders are very similar to each other morphologically and ecologically, with the lower elevation species generally being slightly larger and more robust than those at higher elevations.

Hairston predicted that competition should be stronger in the narrower zone of overlap, and this prediction was

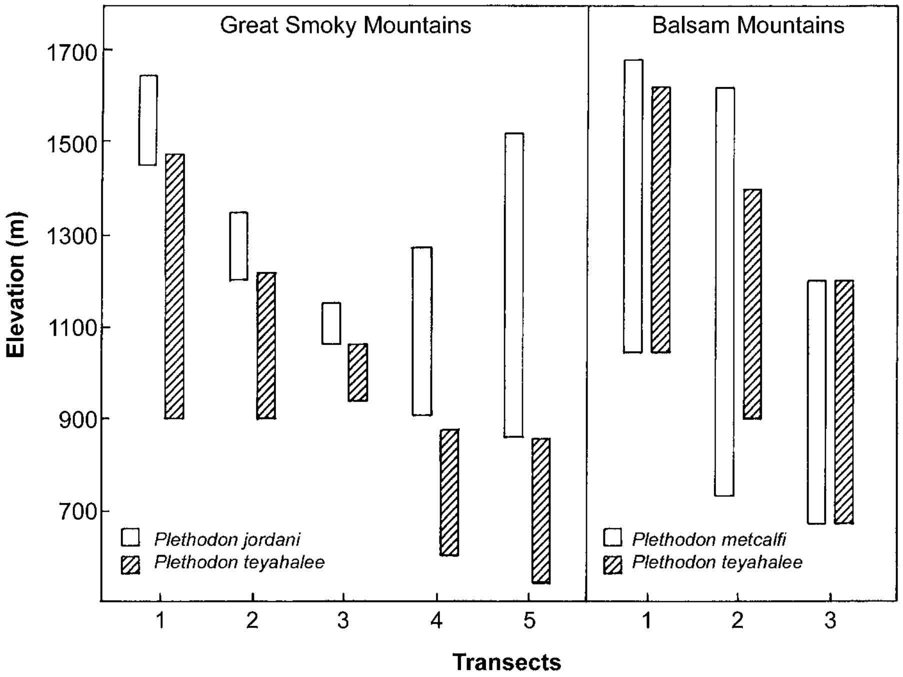

Fig. 15.12. Vertical distribution of members of the *Plethodon jordani* and *P. glutinosus* complexes on five transects in the Great Smoky Mountains and three transects in the Balsam Mountains. The distribution of *P. teyahalee* extends to lower elevations than those included in the transects in both mountain ranges. After Hairston (1980b).

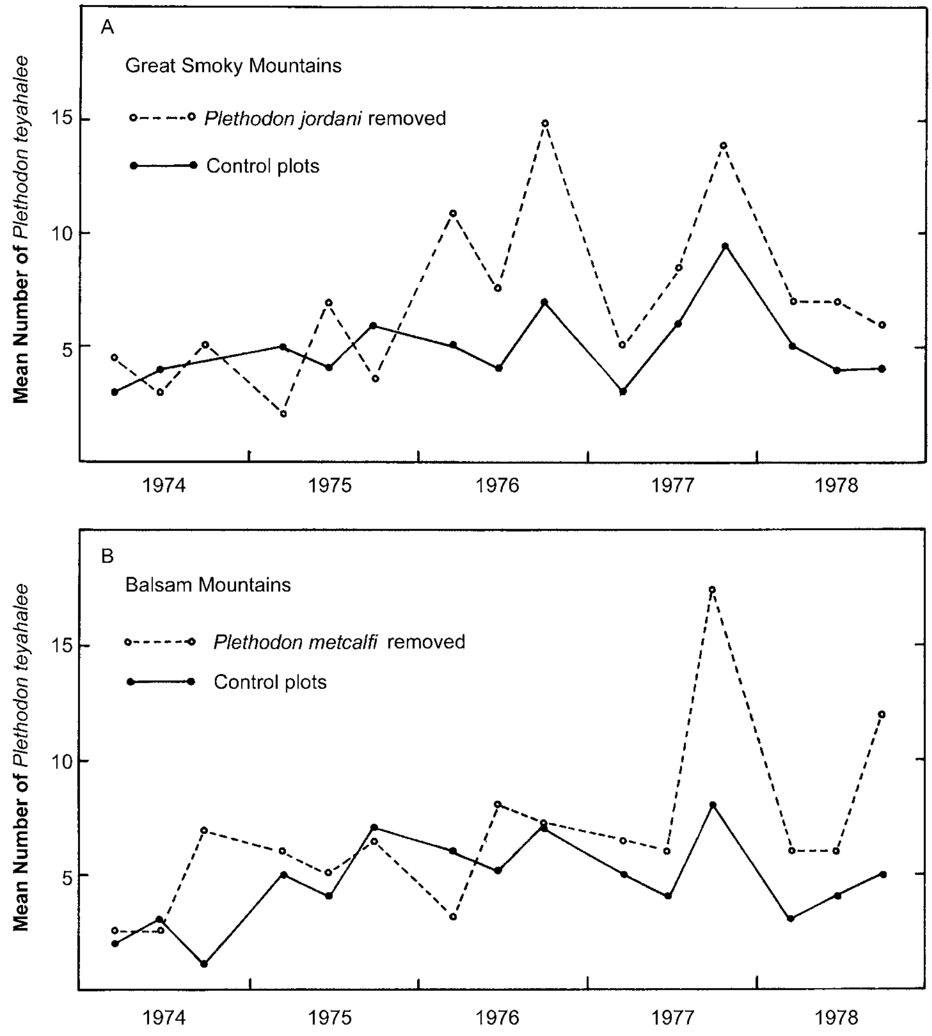

Fig. 15.13. Effect of removal of members of the *Plethodon jordani* complex (high-elevation populations) on the number of *P. teyahalee* in plots established in areas of altitudinal overlap. (A) Removal of *P. jordani* from plots in the Great Smoky Mountains produced a strong effect on the population of *P. teyahalee*. (B) Removal of *P. metcalfi* from plots in the Balsam Mountains produced a weaker effect on populations of *P. teyahalee*. After Hairston (1980b).

confirmed. In the Smoky Mountains, removal of *P. jordani* resulted in a significant increase in the abundance of *P. teyahalee* (fig. 15.13 A). In the Balsam Mountains, removal of *P. metcalfi* produced a similar effect, but it was less pronounced and was not evident until several years into the study (fig. 15.13 B). Reciprocal removals of *P. teyahalee* did not increase the abundance of *P. jordani* or *P. metcalfi*, but there was an increase in the proportion of juveniles. Since the unspotted salamanders were numerically dominant when the experiment began, removal of those species would be expected to have a greater effect than removal of *P. teyahalee.* However, the per capita effect of the larger, more robust species, *P. teyahalee,* on *P. jordani* and *P. metcalfi* appeared to be greater than the reverse effect. Several other species of salamanders were present in the experimental plots, but removal of the large *Plethodon* did not affect them, suggesting that not all of the salamanders in the community are competing for the same resources (Hairston 1981, 1984).

Competition between *P. jordani* and *P. teyahalee* is more intense in the Smoky Mountains than is competition between *P. metcalfi* and *P. teyahalee* in the Balsam Mountains. Hairston (1973) had hypothesized that selection may have favored either an increase in the competitive ability of both species in the Smokies, or niche partitioning with a subsequent reduction in competition in the Balsams. These hypotheses were tested by transplanting members of the *P. jordani* complex between the two mountain ranges. This was easily done, because the two species have distinct color patterns. When *P. metcalfi* from the area of lower competition were substituted for *P. jordani* in the Smoky Mountains, the abundance of *P. teyahalee* increased over a period of several years (Hairston 1980a). In contrast, when *P. jordani* from the high-competition population were introduced into the Balsam Mountains, the abundance of *P. teyahalee* decreased (Hairston 1983a). Hence the competitive ability of Smoky Mountain *P. jordani* appears to be greater than that of Balsam Mountains *P. metcalfi* in competition with *P. teyahalee* (Hairston, Nishikawa, and Stenhouse 1987).

These experiments provide strong evidence that these pairs of large *Plethodon* compete for similar resources, but they do not directly assess the mechanism of competitive exclusion. This problem was addressed in additional work on interspecific aggressive behavior by Nishikawa (1985, 1987; (see also Hairston, Nishikawa, and Stenhouse 1987). Nishikawa compared the aggressive behavior of both species in intra- and interspecific encounters in the laboratory, using individuals from both the Balsam and Smoky Mountains.

Differences in the intensity of interspecific aggression paralleled the differences in intensity of competition reported by Hairston. *Plethodon teyahalee* from the Smokies were more aggressive toward heterospecifics than were those from the Balsams (fig. 15.14). There was almost no difference between areas in the per capita effect of *P. jordani* or *P. metcalfi* on the *P. teyahalee* population, and there was no significant difference between *P. jordani* and *P. metcalfi* in the intensity of interspecific aggressive behavior. However, *P. metcalfi* from the Balsams, where interspecific competition is less severe, were more aggressive toward conspecifics than heterospecifics, whereas *P. jordani* from the Smokies showed equal levels of aggression toward conspecifics and heterospecifics (Nishikawa 1987). These experiments provide strong evidence that natural selection has resulted in high levels of interspecific aggressive behavior in both species in the Smoky Mountains. Nishikawa further suggested that because the higher elevation species always are the most common species in zones of overlap, the survival and reproduction of individuals are more likely to be affected by intra- than by interspecific competition. For *P. teyahalee,* interspecific competition probably is more important, and selection for aggressiveness against *P. jordani* in the Smokies may have resulted in greater aggressiveness toward conspecifics as well.

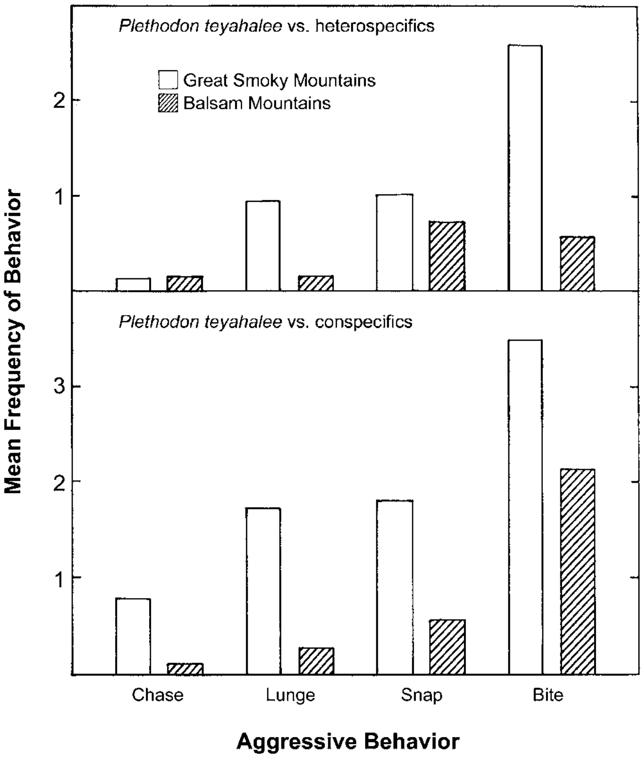

Fig. 15.14. Average frequency of aggressive behavior patterns exhibited by *Plethodon teyahalee* in encounters with sympatric conspecifics and heterospecifics. Heterospecific salamanders were *P. jordani* in the Great Smoky Mountains and *P. metcalfi* in the Balsam Mountains. After Nishikawa (1985).

An interesting twist to this story was provided by a study at Mountain Lake Biological Station in Virginia (Rissler, Barber, and Wilbur 2000). *Plethodon glutinosus* is native to this region, but *P. montanus* was introduced to the station in the 1930s after a class field trip to a nearby area (Mt. Rogers) where they occur (this is called *P. jordani* in the paper). In a field survey, Rissler, Barber, and Wilbur (2000) found little evidence of microhabitat partitioning or other indications of competitive interactions between these species. In field enclosures, there were slight differences in foraging behavior of *P. glutinosus* in the presence of *P. montanus,* but neither species showed any effect of interspecific interactions on body condition. In the laboratory, neither species showed much aggression toward conspecifics or heterospecifics. Unfortunately, interspecific interactions have not been studied in the locality from which the introduced *P. montanus* originated (where the *P. glutinosus* is replaced by *P. cylindraceus;* Highton and Peabody 2000), so the level of competition there is unknown. The lack of overt aggression between these species or between conspecifics is perhaps unusual, but Nishikawa's work has shown that levels of aggressiveness can vary among populations. Interpretation of the results is complicated by evidence of hybridization or genetic introgression between the two species at Mountain Lake, although Rissler, Barber, and Wilbur (2000) excluded individuals with apparent hybrid morphology from their experiments. These species apparently do not hybridize where their ranges naturally overlap (Highton and Peabody 2000), but it is possible that the small numbers of *P. montanus* originally released at Mountain Lake forced these individuals to seek matings with the more abundant native species.

Intra- and interspecific aggression and territoriality have been reported in other large species of *Plethodon* (see chapter 8) as well, but in most cases, the species are not as clearly separated spatially as the salamanders in the Balsam and Great Smoky Mountains. For example, in the Ouachita Mountains of Arkansas, *P. ouachitae* can be found in the same habitats as *P. albagula,* but the former species tends to be more abundant. *Plethodon ouachitae* is extremely aggressive toward both conspecifics and *P. albagula,* and it is able to displace the latter species from prime retreat sites (Anthony and Wicknick 1993; Anthony, Wicknick, and Jaeger 1997). Similar interactions occur between *P. glutinosus* and a smaller species, *P. kentucki,* in Kentucky (Marvin 1998a, b). Again, these two species share the same habitat. Both tend to be aggressive and defend retreat sites against conspecifics, but the larger *P. glutinosus* can exclude *P. kentucki* from choice retreat sites. In the Pigeon Mountains of Georgia, *P. glutinosus* is widespread in forested habitats, whereas a similar species, *P. petraeus,* is largely restricted to drier rock outcrops. Both species are aggressively territorial, but *P. glutinosus* is competitively superior to *P. petraeus* and probably limits the latter species to drier patches of habitat (Marshall, Camp, and Jaeger 2004).

Habitat Separation in Small *Plethodon*

The distributional interactions of small species of *Plethodon* in the southern Appalachians are extremely complex, and taxonomic relationships are confusing as well (Highton 1971). Several species appear to be relict populations restricted to very limited habitats, while others are much more widespread. All of the species are morphologically and ecologically similar, and it is rare for more than two species of similar size to coexist in the same habitat. Species may occasionally hybridize in sympatry, but usually they maintain their genetic identity. The nonoverlapping ranges of some of these small species suggest a role for competition in determining their geographical distributions. For example, Highton (1971) suggested that small, isolated populations of species such as *P. hubrichti, P. richmondi, P. shenandoah,* and *P. welleri* have been prevented from extending their ranges because of competition from the more widespread red-backed salamander (*P. cinereus*).

The interactions between *P. cinereus* and *P. shenandoah* on a microgeographic scale were studied by Jaeger (1970, 1971a, b, 1972, 1974, 1980a) in Shenandoah National Park, Virginia. *Plethodon cinereus* is widespread in forested habitats throughout the park, whereas *P. shenandoah* is restricted to talus slopes consisting of a mixture of loose rocks and patches of soil (fig. 15.15). Jaeger (1971a) placed individuals of the two species in field enclosures in three different types of talus and deep soil in both single-species and mixed-species groups. Neither species was able to survive in bare rocks. *Plethodon shenandoah* had higher survivorship than *P. cinereus* in relatively dry talus, either in single-species or mixed-species groups. Both species did well alone in talus consisting of rocks imbedded in shallow soil and in deep soil, but the presence of *P. cinereus* reduced the survivorship of *P. shenandoah* in both habitats.

Subsequent laboratory experiments revealed that both species preferred soil to rocky substrates, and moist over dry habitats, but *P. shenandoah* had a higher physiological tolerance for dry conditions (Jaeger 1971b). Thus, *P. shenandoah* appears to be excluded from choice habitats by competition from *P. cinereus,* but *P. cinereus* is unable to invade the talus habitat because of physiological intolerance. Because *P. shen-*

andoah is restricted to relatively poor-quality habitats, its status is precarious, and at least one local deme apparently went extinct during an extended drought (Jaeger 1980a). The microgeographic distributions of these two species are the result of complex interactions between the physiological ecology of each species and interspecific competition.

Exploitative competition for food does not appear to explain the relative success of these species. Instead it appears that interference competition in the form of interspecific territoriality is the principal mechanism of competitive exclusion (Jaeger 1974; Jaeger and Gergits 1979; Wrobel, Gergits, and Jaeger 1980). This hypothesis was tested experimentally by Griffis and Jaeger (1998). They removed individuals of *P. cinereus* from underneath rocks at the edge of a *P. shenandoah* population and left other individuals in place in their retreat sites. Individuals of *P. shenandoah* were much more likely to invade rocks that were not inhabited by *P. cinereus* than those that were inhabited. A somewhat surprising result of the study was that *P. cinereus* was no more aggressive toward territorial intruders than was *P. shenandoah*. This partially contradicted earlier work by Wrobel, Gergits, and Jaeger (1980), which had found evidence of greater aggressiveness by *P. cinereus*. Hence, the behavioral mechanisms that result in competitive exclusion of *P. shenandoah* by *P. cinereus* still are not fully understood. *Plethodon cinereus* was similarly found to be more aggressive than *P. hoffmani,* which has a much more limited distribution (Jaeger, Prosen, and Adams 2002).

Red-backed salamanders are aggressive toward several other species of salamander as well, but in these cases, interspecific competition sometimes results in the exclusion of one species from individual retreat sites, but does not result in separation of species into discrete habitat patches (see chapter 8). For example, adults of *P. cinereus* can defend territories against juveniles of the much larger species, *P. glutinosus,* but not against adults of that species (Lancaster and Jaeger 1995; Jaeger et al. 1998; Price et al. 2002). *Plethodon cinereus* also is aggressive toward *Eurycea cirrigera* (Jaeger, Gabor, and Wilbur 1998) and *E. bislineata* (Joseph Markow, personal communication), both of which tend to be relatively nonaggressive. Possibly red-backed salamanders could influence the choice of retreat sites by *Eurycea,* but this has not been demonstrated conclusively. On the other hand, red-backed salamanders can be displaced from streamside habitats and small seeps by various species of *Desmognathus,* which tend to be even more aggressive (E. Smith and Pough 1994; Fauth 1998; Jaeger, Gabor, and Wilbur 1998; Grover 2000; Grover and Wilbur 2002).

Microhabitat Separation in *Desmognathus*

Streambank salamanders of the genus *Desmognathus* exhibit a complex array of ecological interactions. Communities of these salamanders consist of as many as five sympatric species in the mountains of North Carolina and southwestern Virginia (Hairston 1949, 1980c; Organ 1961c), but only two or three species farther north (Krzysik 1979) or south (Means 1975). In areas where several species occur together, they often show horizontal separation of microhabitats. Large species are the most aquatic, medium-sized species are semiaquatic, and the smallest species are terrestrial (fig. 15.16). In the mountains of Virginia, for example, the largest species, *D. quadramaculatus,* is restricted to streams and streambanks. *Desmognathus monticola,* a slightly smaller species, is found on streambanks and in seepage areas, while *D. fuscus* is found in the headwaters of streams and in seepage areas. *Desmognathus orestes* is much more terrestrial, being found mainly on the forest floor, while the smallest species, *D. wrighti,* is seldom found near streams and often climbs on forest plants to feed (Organ 1961c). Similar habitat segregation has been reported in other regions (fig. 15.17; Hairston 1949, 1980c; Krzysik 1979), with *D. ocoee* or *D. ochrophaeus* taking the place of *D. orestes* (these species were all considered to be *D. ochrophaeus* when the original ecological studies were done; see Tilley and Mahoney 1996; Petranka 1998).

This gradient from aquatic to terrestrial habits is paralleled by differences in life-history strategies. Since clutch size is positively correlated with body size (see chapter 10), there is a general trend from large to small clutches that parallels the gradient from aquatic to terrestrial life (Organ 1961c; Tilley 1968). While all species lay their eggs in relatively wet sites, the terrestrial species are more likely to lay eggs in seepage areas than in streams. All of the large and medium-sized species have free-living aquatic larvae, but the two smallest species, *D. wrighti* and *D. aeneus,* lack an aquatic larval stage (Organ 1961b, c; J. R. Harrison 1967). The placement of eggs at greater distances from streams and a shorter larval period in the smaller species is paralleled by higher survivorship early in life.

This gradient from aquatic to terrestrial life traditionally has been thought to reflect an evolutionary progression from an ancestral aquatic life history to a more derived terrestrial life history (Hairston 1949, 1987; Organ 1961c). Indeed, this apparent evolutionary progression toward terrestrial life was used by Dunn (1926c) to illustrate a general trend in the evolution of terrestrial habits in the family Plethodontidae. Tilley and Bernardo (1993) argued that in the absence of a rigorous phylogenetic analysis of the subfamily Desmognathinae, it is impossible to determine whether the large aquatic species are most like the ancestor of all *Desmognathus*. Subsequent phylogenetic studies by Titus and Larson (1996) and Chippindale et al. (2004) suggested that the small, fully terrestrial species *D. wrighti* belongs to a lineage that branched off early in the evolution of the genus, while the larger semiaquatic and aquatic species are not basal species, and in fact, are derived from within a clade of

direct-developing terrestrial salamanders. These studies also indicated that the other very small, highly terrestrial species, *D. aeneus,* also represents an early line of desmognathine evolution that may or may not be closely related to *D. wrighti.* One controversial implication of these studies is that most species of *Desmognathus* appear to have secondarily reevolved an aquatic reproductive mode with aquatic larvae from a direct-developing ancestor. This view of desmognathine phylogeny would alter some interpretations of the evolutionary responses of these species to competition or predation (e.g., Hairston 1987), but does not affect interpretation of experiments designed to unravel current ecological interactions among the species.

The ecological separation of these species has been explained by a number of competing hypotheses. Originally, Hairston (1949) attributed their horizontal distribution to interspecific competition, but later suggested that the smaller species were excluded from the vicinity of streams by predators, including fish and larger species of salamanders (Hairston 1980c). Tilley (1968) also supported the view that predation by the larger, more aquatic species, such as *D. quadramaculatus,* tends to exclude smaller species from the most aquatic habitats. Alternatively, the ecological segregation could be the result of habitat preferences that are independent of the presence of other species, although it is difficult to rule out the possibility that competition in the past has favored divergence in the use of microhabitats.

Hairston (1986) tested the predation hypothesis in the Nantahala Mountains of North Carolina. The streamside salamander community included *Desmognathus quadramaculatus, D. monticola,* and *D. ocoee,* with *D. aeneus* living in adjacent terrestrial habitats. Hairston conducted a series of experiments involving removal of either *D. monticola* or *D. ocoee* from plots and measuring the effects of the removals on each other and on the other species. Although it was not possible to completely remove populations from the plots, a sufficient number was removed to have a measurable effect on the other species. Removal of *D. monticola* resulted in a significant increase in the population of *D. ocoee*. This result would be expected if *D. monticola* were either an important predator or competitor of *D. ocoee*. However, the reciprocal experiment of removing *D. ocoee* was interpreted as support for the predation hypothesis. The number of *D. monticola* decreased on the experimental plots, suggesting that *D. ocoee* is an important source of food for this species. There also was evidence, but less conclusive, of a reduction in the number of *D. quadramaculatus* when *D. ocoee* were removed. The more terrestrial *D. aeneus* was not strongly affected by either removal experiment.

The removal experiments also resulted in some shifting in the horizontal distribution of species perpendicular to the stream. When *D. monticola* were removed, *D. ocoee* showed an initial shift toward the stream, perhaps because of reduced predation on this species. However, in subsequent years, *D. ocoee* moved back toward the land. Hairston attributed this to replacement of the missing *D. monticola* by *D. quadramaculatus* and subsequent predation by this species on *D. ocoee*. There was a tendency for *D. quadramaculatus* to shift landward when *D. monticola* was removed, but the pattern was not consistent in all months. Hairston suggested that both predation by the larger *D. quadramaculatus* and competition are important interactions between this species and *D. monticola,* but he provided little direct evidence of predation.

Several other workers have investigated the effect of interspecific interactions on the use of microhabitats by various species of *Desmognathus*. Both laboratory and field experiments have shown that species of *Desmognathus* exhibit preferences for substrate texture, substrate moisture, and size of cover objects that are partly independent of the presence of the other species (Krzysik and Miller 1979; Keen 1982; Carr and Taylor 1985; Southerland 1986a; Grover 2000). For example, *D. monticola* and *D. quadramaculatus* usually are segregated by microhabitat because of the affinity of *D. quadramaculatus* for a stream habitat (Keen 1985). Nevertheless, the larger species may inhibit diurnal activity in *D. monticola* (Carr and Taylor 1985) or prey on juveniles of that species (Southerland 1986b), thereby causing *D. monticola* to shift toward the stream bank. Grover (2000) reported that *D. monticola, D. fuscus,* and *Eurycea cirrigera* were found farther from water at two streams where *D. quadramaculatus* was present than at two where this species was absent. This was taken as evidence that predation by *D. quadramaculatus* resulted in smaller species avoiding microhabitats close to streams, but Grover did not report any observations of actual predation. In experimental enclosures, the presence of *D. quadramaculatus* always resulted in *D. monticola* shifting to more terrestrial microhabitats, where food availability appears to be inferior to that in the aquatic habitat (Rissler, Wilbur, and Taylor 2004). There also is evidence for an evolutionary response to the presence of *D. quadramaculatus* by *D. monticola*. Individuals of *D. monticola* from areas where *D. quadramaculatus* occurs were more terrestrial than those from areas without *D. quadramaculatus,* even in the absence of the latter species.

In some communities, the presence of *D. monticola* can restrict access of *D. fuscus* to streambank microhabitats (Krzysik 1979). This has been attributed mainly to interference competition rather than predation because of the similarity in size of the two species (Keen 1982; Keen and Sharp 1984). Species of *Desmognathus* are known to aggressively defend retreat sites against both conspecifics and heterospecifics, so larger species would be expected to displace smaller ones even if predation is rare (Keen and Sharp 1984; Keen and Reed 1985; Jaeger 1988; Colley, Keen, and Reed 1989; Camp and Lee 1996; see also chapter 9).

Camp (1997) argued that the role of *D. quadramaculatus* as a major predator on smaller species of salamanders has been overstated. He used data on stomach contents from his own work and previously published studies to show that metamorphosed salamanders rarely, if ever, appear in the diet of this species, which eats mostly invertebrates. He also did not find any evidence that *D. monticola,* the next largest species in many streamside communities, feeds regularly on smaller salamanders. In laboratory experiments, Formanowicz and Brodie (1993) found that *D. quadramaculatus* is less effective in capturing salamanders than is another plethodontid that often lives in the same habitats, *Gyrinophilus porphyriticus*. The latter could be an important predator on small species of *Desmognathus,* but its impact on habitat selection by desmognathines has not been studied. Even if predation on adults of smaller species is rare, the threat of predation still could be sufficient to cause smaller species to avoid habitats where the larger species are present. With the data currently available, it is impossible to distinguish between the roles of predation and interference competition in the spatial structuring of *Desmognathus* communities. Another threat to small species of *Desmognathus* may come from the larvae of both *D. quadramaculatus* and *G. porphyriticus,* both of which reach a very large size and prey on the larvae of other plethodontids (Resetarits 1991; Beachy

1993b, 1994, 1997b; Gustafson 1993, 1994). Predation on larvae could affect the relative abundance of smaller species in the community, but is unlikely to have any impact on the spatial distribution of adults.

Other Terrestrial Salamander Communities

The ecological relationships of other assemblages of terrestrial salamanders, particularly those found in the tropics, are poorly understood (Hairston 1987). The Neotropical plethodontids were once considered to be a relatively minor and uninteresting group, but they are now known to include half of the world's salamander species (D. Wake 1970, 1987; Garcia-Paris et al. 2000). They exhibit a wide range of morphological and ecological adaptations that have scarcely been investigated (D. Wake and Lynch 1976). Of particular interest are microgeographic patterns of distribution along elevation gradients. In the mountains of Guatemala, most species exhibit very narrow vertical distributions (fig. 15.18), so sympatric species often are separated from one another (K. Schmidt 1936; D. Wake and Lynch 1976; Elias 1984). In some cases, this may reflect major changes in vegetation and climate, such as that occurring at the transition from cloud forest to high-elevation woodlands. In other cases, the boundaries between species do not correspond to obvious changes in vegetation or climate, suggesting the possibility of competitive interactions similar to those described for species of *Plethodon* in the Appalachians. Those species that do overlap spatially tend to differ in their use of microhabitats, but the mechanisms responsible for this ecological separation are completely unknown (D. Wake and Lynch 1976).

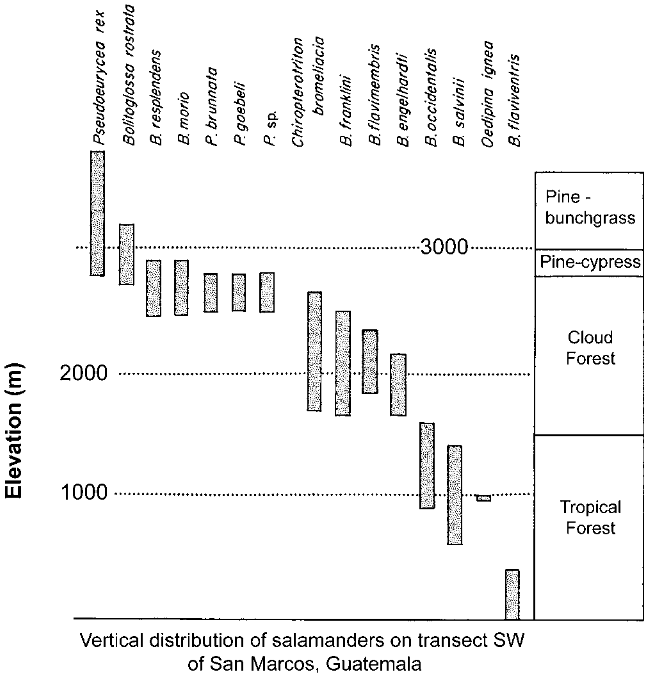

Fig. 15.18. Altitudinal distribution of bolitoglossine salamanders along a vertical transect in Guatemala. Many species are restricted to certain vegetation zones and tend to have narrow altitudinal distributions. After D. Wake and Lynch (1976).

Nonplethodontid salamanders have received relatively little attention from community ecologists, except for studies of larval communities (see the following discussion). In North America, adults of several species of *Ambystoma* sometimes occupy the same pond during the breeding season, but they probably do little feeding at that time and therefore are unlikely to compete with one another for food. There is evidence for minor differences in microhabitat selection among adults of several species of *Ambystoma* in Illinois (Parmelee 1993), but there has not been any experimental work to determine whether these differences are due to competitive interactions among the species. Aggressive interactions have been observed between juveniles of different species of *Ambystoma* in the laboratory (Walls 1990), but whether such aggression mediates use of microhabitats in the field is unknown. Most of these species are underground outside of the breeding season, so direct interaction among species is likely to be rare.

Community Ecology of Pond-Dwelling Adult Salamanders

The importance of ecological interactions among adults of pond-dwelling salamanders is poorly understood. Adults of many salamanders, such as the various species of *Ambystoma,* are present in ponds only during the breeding season, when they probably do not feed, and are terrestrial for the rest of the year, so interaction in ponds probably are minimal. The exceptions are those species that remain in ponds as paedomorphic adults (see chapter 13). Because of their large size, paedomorphic *Ambystoma* are potential predators of other salamander larvae and tadpoles (Morin 1995; Fauth 1999b). The adults of other aquatic salamanders, such as sirens, are potential competitors of paedomorphic *Ambystoma,* and they may prey on them as well (Resetarits and Fauth 1998; Fauth 1999a, b). Adult newts may interact with *Ambystoma* larvae either as competitors or predators (Brophy 1980; Morin 1983b), while newts and sirens can be either predators or competitors with each other (Fauth, Resetarits, and Wilbur 1990; Fauth and Resetarits 1991). Snodgrass et al. (1999) reported that *Siren intermedia* tends to be absent from ponds inhabited by the larger *S. lactertina,* and the latter seldom co-occurs with *Amphiuma means.* These species could interact in either the larval or adult stage as predators, competitors, or both, but the precise nature of the interactions among these species is not known.

Several experimental studies have examined ecological interactions among some of these pond-dwelling species. On the Coastal Plain of North Carolina, red-spotted newts (*Notophthalmus viridescens*) are considered keystone predators in temporary ponds, because they affect the species composition and structure of anuran tadpole communities. In some ponds, lesser sirens (*Siren intermedia*) may play a similar role. Fauth and Resetarits (1991) used experimental ponds (cattle tanks) to investigate the effect of these two species on each other. They housed newts at different densities (two or four adults per pond) with or without a single adult siren. Sirens can eat newt larvae, but they do not eat adults, which are highly toxic. Growth rates of newts were higher at low density than at high density, both with and without sirens, indicating that strong intraspecific competition was occurring in the ponds. Growth rates of newts were even lower in the presence of one siren, especially for those at high density. Newt reproduction also was affected by the presence of sirens, mainly through predation on newt larvae. The newts had no detectable effect on the sirens, but the experiment provided a relatively weak test for such effects because only one siren was present in each pond.

Fauth (1999b) later examined ecological interactions between lesser sirens and paedomorphic adults of *Ambystoma talpoideum,* which often live in the same ponds. Neither of these species is toxic or distasteful, so either potentially could be a competitor or predator of the other, depending on body size relationships. In fact, sirens had a much greater effect on *Ambystoma* than the latter had on sirens. Cattle tanks were set up with zero, four, or eight adult *Ambystoma* per tank and either one siren or no sirens. The presence of one siren significantly reduced the growth rates of adult *Ambystoma,* presumably because of competition. The sirens also virtually eliminated larval *Ambystoma* from the tanks, so predation is important as well. As in the experiment with newts, there was no detectable effect of the treatments on growth or survival of sirens, but again, with only a single siren in each tank, this test is relatively weak. It also is possible that in natural ponds, large *Ambystoma* prey on larval sirens, but this has not been studied. In the field, there was evidence that *Ambystoma* avoided sirens, suggesting that they may be important predators on *Ambystoma.* Nevertheless, the effect is not sufficiently strong to exclude *Ambystoma* from ponds with sirens; in fact, the distribution of the two species in natural ponds was independent.

In Europe, several species of newts in the genus *Triturus* sometimes co-occur in ponds. Competitive interactions have not been studied experimentally, but there have been several descriptive and quantitative analyses of food habits and niche overlap in species sharing the same habitats. Often these species are very similar in size and overall morphology (J. D. Harrison, Gittins, and Slater 1984), suggesting the potential for interspecific competition. In general, results for these species are similar to those for terrestrial salamanders. The newts feed on a broad assortment of invertebrates and show little evidence of taxonomic selectivity (Avery 1968; Griffiths 1986). There often is broad overlap in prey taxa among coexisting species (Avery 1968; Dolmen and Koksvik 1983; Griffiths 1986). The newts feed selectively on larger prey when it is available (Ranta and Nuutinen 1985), as do North American *Notophthalmus* (Attar and Maly 1980; Morin, Wilbur, and Harris 1983). Larger species generally eat larger prey (Avery 1968; Dolmen and Koksvik 1983), leading to some resource partitioning along a prey-size axis, but in some cases, the diet of large species encompasses most of the diet of smaller species (Joly and Giacoma 1992). In Norway and Wales, the relatively large species *Triturus cristatus* tends to feed mainly on the bottom of ponds in deep water, while *T. vulgaris,* a smaller species, spends more time feeding in the water column. This microhabitat partitioning has been interpreted as a mechanism to avoid competition (Dolmen 1983b; Griffiths and Mylotte 1987), but in some ponds, food may be so abundant that competition does not occur (Griffiths 1986). Newt species are not always consistent in their use of microhabitats across their ranges, however. For example, both *T. vulgaris* and *T. helviticus* were primarily bottom dwellers in a pond in Wales and ate very similar prey (Griffiths 1987). In Italy, *T. carnifex,* a large species that is closely related to *T. cristatus,* fed mostly on prey that fell onto the water surface, while even the smallest species, *T. italicus,* consumed prey from the bottom of a pond (Joly and Giacoma 1992).

Amphibian Larval Communities: General Characteristics

Because of their double life in the water and on land, most aquatic-breeding amphibians are members of two very distinct ecological communities at different times in their lives. Although some amphibians remain in the water after metamorphosis, most adult amphibians have few interactions with larval stages except as predators (see chapter 14). However, since the size of adult populations of many species may be largely controlled by recruitment of metamorphosing individuals into the population, knowledge of interspecific interactions at the larval stage is essential for a complete understanding of the structure and organization of amphibian communities (Wilbur 1980, 1984; Hellriegel 2000; Skelly 2001). There is now a large literature on competitive interactions and predator-prey relationships among species of amphibian larvae. In contrast to the largely descriptive literature on the community ecology of adult amphibians, especially anurans, the literature on larval communities is heavily experimental, in part because larvae are suitable for both laboratory and field manipulation.

The ecology of larval amphibians differs from that of adult amphibians in several ways. Perhaps most important is the fact that the initial composition of a larval assemblage is not governed solely by interactions among the larvae themselves, but also is a result of choice of oviposition sites by adults (Alford 1999; Skelly 2001). In general, different species of amphibians probably select breeding sites independently, based mostly on physical characteristics of the habitat (see chapter 10), although some amphibians will avoid breeding sites where predators are present (see chapter 14). This means that the composition of the larval community depends on which species breed at a particular site, and this may change from year to year. The timing of breeding by different species may vary as well, as each species responds slightly differently to environmental cues such as temperature and rainfall. Experimental studies have shown that temporal differences in the introduction of various species can have a large effect on interactions among species (see the following). Another major difference between the community ecology of larval and adult amphibians is that larvae are not reproductive animals. Nevertheless, the outcome of competitive interactions among larvae in a pond or stream can affect the timing and success of reproduction by adults, because larval interactions affect the size and competitive ability of metamorphosed adults. The initial number of larvae of each species present in the pond is fixed by the number of eggs laid by females each year, or by the experimenter. Since all populations are expected to suffer mortality, the experimenter can monitor rates at which a population declines, but not population growth rates. Studies of larval competition usually rely on measures of performance thought to be reliable indicators of individual fitness, including (1) survival to metamorphosis, (2) length of the larval period, (3) individual growth rates, and (4) size at metamorphosis.

Reproductive Input and Output in Pond Communities

In natural ponds, the number of breeding adults and the number of eggs laid by each species often are poor predictors of the final composition of the larval community, especially in temporary ponds (Heyer 1976, 1979a; Seale 1980; Pechmann et al. 1989; Semlitsch et al. 1996). Some species lay thousands of eggs in a pond, but contribute very few metamorphosing young to the next generation; others lay fewer eggs, but have much greater reproductive success. This indicates that processes that occur after eggs have been laid are important in determining the relative reproductive success of different species in the community. These processes can include responses of individual species to physical factors such as temperature and pond drying, as well as biological interactions such as competition and predation. The number of metamorphosing juveniles emerging from a breeding site in any given year may or may not be a good predictor of future adult population size. Adult amphibians typically return to the same pond year after year, although limited migration among sites also occurs (see chapter 6). Juveniles, on the other hand, either return to their natal ponds or disperse to new ponds. In ponds that seldom produce juveniles, populations may be maintained by occasional migration of juveniles from more productive ponds nearby (Sjögren 1991a; Sinsch 1992b; Sinsch and Seidel 1995; Skelly 2001).

The best example of variability in amphibian population dynamics in temporary ponds is a long-term study conducted at Rainbow Bay, a Carolina bay, on the Coastal Plain of South Carolina (Semlitsch et al. 1996). Investigators enclosed the entire pond with a drift fence that trapped adult amphibians as they migrated into and out of the pond during the breeding season, as well as juveniles that left the pond after metamorphosis. The population dynamics of all species using the pond were monitored for 16 years, providing the longest record for any pond in the world used by a large number of amphibian species. A striking result of this study is that most species experienced only a few good reproductive years in the 16 years of the study, and several species failed to reproduce successfully in most years of the study (fig. 15.19).

Much of this variation was due to variation in hydroperiod, the number of days that the pond held water. Four years were drought years in which the pond held water for less than 100 days. This resulted in almost complete reproductive failure for all amphibian species. In other years, the hydroperiod was longer, but not long enough to allow species with relatively long larval periods to reach metamorphosis (e.g., *Rana sphenocephala* and *R. clamitans*). Species with short larval periods, however, did well in those years (e.g., *Pseudacris crucifer* and *P. ornata*). There was evidence for interspecific competition as well. For example, *P. ornata* did relatively poorly when *Rana clamitans* tadpoles were abundant, but did well when *R. clamitans* tadpoles were scarce. Some species, such as *P. crucifer,* showed evidence of density-dependent intraspecific competition as well, while others, such as *R. clamitans,* seemed to do better at high larval densities.

Salamander larvae in this system are predators on some species of tadpoles, and two species, *R. sphenocephala* and *R. clamitans,* did poorly when initial densities of salamander larvae were high. Two species, *Scaphiopus holbrookii* and *Gastrophryne carolinensis,* had only one good reproductive year out of 16. These species breed opportunistically after heavy rains, especially in the summer. In each case, they were successful when the pond dried and then subsequently was refilled by summer rains. The initial drying eliminated other species that were potential predators or competitors of these species. The poor reproductive success of these anurans is especially striking because breeding adults appeared at the pond in most years of the study (fig. 15.19). Overall, the results of this study indicated that the relative

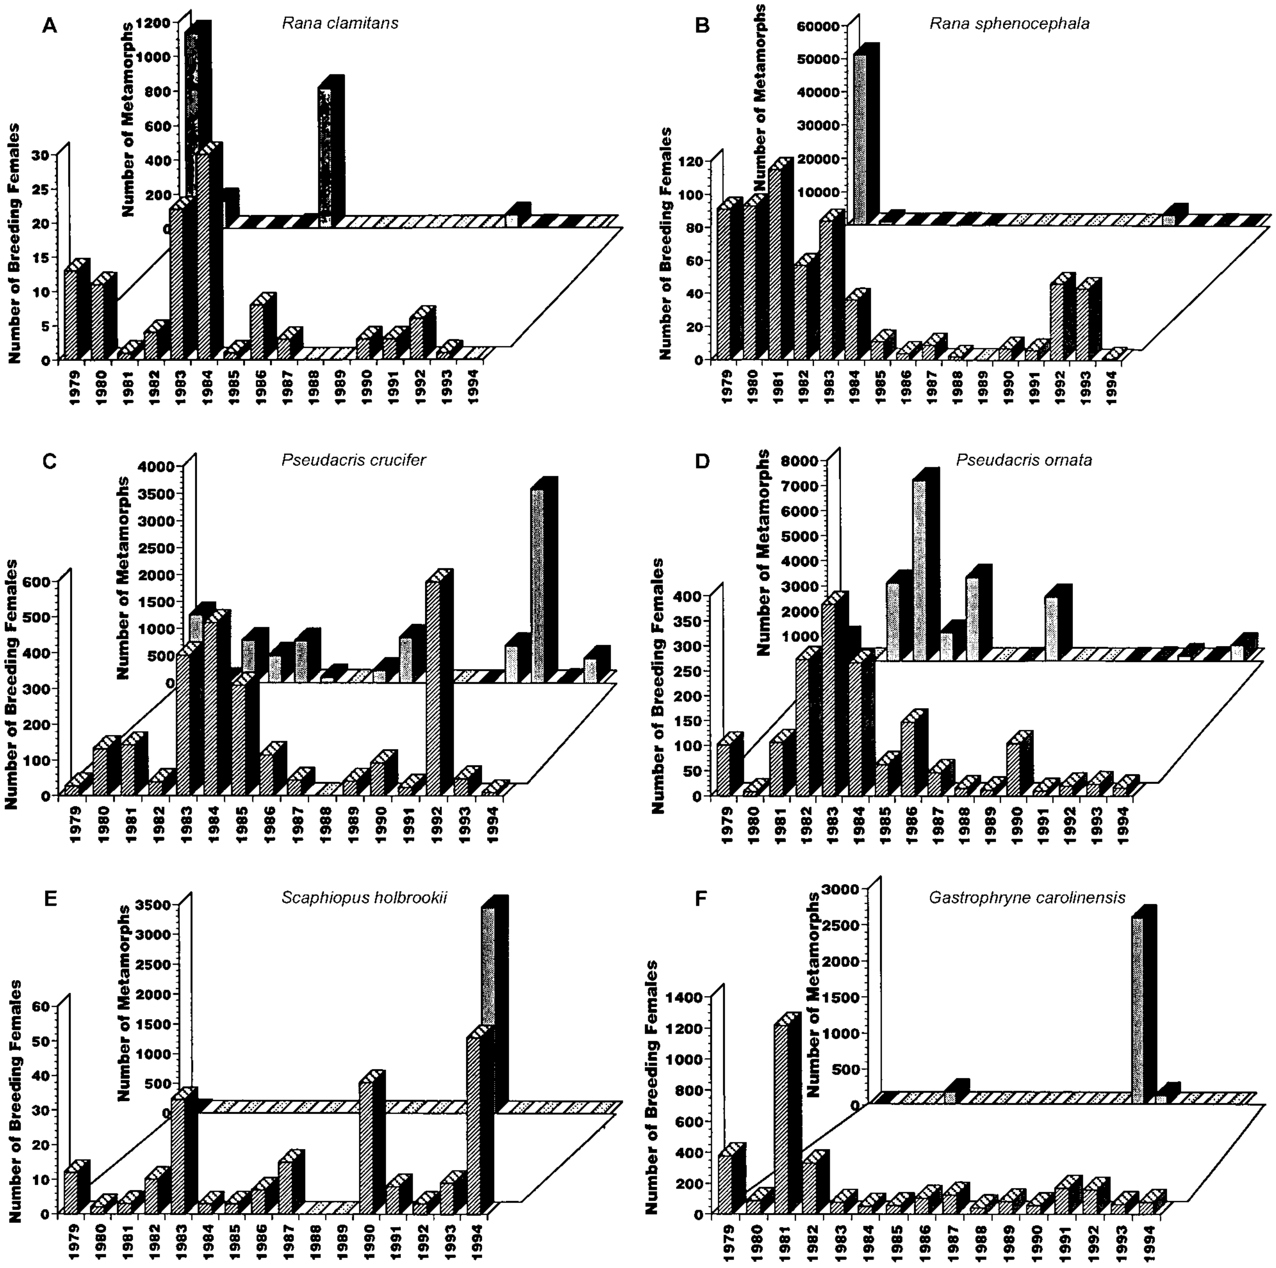

Fig. 15.19. Variation in number of breeding females and metamorphosing juveniles for six species of anurans for 16 years at Rainbow Bay, South Carolina, a Carolina bay that dries in most summers. These graphs represent the range of variation in annual reproductive success for a study that included a total of five species of salamanders and eight species of frogs. After Semlitsch et al. (1996).

success of different species in the community is a function of complex interactions between pond hydroperiod, intraspecific and interspecific competition, and predation.

The Pond Permanence Gradient and the Structure of Larval Communities

The studies at Rainbow Bay illustrate the importance of considering physical factors, such as pond hydroperiod, and the way that they interact with competition and predation to structure larval communities. Amphibians use a spectrum of ponds for breeding, ranging from ephemeral rain pools that often last only a few days to permanent ponds that never dry up (fig. 15.20). In between are vernal pools that typically fill during the winter and spring and often are dry by midsummer, and semipermanent ponds that often hold water for most of the summer, but may dry up every few years (Wellborn, Skelly, and Werner 1996; Skelly 1997, 2001;

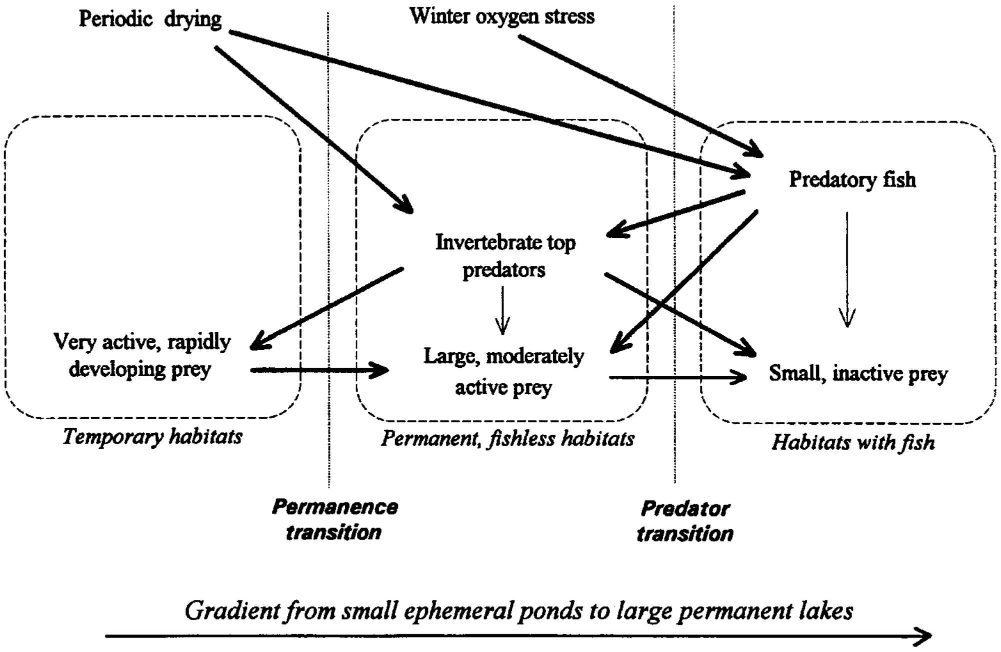

Fig. 15.20. Schematic diagram of the gradient in freshwater habitats from ephemeral ponds to permanent lakes. Arrows indicated the direction of negative effects. Thick arrows indicate strong effects that constrain the distribution of species. Thinner arrows indicate weaker effects that do not prevent the coexistence of interacting species. Two major transitions between habitats are indicated. The first is between temporary habitats with few predators and permanent habitats with many invertebrate predators. The second is between permanent habitats that lack fish and those that contain fish. Within temporary ponds, variation in the frequency and timing of drying will effect the composition of both predator and prey communities. From Wellborn, Skelly, and Werner (1996). Reprinted, with permission, from the *Annual Review of Ecology and Systematics,* vol. 27, 1996, by Annual Reviews (www.annualreviews.org).

Baber et al. 2004). The diversity of amphibian species that use ponds along this gradient tends to be low at either end of the gradient, but high in the middle. In other words, relatively few species use either extremely ephemeral pools or permanent ponds for reproduction. In contrast, ponds of intermediate permanence often harbor complex communities of many amphibian species. For example, ponds known as Carolina bays in the southeastern United States, most of which dry periodically, may have the most diverse assemblages of amphibian species of any aquatic habitats, especially when fish are absent from these ponds (Resetarits and Fauth 1998; Snodgrass, Bryan, and Burger 2000).

Amphibians that use different types of ponds along this permanence gradient tend to have very different life-history characteristics (see chapter 13). Highly ephemeral ponds tend to have relatively poor nutrients, and their rapid rate of drying favors rapid larval development and early metamorphosis. These ponds also tend to have fewer predators than do more permanent bodies of water, so the larvae of species that use such sites can afford to be very active in their foraging behavior without exposing themselves to predation (see chapter 14). In contrast, larvae that develop in longer-lasting ponds with many predators tend to be less active, and they often reduce activity in response to the presence of predators, but they also have slower rates of growth and development (Woodward 1983; Skelly 1996; Dayton and Fitzgerald 2001). Although hydroperiod does not vary among permanent ponds, other physical factors such as acidity, dissolved oxygen, maximum depth, surface area, and habitat stucture can influence the distribution of amphibian larvae (e.g., R. Hoffman, Larson, and Brokes 2003).

The presence of predatory fish in many permanent ponds tends to exclude many species of amphibians from using such ponds for breeding (see chapter 14). Ponds with fish tend to have communities composed of fewer species of amphibian larvae than do ponds without fish (e.g., Snodgrass, Bryan, and Burger 2000), although different species of fish have different effects on larval communities (Chalcraft and Resetarits 2003). Different kinds of tadpoles also have evolved different phenotypic responses to predatory fish. Hylid tadpoles in ponds with fish tend to grow more rapidly than do ranid tadpoles, for example (Richardson 2002b). Predation thus assumes a key role in the structuring of permanent pond communities and favors the evolution of antipredator adaptations in species that live in these ponds. Predator avoidance often comes at a cost in reduced rates of growth and development, and some permanent pond species, such as bullfrogs (*Rana catesbeiana*), have tadpoles that spend one or more winters in the pond before reaching metamorphosis. The slower lifestyle of permanent pond species also tends to put them at a competitive disadvantage against more active temporary pond species where they co-occur in semipermanent ponds that lack predatory fish (Skelly 1997). On the other hand, in permanent ponds, the presence of large overwintering tadpoles can have negative effects on the larvae of other species that enter ponds in the spring (Boone, Little, and Semlitsch 2004).

Interactions among different types of predators can directly affect the survivorship of amphibian larvae and can indirectly affect competitive interactions among different species (e.g., Werner and McPeek 1994). In temporary ponds, where many species of amphibian larvae often co-occur, the role of predation may be secondary to interspecific competition in determining the structure of the larval community, although differential vulnerability to predation can influence the outcome of competitive interactions (e.g., Morin 1981, 1983a, 1986, 1987a; Relyea 2000). The Rainbow Bay studies have shown that the rate of pond drying can interact in complex ways with competition and predation to determine the relative success of different species in the community (Pechmann et al. 1989; Semlitsch et al. 1996). The difficulty with such studies is that the relative importance of different factors is hard to determine from statistical correlation alone. Consequently, much of the experimental work on the community ecology of larval amphibians has focused on trying to understand the relative importance of each of these factors and the interactions among them in determining the structure of communities.

Competition and Predation in Larval Salamander Communities

Salamander larvae generally are the top predators in their communities, especially in temporary ponds, sometimes functioning as keystone predators that affect the structure of the aquatic vertebrate and invertebrate community at lower trophic levels (Holomuzki and Collins 1987; Taylor et al. 1988; P. Harris 1995; Morin 1995; Blaustein et al. 1996; Wissinger et al. 1999; Davic and Welsh 2004). Salamander larvae obviously interact with anuran tadpoles in the same communities, but here I focus on their interactions with one another. The role of larval and adult salamanders as predators of tadpoles is discussed in a later section. Depending on the relative sizes of coexisting species, salamander larvae can affect one another as predators, competitors, or both. Descriptive studies of larval salamander communities have focused mainly on differences in diet and microhabitat use among co-occurring species, whereas experimental studies have mostly dealt with the role of competition and predation in structuring the community.

Niche Partitioning and Habitat Segregation

Most studies of niche partitioning in salamander larvae have focused on pond-breeding species of *Ambystoma* in the United States. It is common for two or three species of *Ambystoma* to coexist in the same pond, and sometimes as many as five species are present. Larvae and adults of the newt *Notophthalmus viridescens* often occur in the same ponds as well. All of these species tend to be generalist predators on small invertebrates and tadpoles. Overlap in diet among co-occurring species often is high (C. K. Smith and Petranka 1987; B. Taylor et al. 1988; Nyman 1991), as it is for salamander larvae in other parts of the world (Braña, de la Hoz, and Lastra 1986). Some separation in diet may be an indirect effect of the timing of breeding by different species. Typically there is a sequential entry of larvae of different species into the community. For example, in the eastern and southern United States, *Ambystoma annulatum* and *A. opacum* are fall breeders, with the latter species laying eggs in shallow depressions that eventually fill with water to become ponds (Noble and Brady 1933; Petranka and Petranka 1980; Petranka 1998). Larvae hatch and overwinter at a small size, growing steadily during the spring. *Ambystoma tigrinum, A. talpoideum,* and *A. texanum* typically are winter breeders, with the exact date depending on local climatic conditions. *Ambystoma maculatum* breeds in early spring, as do members of the *A. jeffersonianum* complex. Where *A. maculatum* and the *A. jeffersonianum* complex co-occur, the latter often arrives in ponds slightly earlier (Nyman 1991). *Notophthalmus* adults usually enter ponds later in the spring to breed, although in some regions they may remain in the ponds for much of the year.

This staggered breeding pattern has been interpreted as a mechanism for reducing competition, because it leads to separation of species by body size (Worthington 1968, 1969; Hassinger, Anderson, and Dalrymple 1970; Keen 1975; Nyman 1991). There is, however, little evidence to indicate that timing of breeding has evolved as a response to the presence of other species in the community, as opposed to independent responses to factors such as temperature and rainfall. Nevertheless, differences in timing can result in divergence in prey size among species living in the same pond. Small *Ambystoma* larvae typically feed on zooplankton suspended in the water column. As they grow, they shift to larger prey, although they continue to take some small zooplankton (Dodson and Dodson 1971; Collins and Holomuzki 1984; Leff and Bachmann 1986; Holomuzki and Collins 1987; Sredl and Collins 1991). Differences in time of entry into a pond may result in different species using somewhat different prey at any given time, because the earliest arriving species will tend to eat the largest prey (Hassinger, Anderson, and Dalrymple 1970; Nyman 1991).

Species that have similar diets early in life may diverge if they grow at different rates. For example, *A. californiense* larvae in California have faster growth rates than do *A. macrodactylum* larvae, and soon reach a size that enables them to take large prey such as tadpoles, which are not available to the smaller species (J. Anderson 1968a). Nevertheless, there still is substantial overlap in food niches of the two species, and there is no direct evidence that the selection of prey by one species is influenced by the presence of the other. In British Columbia, the slow-growing *A. macrodactylum* often occurs in ponds with a faster-growing species, *A. gracile*. The latter is more affected by increased density of heterospecifics than in the former, whereas *A. macrodactylum* appears to be more sensitive to intraspecific competition (Pearman 2002). Because all salamander larvae are predators, ontogenetic shifts in diet can result in the larger or faster-growing species in a community changing from being primarily competitors to primarily predators of smaller species (Stenhouse 1985b; Cortwright 1988).

Some salamander larvae exhibit differences in use of microhabitats in the same ponds. For example, larvae of the European newt *Triturus vulgaris* spend most of their time on the bottom of ponds, hunting for benthic invertebrates, whereas the larvae of *T. cristatus* spend more time feeding on plankton in the water column (Dolmen 1983a). This difference in microhabitat use is the reverse of that seen in adults, so direct competition between larvae and adults of the same species may be relatively uncommon. In ponds in New Jersey, larvae of *A. maculatum* spent most of their time on the bottom in shallow water, whereas larvae of the *A. jeffersonianum* complex foraged mostly in the water column (Nyman 1991). In some ponds, there is a sequential shift in use of microhabitats that parallels the staggered entry of larvae into the community (Hassinger, Anderson, and Dalrymple 1970). *Ambystoma* larvae typically exhibit a daily cycle of vertical movements in the water column that apparently follow the movements of their prey (J. Anderson and Graham 1967; Hassinger and Anderson 1970; Hassinger, Anderson, and Dalrymple 1970; J. Anderson and Williamson 1974; Petranka and Petranka 1980; Branch and Altig 1981; Holomuzki and Collins 1983). Different species may differ slightly in their patterns of vertical migration, but there is little evidence that species are clearly segregated into distinct strata in the pond. Again, it is not clear whether interactions between the species are responsible for these shifts in microhabitats, or whether they simply reflect the availability of prey of a suitable size for each species.

Habitat segregation at larger spatial scales, such as the use of different types of ponds, results from choices of oviposition sites by adults. Nevertheless, habitat segregation could be an indirect result of interactions among larvae if one species tends to exclude another through competition or predation and adults tend to avoid laying eggs in habitats likely to contain competitors or predators (see chapter 14). Alternatively, such differences in habitat use could result from independent responses of different species to factors such as pond permanence or the presence of predators such as fish. A well-studied example is the microgeographic distribution of *Ambystoma maculatum* and *A. talpoideum* in ponds in the coastal plain of South Carolina. *Ambystoma maculatum* is relatively uncommon in this region, whereas *A. talpoideum* is abundant and widespread. The former is almost entirely restricted to permanent ponds or stream pools that contain predatory fish, whereas the latter is found almost exclusively in fish-free temporary ponds. Although larvae of both species are vulnerable to predation by fish, the larvae of *A. maculatum* have higher survivorship in the presence of fish than do larvae of *A. talpoideum,* provided that spatial refuges are available (Semlitsch 1988). When larvae of the two species were reared together in artificial ponds, there was little evidence that competition affected survivorship. There also was little evidence that *A. maculatum* was incapable of reaching metamorphosis in temporary ponds. Semlitsch (1988) suggested that *A. maculatum* are excluded from temporary ponds because the relatively dry habitats surrounding such ponds are not very suitable for adults. The situation is different in Mississippi and Louisiana, where the two species occur together, usually in ponds without fish. The larvae of *A. talpoideum* are more aggressive than are those of *A. maculatum,* and tend to be competitively superior when the two species are raised together, although the difference is not sufficient to enable *A. talpoideum* to exclude *A. maculatum* from ponds (Semlitsch and Walls 1993).

Experimental Studies of Competition and Predation

Pond-Dwelling Salamander Larvae

In addition to the work on *Ambystoma maculatum* and *A. talpoideum* described earlier, there have been a number of other experimental studies of competition and predation in pond-dwelling salamanders (Hairston 1987, 1996). The first detailed work was done by Wilbur (1971, 1972), who studied a community in Michigan that included *Ambystoma tigrinum, A. maculatum, A. laterale,* and triploid all-female populations of the *A. jeffersonianum* complex. Adult and larval *Notophthalmus viridescens* also were found in natural ponds, as were *Rana sylvatica* tadpoles and a variety of invertebrates

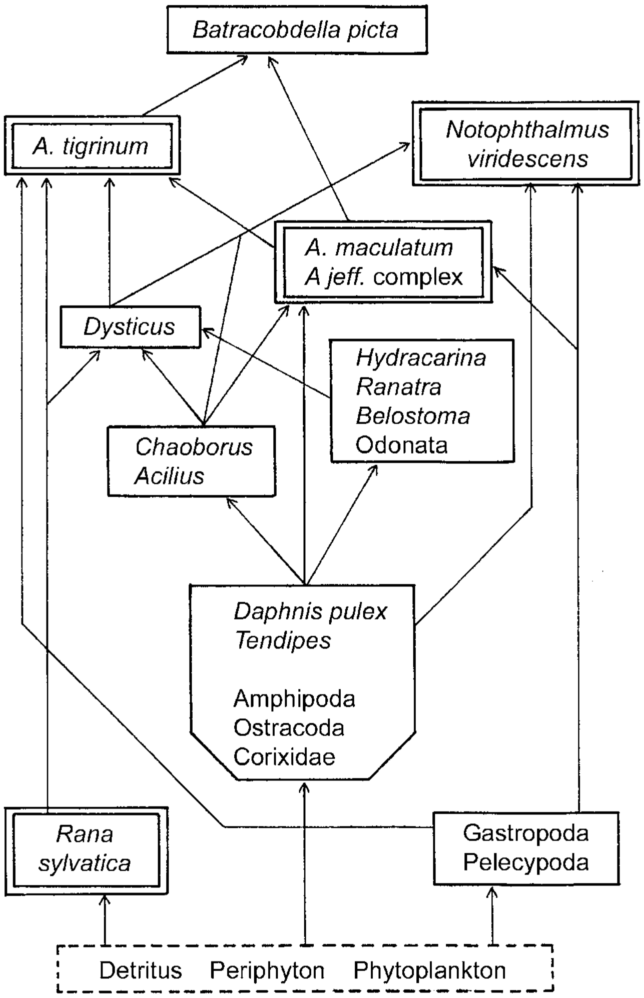

Fig. 15.21. Food web of a temporary pond community in Michigan. Arrows show connections between prey species and consumers at the tips of the arrows. Amphibian members of the community are indicated by double boxes. Invertebrates are indicated by single boxes. After Wilbur (1972).

(fig. 15.21). Wilbur used a hierarchical approach, first testing for density effects in single-species enclosures and then extending the work to two-species systems (all combinations of *A. laterale, A. maculatum,* and the triploids) and three-species systems (all three together in different density combinations). The results were variable, with many significant higher-order interactions between treatment effects, some of which are hard to interpret biologically.

Larvae in single-species tests exhibited density-dependent changes in growth and survivorship, but did not respond in exactly the same way. Survivorship of *A. laterale* actually was higher at high than at low densities, but the survivors metamorphosed at a smaller size. *Ambystoma maculatum,* on the other hand, showed greatly reduced survivorship at high densities, but the survivors transformed at a larger size than those raised at low densities, presumably because of reduced competition for food. Density had little effect on survivorship or size at metamorphosis in the triploids, but those at high density had a longer larval period. There also were consistent differences among species in length of the larval period and size at metamorphosis, even when they were raised at the same density. Hence, there appear to be inherent differences between the species that could affect the outcome of competitive interactions among them.

When raised in two- and three-species enclosures, all species showed density-dependent changes in growth and survivorship, and all species were affected by competition from all other species. In some treatments, the differences between species seen in the single-species experiments were maintained or even intensified in the competitive situation. For example, in both two- and three-species systems, there were significant differences among species in the length of the larval period and size at metamorphosis that were consistent with those observed in the single-species treatments. However, interactions in the multispecies systems were not simple functions of adding more larvae to the community; the identity of the species added, their relative proportions in the community, and their absolute abundance all influenced the outcome of competitive interactions. In a natural community, these variables would be governed by a variety of stochastic processes, such as the timing of breeding by each species and the number of adults entering the pond to breed. Consequently, the relative success of each species might vary considerably from year to year and from pond to pond.

The presence of predators in the community can further complicate the picture. Wilbur (1972) compared the performance of the three types of salamander larvae in enclosures with predatory *A. tigrinum* larvae and those without predators. *Rana sylvatica* tadpoles also were added to some enclosures. These served as alternative prey for the *A. tigrinum* larvae, but were seldom eaten by the other species. Again, the results were rather complex. All species had lower survivorship when predators were present. The presence of *R. sylvatica* tadpoles in addition to predators further decreased larval survivorship. This seems paradoxical, since the tadpoles were alternative prey for *A. tigrinum.* However, small *A. tigrinum* larvae cannot prey on the larvae of the other species because they are similar in size. When tadpoles were absent, the *A. tigrinum* larvae evidently preyed mainly on the same small invertebrates eaten by the other salamanders (fig. 15.21). Under these conditions, they had low survivorship, long larval periods, and a small size at metamorphosis, probably because competition limited their food supply. However, small *A. tigrinum* fed preferentially on tadpoles when they were available; this allowed some individuals to gain a rapid size advantage and reach a size that enabled them to prey on the other salamander species. On the other hand, the tadpoles probably reduced the food supply for the invertebrate prey of the other salamander species. Predation by *A. tigrinum* greatly reduced survivorship of the other salamander species. Those that did survive were better off because of reduced competition for their invertebrate prey, and because the *A. tigrinum* larvae also reduced the tadpoles that compete with the invertebrates for food.

Subsequent studies of larval salamander communities have revealed similar complex interactions between competition and predation. In some ponds, fall-breeding *A. opacum* take the place of *A. tigrinum* larvae as top predators. Stenhouse, Hairston, and Cobey (1983) found that the impact of *A. opacum* on *A. maculatum* depended on both the size and density of the predators. *Ambystoma maculatum* larvae were quickly eliminated from laboratory tanks when large *A. opacum* or high densities of predators were present; they were eaten at much slower rates when predators were smaller or present at lower densities. Although there was evidence from field experiments of interspecific competition if *A. opacum* was prevented from reaching a large size, their role as predators appeared to be much more important in determining the success of *A. maculatum.* Because the size and density of *A. opacum* varies from one pond to another and from year to year, the growth and survival of *A. maculatum* varies as well (Stenhouse 1985b). Other experiments in artificial ponds showed that *A. opacum* affects the survivorship of *A. talpoideum* larvae primarily through predation, with early-hatching *A. opacum* larvae having a larger effect than late-hatching larvae (Boone, Scott, and Niewiarowski 2002).

In another set of experiments with artificial ponds (cattle tanks), Walls and Williams (2001) found that *A. maculatum* larvae did poorly in the presence of either *A. opacum* or *A. jeffersonianum* larvae, and they did especially poorly when both species were present. The negative impact of these species was due both to direct predation and reduced foraging activity of *A. maculatum* larvae in the presence of the other species. The worst performance was in ponds with both species of predatory salamander larvae and wood frog (*Rana sylvatica*) tadpoles. Although the tadpoles are potential alternative prey for the larger salamander larvae, they also removed most of the filamentous algae from the tanks. This might have removed a source of food for herbivorous invertebrates that serve as prey for the salamander larvae, but it also is possible that tadpoles removed a source of cover for *A. maculatum* larvae. As in the experiments by Stenhouse (1985b), these experiments suggested that *A. maculatum* probably persists in ponds in which the other two salamander species breed because larvae do well in years in which the other two species do poorly. Neither of these studies directly addressed the question of what governs year-to-year differences in larval performance by the predatory species.

The previous experiments ignored the effects of salamanders other than *Ambystoma,* but both larval and adult newts also can be important components of aquatic salamander communities (fig. 15.21). Larval *Notophthalmus* and *Ambystoma* have similar diets and therefore are potential competitors (Brophy 1980). In addition, adult newts prey on *Ambystoma* eggs, while *Ambystoma* larvae eat newt eggs and larvae. Morin (1983b) enclosed *Ambystoma* egg masses in predator-exclusion cages while leaving others unprotected. Survivorship of unprotected eggs was only about 4%, whereas 98% of the caged eggs survived. Hence, newts are capable of nearly eliminating *Ambystoma* from some ponds. In fact, natural ponds with high densities of newts generally had very few *Ambystoma* eggs, whereas ponds with small newt populations had many eggs. The presence of adult newts also reduced the growth rates and size at metamorphosis of *Ambystoma* larvae, indicating an effect of interspecific competition. On the other hand, *Ambystoma* larvae were predators on newt larvae. In the presence of *Ambystoma,* survivorship of newt larvae was reduced, but size at metamorphosis was greater, presumably because of reduced intraspecific competition.

In some ponds in the southeastern United States, newts interact with sirens in both the adult (Fauth and Resetarits 1991) and larval stages. Fauth, Resetarits, and Wilbur (1990) reared larval newts (*Notophthalmus viridescens*) and larval lesser sirens (*Siren intermedia*) in cattle tanks. Each species was raised alone at low (three larvae per tank) or high density (six larvae per tank), or together with three of each species. Both densities were low compared to those in many natural ponds, however (Harris, Alford, and Wilbur 1988). Although these two species are quite different morphologically, they eat similar prey. They were relatively equal competitors in the conditions of the experiment, but each species affected the other in slightly different ways. The presence of siren larvae decreased the survival of newt larvae, but not their growth or the length of the larval period. Newt larvae, on the other hand, decreased growth rates of siren larvae, but not their survival. The presence of three newt larvae in a tank had the same effect on growth rates of larval sirens as did the presence of three additional siren larvae, indicating that the effect is mainly a response to density and not to a specific competitor.

Stream-Dwelling Larvae

Interactions of stream-dwelling salamander larvae have received less attention than those of pond-dwelling species. One difference between pond and stream larvae is that the latter seldom have either anuran tadpoles or small zooplankton available as food. In the southern Appalachians, stream communities are composed entirely of plethodontid salamanders, including species of *Desmognathus, Eurycea, Gyrinophilus,* and *Pseudotriton.* The identity and relative abundance of different species varies geographically. The structure of the stream community also is related in part to the presence or absence of fish such as brook trout (*Salvelinus fontinalis*), which are potential predators on small salamander larvae and potential competitors with larger larvae and aquatic adults (Resetarits 1991, 1995, 1997). All of the stream-dwelling salamanders tend to be generalist predators on small invertebrates, but the larvae of some species, including *Gyrinophilus porphyriticus, Pseudotriton ruber, Desmognathus quadramaculatus,* and *Desmognathus marmoratus,* reach very large sizes and are capable of consuming smaller salamander larvae. As in communities of pond-dwelling larvae, this means that species may interact as competitors, predators, or both.

Several experimental studies have shown that large species can have a major impact on smaller species as predators, but evidence for strong interspecific competition is mixed. For example, Beachy (1993b 1994) found little evidence for either intra- or interspecific competition among salamander larvae raised at relatively high densities in cages placed in a stream in North Carolina. However, the larvae of both *Desmognathus quadramaculatus* and *Gyrinophilus porphyriticus* consumed larvae of *Eurycea wilderae.*

Resetarits (1991) constructed artificial streams in Virginia and stocked them with two large predators, larvae of the spring salamander (*Gyrinophilus porphyriticus*) and brook trout (*Salvelinus fontinalis*), and two smaller predators, larvae of the two-lined salamander (*Eurycea cirrigera*) and a crayfish (*Cambarus bartonii*). In this experimental system, brook trout had a large effect on both growth and survival of *Gyrinophilus,* but the salamander larvae had little effect on the trout. The precise mechanism leading to reduced growth and survival of the salamander larvae was not clear, but aggressive interference competition and attempted predation are the most likely explanations (the *Gyrinophilus* larvae were mostly too large to be consumed by the trout). Neither trout nor *Gyrinophilus* larvae had a significant effect on the survival of the smaller *Eurycea* larvae, but both predators did reduce their growth rates, especially when both were present together. This effect was largely due to reduced feeding activity in the presence of the predators.

Using the same array of artificial streams, Gustafson (1993, 1994) investigated ecological interactions among larvae of *Gyrinophilus porphyriticus, Pseudotriton ruber,* and *Eurycea cirrigera* in the absence of fish. The first two species are much larger than *Eurycea* and therefore are potential predators on that species and on each other. In fact, Gustafson (1993) found evidence for strongly negative effects of large *Gyrinophilus* and *Pseudotriton* larvae on the survival of smaller *Pseudotriton* larvae and a weaker effect on growth rates of *Eurycea* larvae. As in the experiments by Resetarits, the effect on *Eurycea* growth was largely due to reduced activity in the presence of large predators. A subsequent experiment showed that *Gyrinophilus* also can affect the survival of *Eurycea* larvae, and the effect is greatest when the *Gyrinophilus* larvae are large (Gustafson 1994). This indicates that *Gyrinophilus* larvae become more serious predators on *Eurycea* larvae as they grow. Gustafson's (1993) experiments also showed some reduction in growth rates of large *Pseudotriton* larvae in the presence of *Gyrinophilus,* possibly because of competition. Nevertheless, all of these experiments together provide relatively weak evidence for competition among stream-dwelling salamander larvae, and strong evidence for size-related interspecific predation as a major determinant of community structure.

Ecology of Anuran Tadpole Communities

Assemblages of anuran tadpoles often are much more diverse than assemblages of salamander larvae. This is especially true in the tropics, where many species of anurans use the same breeding sites, and a dozen or more species of tadpoles can be found at the same site (Heyer 1973; Duellman 1978; Blommers-Schlösser and Blommers 1984; Schlüter 1984; Inger, Voris, and Frogner 1986; Aichinger 1987a; Gascon 1991; Magnusson and Hero 1991; Azevedo-Ramos, Magnusson, and Bayliss 1999). Even in the temperate zone, tadpole communities can be very diverse, with more than a dozen species of tadpoles found in some ponds in the Coastal Plain of the southeastern United States (Wilbur 1997; Resetarits and Fauth 1998; Alford 1999; Snodgrass, Bryan, and Burger 2000). Adult anurans using the same breeding sites often have different temporal patterns of reproduction. Consequently, most sites exhibit a staggered introduction of larvae into the community, and the number of species present varies over time (Blair 1961; Berry 1964; Dixon and Heyer 1968; Heyer 1973, 1976, 1979a; Wiest 1982; Gascon 1991; Semlitsch et al. 1996; Azevedo-Ramos, Magnusson, and Bayliss 1999). This temporal separation has been interpreted as one dimension of resource partitioning among tadpole species. As in the case of salamanders, however, there is little evidence that differences in timing of breeding have evolved in response to interactions among species. It is more likely that each species responds independently to environmental cues, and the resulting pattern of breeding activity then sets the stage for interactions among different tadpole species.

Variation in temporal patterns of reproduction results in different species of tadpoles experiencing different environmental conditions, especially in temporary ponds. Physical factors such as water depth, temperature, and oxygen content often vary over time, as do biological factors such as nutrient availability, fouling of water by waste products from tadpoles and other organisms, and densities of predators and competitors. For species with prolonged breeding seasons, tadpoles may be continuously or episodically added to the community, and different age cohorts of the same species may experience very different conditions (Alford 1999). Furthermore, the nature of interactions with competitors or predators often depends on tadpole body size, so different age cohorts may interact with each other and with other species in different ways. In some cases, this can result in animals switching from being competitors to predators of other species, or even members of their own species, as they grow (Crump 1983; Pfennig 1990a, 1992a, b). All of this variability makes accurate characterization of community structure especially difficult.

Niche Partitioning and Microhabitat Segregation

Interspecific Differences in Diet

There have been relatively few studies of dietary differences among tadpoles living in the same habitat (Diaz-Paniagua 1985, 1989a; Inger 1986; Pavignano 1990; Sekar 1992; Alford 1999). This is due in part to the difficulty of determining exactly what these animals are eating. In contrast to salamander larvae, tadpoles are not gape-limited predators, but suspension feeders on algae, phytoplankton, and other particulate matter (see chapter 12). This makes gut contents difficult to identify, especially for those who are not experts on the identification of algae. Furthermore, tadpole body size is not necessarily related to the type or size of food particles ingested (Seale 1980), but it may be related to the rate at which food can be processed (chapter 12). Tadpoles may differ in their ability to capture food particles at various concentrations (Seale and Beckvar 1980; Viertel 1990) and to process different types or sizes of food particles (Altig and McDearman 1975; Altig et al. 1975; Viertel 1992). They also may vary in the efficiency with which food is digested (C. G. Peterson and Boulton 1999) and in the types of nutrients extracted from the food (Steinwascher and Travis 1983).

Tadpoles in a natural environment may be exposed to foods of different quality, and this in turn can impact their growth and development. For example, tadpoles of *Pseudacris regilla* grew faster when fed algae that harbored many epiphytic diatoms than on algae that lacked these organisms (Kupferberg, Marks, and Power 1994). Tadpoles often have been characterized as unselective grazers, but some species are capable of evaluating differences in the quality of food in different habitat patches and choose to feed in higher quality patches (Kupferberg 1997a, 1998). Tadpoles sometimes may be forced by predators to feed in low-quality patches and may grow more slowly than those that have access to high-quality food (Kupferberg 1998). There is no information, however, on how competitive interactions with other species of tadpoles directly affect diet selection in tadpoles. There is evidence from laboratory studies that some species of tadpoles can reduce growth in other species through aggressive interference competition (Faragher and Jaeger 1998), but this effect probably is due to reduced feeding activity rather than changes in diet composition.

Microhabitat Segregation

In complex assemblages of anuran tadpoles, different species often use slightly different microhabitats, and this can lead to differences in the types of food consumed. Species often differ in their choice of water depth, substrates, or types of vegetation used for shelter and feeding (Inger 1969; Heyer 1973, 1974, 1976, 1979a; Heyer, McDiarmid, and Weigmann 1975; Degani 1986; Inger, Voris, and Walker 1986; Löschenkohl 1986; Diaz-Paniagua 1987; Waringer-Löschenkohl 1988; Zhao et al. 1994; Barreto and Moreira 1996; Wild 1996; Alford 1999). These differences typically are correlated with morphological differences in body form and mouthparts (see chapter 12 for a discussion of the ecomorphology of tadpoles). Although the basic mechanism of suspension feeding is similar for all species, they often differ in the way that food is initially acquired. Some species utilize phytoplankton suspended in the water column, while others feed on particles floating on the water surface. Many species use specialized mouthparts to ingest detritus from the bottom of a pond or scrape algae off of rocks or submerged vegetation. Hence one can find tadpoles feeding in a variety of ways simultaneously in the same pond. Nevertheless, even morphologically distinct tadpoles in different microhabitats in streams often exhibit considerable overlap in diet (Inger 1986; Löschenkohl 1986; Alford 1999). This observation has led some authors to argue that interspecific competition for food is of minor importance in tadpole communities, perhaps because food is always abundant (Heyer 1973, 1974, 1976, 1979a; Heyer, McDiarmid, and Weigmann 1975; Inger 1986; Zhao et al. 1994). There is, however, evidence that tadpoles can substantially alter the abundance and species composition of algae and other vegetation in ponds and streams, suggesting that dense populations of tadpoles are food limited (Dickman 1968; Seale, Rodgers, and Boraas 1975; Seale 1980; Morin and Johnson 1988; Brönmark, Rundle, and Erlandsson 1991; Leibold and Wilbur 1992; Werner 1994; Morin 1995; Kupferberg 1997a; see also chapter 13).

Many of the microhabitat differences seen in assemblages of pond- or stream-dwelling tadpoles probably result from phylogenetic differences in morphology and behavior, not from competitive interactions among species. In fact, there is surprisingly little evidence that the presence of one species of tadpole can cause another species to alter its use of microhabitats. Two examples that do suggest a role for interspecific competition come from Australia. Two species of pond-breeding frogs, *Pseudophryne bibroni* and *P. semimarmorata,* are largely allopatric, but have a narrow zone of overlap in southeastern Australia. *Pseudophryne bibroni* tadpoles consistently out-competed those of *P. semimarmorata* when the two species were reared together, suggesting that competition at the larval stage is one factor preventing greater overlap in these species' ranges (Wiltshire and Bull 1977). A stronger example involves habitat segregation between *Crinia signifera* and *C. riparia.* The former is widely distributed throughout southeastern Australia, while the latter is restricted to streams in the Flinders Range, where it overlaps slightly with *C. signifera* (Odendaal and Bull 1982). *Crinia signifera* tadpoles are typical pond-type tadpoles and have difficulty holding their position in flowing water (Odendaal and Bull 1980). When placed in a rocky stream with tadpoles of *C. riparia,* they tend to stay between the rocks and therefore are excluded from the rock surfaces, where most of the food is located (Odendaal, Bull, and Nias 1982). Although they can survive in fast-moving water, their survival is significantly lower than that of *C. riparia* when the two are housed together in flowing water (Odendaal and Bull 1983). This does not seem to be simply the result of exploitative competition for food, but may result from the more active *C. riparia* tadpoles displacing *C. signifera* from sheltered sites, exposing them to the current and reducing their ability to remain in one place to feed (Odendaal, Bull, and Richards 1984).

Experimental Methods for Investigating Community Structure and Dynamics

Most studies of tadpole community ecology have been experimental studies in which different combinations of competitors and predators have been raised in artificial ponds and the performance of the various species has been monitored. Most commonly, large cattle watering tanks have been used to simulate conditions in temporary ponds (Wilbur 1989, 1997; Morin 1998; Resetarits and Fauth 1998). These have the advantage of allowing investigators to control tadpole and predator densities and food availability, and treatments can be easily replicated. There are certain features of cattle tanks that do not precisely mimic natural temporary ponds, however. One difference is that cattle tanks typically have straight sides, which removes shallow water habitats that may be important for some species. Some investigators have placed tanks on a slope to simulate a sloping shoreline (Griffiths, Denton, and Wong 1993). When water levels are reduced to simulate pond drying in a straight-sided tank, the surface area of the water remains the same, something that would not be true in natural ponds. The regular size and shape of the tanks also reduces the spatial complexity and diversity of microhabitats typically found in natural ponds.

Investigators have used several other types of containers to perform replicated experiments on competition and predation. These include fiberglass tanks (Semlitsch, Hotz, and Guex 1997), small plastic tubs (Gascon 1992a; G. R. Smith 1999), children's wading pools (Fauth 1999b), plastic barrels cut in half (Lardner 1995), cages placed in natural ponds (Brockelman 1969; Werner 1994; Skelly 1995a, b; Bardsley and Beebee 2000) or streams (Kupferberg 1997a), shallow ponds with plastic liners (Griffiths 1991), large man-made ponds with natural vegetation (Werner and McPeek 1994), natural ponds of similar size (Bardsley and Beebee 1998b), and shallow natural rock pools (D. C. Smith 1983; Laurila 2000b). The various types of experimental systems provide different degrees of realism in replicating conditions in natural ponds and the spatial scale at which interspecific interactions can be examined. Differences in spatial scale can be important in interpreting the results of competition experiments. For example, some studies done in small laboratory containers have yielded very different results from studies conducted on the same species in larger, more natural environments (Werner 1992, 1998; Werner and Glennemeir 1999; Laurila 2000b). The intensity of competition also can differ between artificial ponds such as cattle tanks and natural ponds, with the latter providing weaker evidence of competition (Skelly and Kiesecker 2001; Skelly 2002).

Tadpole Competition in the Absence of Predators

A number of studies have examined competitive interactions among species of tadpoles in the absence of predators, both in the laboratory (Wilbur 1977b, 1982; Smith-Gill and Gill 1978; Travis 1980b; Alford, 1989b; Werner 1992; Gollmann and Gollmann 1993) and in various kinds of artificial ponds. Most of these studies have revealed competitive effects among species, but the intensity of competition varies considerably.

Weak Interspecific Competition

Some experiments have produced relatively weak evidence for interspecific competition. For example, in an early study by Wilbur (1977a), density of conspecific tadpoles had a strong negative effect on size at metamorphosis in *Bufo americanus.* When these tadpoles were reared with different densities of conspecifics or tadpoles of pickerel frogs (*Rana palustris*) in pond enclosures, there was not a major difference in the effect of conspecifics and heterospecifics (data from Wilbur 1977, reanalyzed by Alford 1999). A subsequent study by Alford (1989a) in cattle tanks was designed to examine competition between these two species in more detail. Again, competitive effects were relatively weak, with each species having little effect on the performance of the other, regardless of when the two species were introduced into the pond. These results contrasted with earlier experiments with *Bufo americanus* and *Rana sphenocephala* in identical ponds. Those experiments showed strong competition between the two species (Alford and Wilbur 1985). The reasons for the different results with the two species of *Rana* are not clear. Alford (1989a) suggested that *R. sphenocephala* is less likely to share ponds with *B. americanus* than is *R. palustris,* so there might have been weaker selection to evolve differences in microhabitat use or type of food consumed. In the absence of detailed information on resource use, however, there is no direct evidence to support this hypothesis.

Skelly (1995b) examined competitive interactions between tadpoles of spring peepers (*Pseudacris crucifer*) and green frogs (*Rana clamitans*) in pond enclosures stocked at different densities. Green frogs breed mostly in relatively permanent ponds, whereas spring peepers tend to favor more temporary sites. Where the species overlap, green frog tadpoles remain in ponds for one or more winters, so large tadpoles of this species often are present when spring peeper tadpoles hatch. Green frog tadpoles had a relatively small effect on size of spring peepers at metamorphosis, and they did not affect survivorship, growth rate, or length of the larval period. In contrast, green frog tadpoles alone exhibited strong density dependence, with substantial reductions in growth rate and size at metamorphosis at high densities. Skelly concluded that interspecific competition among tadpoles was not sufficient to exclude spring peepers from ponds with large green frog populations. It may be that these species use very different food resources, so competition is weak, despite the much larger size of green frog tadpoles. Skelly (1995a) also found little evidence for interspecific competition between *Pseudacris crucifer* and a much more closely related species, *P. triseriata,* reared in pond enclosures. These results are consistent with those of D. C. Smith and Van Buskirk (1995), who found little evidence of interspecific competition between the same two species in natural rock pools, even though *P. triseriata* exhibits strong intraspecific competition at high densities (D. C. Smith 1983).

Bardsley and Beebee (1998b) did not find evidence of strong interspecific competition in experiments with *Rana temporaria* and *Bufo bufo* tadpoles in natural sand dune ponds. Unfortunately, their experimental design confounded the effects of competition and predation, because ponds used to examine mixed-species interactions contained predatory fish, whereas those used to examine intraspecific competition in single-species treatments contained only invertebrate predators. While survival of *R. temporaria* tadpoles was higher in single-species ponds than in mixed-species ponds, Bardsley and Beebee (1998b) attributed this to differences in predation by fish, not to competition with *Bufo* tadpoles.

Strong Asymmetric Competition

The results of these experiments contrast with those of many investigators who have reared tadpoles in cattle tanks and other types of artificial ponds, and with some studies in natural ponds. For example, Morin and Johnson (1988) raised spring peeper (*Pseudacris crucifer*) tadpoles with wood frog (*Rana sylvatica*) tadpoles at different densities in artificial ponds. These two species often begin breeding at the same time in early spring. Wood frogs are explosive breeders, with most eggs being laid on just a few nights, whereas spring peepers breed for up to two months. Wood frog tadpoles were clearly competitively superior to spring peeper tadpoles in these experiments. The effect of wood frog tadpoles on mass at metamorphosis for spring peepers was about twice as great as the effect of spring peeper tadpoles on wood frogs. The effect of wood frog tadpoles on members of their own species also was much greater than the effect of spring peeper tadpoles on conspecifics. The competitive superiority of wood frog tadpoles was related to their ability to deplete standing crops of periphyton, the principal food of both species. Strong asymmetric competition also was observed in experiments with wood frog tadpoles and leopard frog (*Rana pipiens*) tadpoles reared in pond enclosures, with wood frog tadpoles again being the superior competitor (Werner and Glennemeier 1999). This result contrasted with an earlier study of these species in the laboratory, which suggested that leopard frog tadpoles were the superior competitor (Werner 1992).

The strong asymmetric competition between wood frog and other tadpoles is typical of the results of many experimental studies of tadpole competition (Alford 1999). Often one species has a very strong effect on the performance of a second species, while the second species has a relatively weak effect on the first. For example, Woodward (1982d) found that tadpoles of *Scaphiopus couchii,* a species that breeds in temporary desert rain pools, was competitively superior to tadpoles of *Bufo woodhousii,* which usually breeds in permanent ponds, and *Rana pipiens,* which always does so. His experiments were conducted in very small (1 m^2), shallow (0.4 m) excavated ponds lined with plastic, which would tend to favor temporary pond species. He concluded that both species might be excluded from temporary ponds by competition from *Scaphiopus,* although *R. pipiens* probably would be excluded from such habitats because its larval period is longer than the time such ponds usually hold water. The competitive superiority of *Scaphiopus* tadpoles probably is related to their high levels of foraging activity, which may enable them to process food more efficiently than do other tadpoles. Other experiments have consistently shown that tadpoles with high levels of activity, including other species of *Scaphiopus,* tend to outcompete less active species (Morin 1983a; Wilbur 1987; Dayton and Fitzgerald 2001).

Another example of strongly asymmetric competition comes from studies of natterjack toads (*Bufo calamita*) in Britain. This is a pioneering species that favors temporary ponds in sand dune habitats, especially those that are not used by other species of amphibians. Experiments have shown that tadpoles of this species do poorly in competition with the two most common anurans in the region, *Bufo bufo* and *Rana temporaria,* both of which also breed in temporary ponds, but have more generalized habitat requirements. In addition, *B. calamita* is susceptible to egg predation by these two species. The result is that habitats where the other two species are abundant often are not suitable for natterjack toads (Banks and Beebee 1987a, b; Griffiths 1991; Griffiths, Edgar, and Wong 1991). Populations of natterjack toads are disappearing from dune habitats that have undergone succession, which makes them more suitable for the other species, especially *Bufo bufo* (Bardsley and Beebee 1998a).

Asymmetric competition has been reported in several combinations of ranid tadpoles in both temporary and permanent ponds. Tadpoles of the crawfish frog (*Rana areolata circulosa*) had reduced growth, longer larval periods, and smaller size at metamorphosis when they were raised in artificial ponds with tadpoles of either *R. sphenocephala* or *R. blairi,* even at low densities (Parris and Semlitsch 1998). The effect of *R. blairi* on *R. aerolata* was stronger than that of *R. sphenocephala.* The crawfish frog has a patchy distribution in tallgrass prairie habitats and could be susceptible to local extinction, where the other two species are common. In Europe, there is some evidence that tadpoles of *R. temporaria,* a temporary pond breeder, are competitively superior to those of another species that uses the same types of habitats, *R. arvalis,* but in this case, the effect was relatively weak (Lardner 1995).

Asymmetric competition also occurs between tadpoles of the *Rana esculenta* complex in Europe. *Rana esculenta* is a hybridogenetic species originally produced by hybridization between *R. lessonae,* which tends to inhabit temporary and semipermanent ponds, and *R. ridibunda,* which is found almost exclusively in permanent ponds and lakes. The hybridogenetic species is perpetuated by coexistence and interbreeding with one of the parental species, usually *R. lessonae* (Graf and Polls Pelaz 1989). In populations where *R. esculenta* and *R. lessonae* coexist, the former acts as a sexual parasite on the parental species. *Rana esculenta* contains one haploid genome from each parental species, but the *R. lessonae* genome is discarded in each generation, while the *R. ridibunda* genome is clonally inherited. A population may contain several different hemiclones derived from repeated immigration from populations where hybridization between the two parental species has occurred many times.

Rana esculenta often is much more common in natural ponds than is the parental species with which it is associated, especially in disturbed habitats such as gravel pits (Blankenhorn, Heusser, and Notter 1973). One possible reason for this is that *R. esculenta* is competitively superior to the parental species in the tadpole stage, adult stage, or both (Tunner and Nopp 1979). In competition experiments in artificial ponds, *R. esculenta* tadpoles had higher growth rates and tended to emerge earlier from ponds than did *R. lessonae* tadpoles, and the proportion of tadpoles reaching metamorphosis after 60 days was higher for *R. esculenta* as well (Semlitsch 1993). The earlier emergence of *R. esculenta* tadpoles is particularly advantageous in ponds that dry up during the summer (Semlitsch and Reyer 1992b). *Rana esculenta* tadpoles also performed slightly better than did *R. lessonae* tadpoles when competing species of tadpoles (*Hyla arborea* and *Bufo calamita*) were present. The competitive superiority of *R. esculenta* tadpoles derives from their higher level of feeding activity and higher food intake than that of either parental species (Rist et al. 1997).

Competition experiments with three hemiclones from a pond in Switzerland and the two parental species showed that the hemiclones exhibited significant phenotypic variation and performed differently at different densities and combinations of competitors (Semlitsch, Hotz, and Guex 1997). One hemiclone outperformed the other two under most of the conditions of the experiment; this was the most common one in the natural breeding pond, comprising nearly 70% of all tadpoles. The overall competitive superiority of *R. esculenta* over its parental species may derive in part from the diversity of hemiclones inhabiting a pond, each of which may respond slightly differently to environmental variations that occur in all ponds. The three genotypes of water frogs differ physiologically as well, especially in their ability to tolerate low oxygen levels, but experiments to determine whether the hybrid genotype is superior to both parental genotypes in this regard have yielded inconsistent results (Tunner and Nopp 1979; Plénet et al. 2000). Competitive interactions between *R. esculenta* and *R. lessonae* tadpoles also are mediated by different physiological responses to temperature, with *R. lessonae* tadpoles being more tolerant of and performing better at warm temperatures than *R. esculenta* tadpoles (Negovetic et al. 2001).

Bullfrog (*R. catesbeiana*) tadpoles have been shown to be superior competitors to green frog tadpoles (*R. clamitans*) in permanent ponds, where multiple size cohorts of the two species often overlap. One might expect the competitive superiority of bullfrog tadpoles to result from their larger size, but in fact, both large and small bullfrog tadpoles had a negative effect on growth rates and size at metamorphosis of green frog tadpoles (Werner 1994). Small green frog tadpoles had a negative impact on large bullfrog tadpoles, but not on smaller ones. Bullfrog tadpoles tend to be more active foragers than green frog tadpoles, and consequently acquire food at a faster rate (Werner 1991). Werner (1994) argued that the net gain in energy for tadpoles will increase at small body sizes and then begin to decline at larger sizes as the cost of acquiring food approaches and eventually exceeds the gain (fig. 15.22). He also argued that because of their more active foraging, the net gain curve for bullfrogs will be higher than for green frogs at any given body size (fig. 15.23). Even small bullfrog tadpoles may have a net gain that exceeds that of both large and small green frogs, leading to the asymmetric competitive effects observed in the experiments. The interactions of bullfrog and green frog tadpoles in nature are more complicated than indicated by these experiments because competition is mediated by interactions with several kinds of predators (Werner 1991; Werner and Anholt 1993, 1996; Werner and McPeek 1994; Anholt and Werner 1995; see the following discussion).

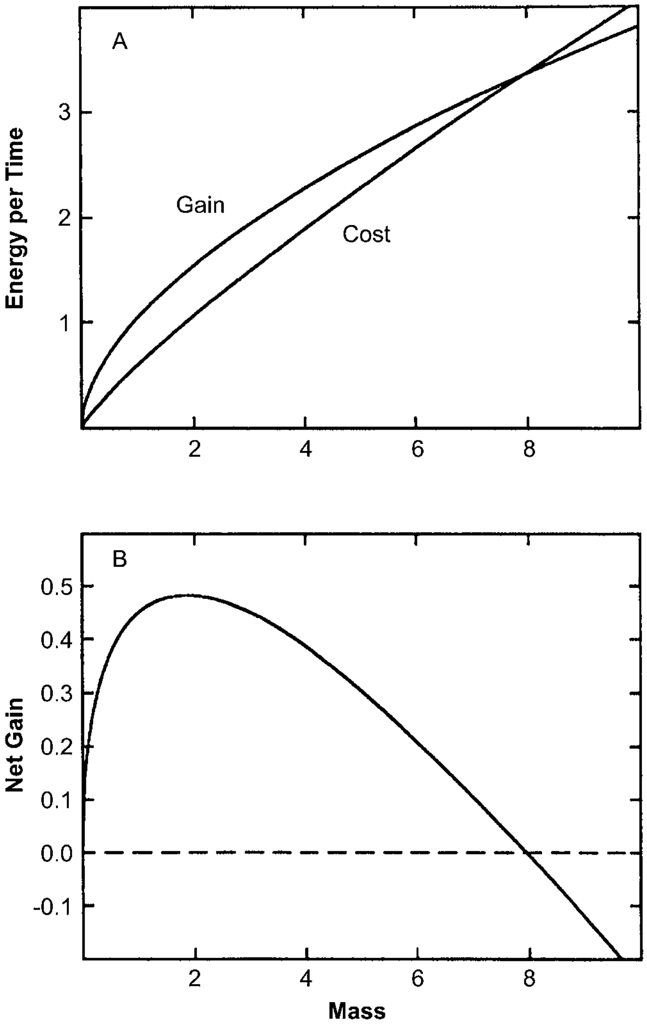

Fig. 15.22. (A) Schematic diagram of energetic costs and gains for feeding tadpoles of different body sizes. Gains exceed costs for small-bodied tadpoles, but at larger sizes, costs exceed gains, at which point the tadpole must metamorphose. (B) Net gain calculated by subtracting the cost curve in A from the gain curve. After Werner (1994).

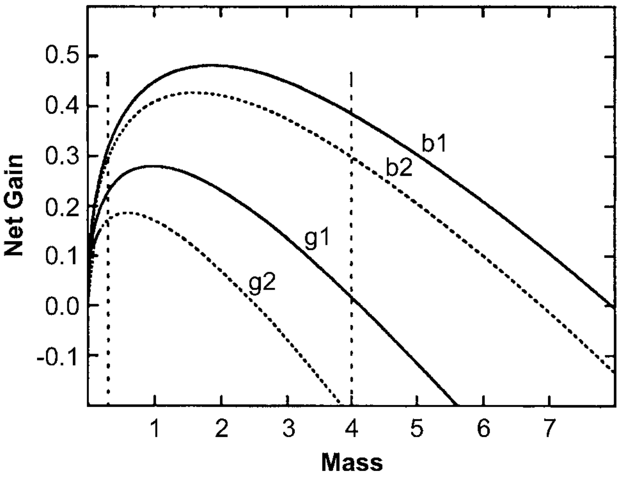

Fig. 15.23. Theoretical net gain curves for feeding bullfrog (*Rana catesbeiana*) tadpoles (b1, b2) and green frog (*Rana clamitans*) tadpoles (g1, g2), estimated as in fig. 15.22. At any given size, the more active bullfrog tadpoles are more efficient than green frog tadpoles at collecting food, so the net gain curve for bullfrogs always exceeds that of green frogs. Curves b1 and g1 are for each species in the absence of heterospecific competitors. Curves b2 and g2 are for each species in the presence of competitors. Bullfrog tadpoles have a greater negative effect on energy intake of green frog tadpoles than green frog tadpoles have on bullfrog tadpoles. Bullfrog tadpoles can depress energy intake by green frog tadpoles at both small (left vertical line) and large (right vertical line) body sizes, whereas green frog tadpoles have a significant effect only on larger bullfrog tadpoles. After Werner (1994).

Bullfrog tadpoles can be superior competitors to other species of ranids even when they are introduced into habitats not normally inhabited by bullfrogs. In California, for example, bullfrogs have been introduced into rivers inhabited by tadpoles of a native ranid, *Rana boylii*, and a hylid, *Pseudacris regilla*. In experiments with enclosures in natural streams, both large and small bullfrog tadpoles had a strong negative effect on growth and survivorship of *R. boylii* tadpoles and a significant, but weaker, effect on *P. regilla* (fig. 15.24; Kupferberg 1997a). Bullfrog tadpoles significantly reduced standing crops of algae, suggesting that exploitative competition for food was mainly responsible for the decreased performance of the other species. Bullfrog tadpoles can have other effects as well, such as predation on smaller species of tadpoles. Kiesecker and Blaustein (1997b) reported evidence for predation by introduced bullfrog tadpoles on native tadpoles of red-legged frog (*R. aurora*) in Oregon. It was not clear, however, whether this resulted from deliberate capture of tadpoles or incidental predation when the two species were feeding together. Bullfrog tadpoles also

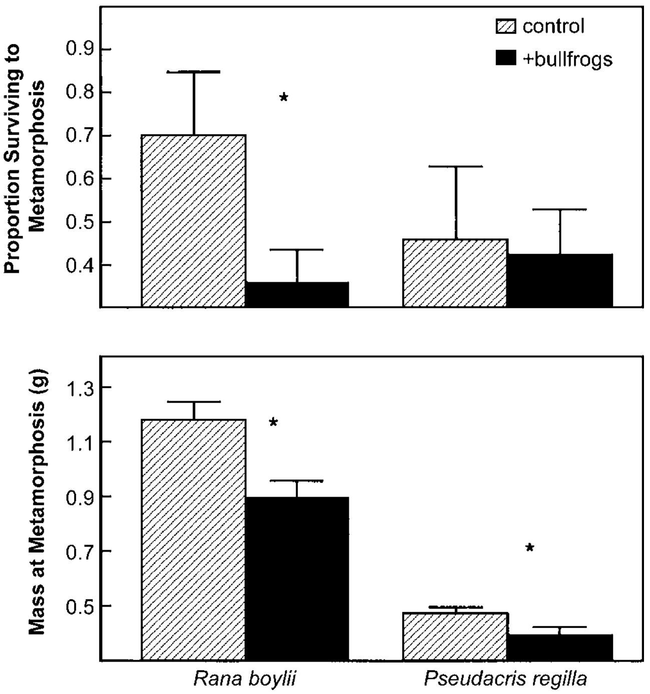

Fig. 15.24. Effect of introduced bullfrog (*Rana catesbeiana*) tadpoles on performance of *Rana boylii* and *Pseudacris regilla* tadpoles. Top: Proportion of tadpoles surviving to metamorphosis in stream enclosures with and without bullfrog tadpoles. Bottom: Mass at metamorphosis for tadpoles in enclosures with and without bullfrog tadpoles. * Indicates a significant difference. After Kupferberg (1997b).

reduce the performance of *R. aurora* tadpoles through passive interference competition, especially when food patches are clumped (Kiesecker, Blaustein, and Miller 2001).

The Effect of Phenology on Interspecific Competition

Although certain species of tadpoles consistently outcompete other species in artificial ponds, the outcome of interspecific competition can be affected by the order in which different species are introduced into the community (Alford 1999). These priority effects are assumed to mimic conditions in natural ponds, in which the order of appearance can vary from year to year because of different responses of breeding adults to environmental cues. Alford and Wilbur (1985) studied priority effects in interactions between *Bufo americanus* and *Rana sphenocephala* tadpoles by varying the presence or absence and time of introduction of each species into cattle tanks. The presence of *Rana* tadpoles had a slightly negative effect on *Bufo,* but the differences were not statistically significant. *Bufo* tadpoles had a strong negative effect on growth and survivorship of *Rana* tadpoles. However, *Rana* tadpoles did better when introduced after *Bufo,* rather than before. A possible explanation for this unexpected result is that *Bufo* tadpoles grow more quickly than *Rana;* when introduced early, they metamorphose early in the season, leaving the *Rana* tadpoles to develop without competition.

Other experiments (Wilbur and Alford 1985) showed that both *Bufo* and *Rana* tadpoles had a negative effect on those of *Hyla chrysoscelis.* The time of arrival of *Rana* tadpoles accounted for more than half the variance in the performance of *Hyla* tadpoles, but the time of arrival of *Bufo* also had a significant effect, even though most of the *Bufo* tadpoles metamorphosed before the *Hyla* were introduced. Evidently, changes in the food supply caused by grazing *Bufo* tadpoles persisted late into the season. In another experiment with *Bufo* and hylid tadpoles, Lawler and Morin (1993) varied the timing of introduction of tadpoles of *Bufo fowleri* and *Pseudacris crucifer.* In natural populations, *Pseudacris* normally breeds earlier than the toads. *Pseudacris* tadpoles were negatively affected by *Bufo* tadpoles, especially when the latter were in the pond at least a week earlier. The negative effect was reduced if *Pseudacris* was in the pond earlier or arrived at the same time as *Bufo.*

Negative effects of one species of tadpole on another sometimes occur even when the species overlap very little in the pond. For example, Morin (1987a) raised spring peeper (*Pseudacris crucifer*) tadpoles in experimental ponds at different densities and then introduced 200 newly hatched gray treefrog (*Hyla versicolor*) tadpoles into each pond shortly before the spring peepers metamorphosed. He found that high densities of spring peeper tadpoles in ponds before the introduction of gray treefrog tadpoles had a negative effect on the growth and survival of the treefrog tadpoles. The two species had little opportunity to interact directly, so this effect must have been due to depletion of food by the spring peeper tadpoles. Morin argued that in some circumstances, an earlier-breeding species might actually exclude a later-breeding species from some ponds. It is not clear how commonly this occurs in nature, however. Many ponds may be so productive that even high densities of tadpoles early in the season do not deplete food resources for later species. For example, large populations of spring peepers and gray treefrogs frequently breed in the same ponds, and may even overlap in breeding seasons (Collins and Wilbur 1979; personal observations).

Very little experimental work has been done with tadpoles in tropical habitats. However, Gascon (1992b) studied interactions among the three most common species of tadpoles in temporary ponds in Amazonian Brazil, including the importance of priority effects. One of the first species to breed is a large hylid, *Osteocephalus taurinus,* which usually lays eggs soon after a pond fills. A second hylid, *Phyllomedusa tomopterna,* lays eggs on vegetation overhanging ponds, and its tadpoles usually appear after *Osteocephalus* is present. Tadpoles of a dendrobatid, *Allobates* *femoralis,* typically appear later as well, having been carried to water by adults from a terrestrial nest site (Gascon 1992a). In this system, the earliest-arriving species, *Osteocephalus,* did well regardless of when it arrived or what other species were present. *Phyllomedusa,* on the other hand, performed relatively poorly when *Osteocephalus* was already present, while *Allobates* tadpoles always did poorly in the presence of *Osteocephalus.* This study suggests that *Phyllomedusa* may gain some competitive advantage by breeding early, but *Osteocephalus* gains relatively little advantage from its early breeding.

Mechanisms of Interspecific Competition

The precise mechanisms of competition between species of tadpoles are not fully understood. Most studies have focused on exploitative competition and depletion of food resources by superior competitors; several of the studies already mentioned have found evidence that this occurs. Most of the evidence for exploitative competition is based on the effects of high densities of one species on the performance of another. As discussed in chapter 13, there is considerable evidence that food is often limiting in natural tadpole habitats, with substantial reductions in algal biomass as a result of tadpole grazing (Dickman 1968; Seale, Rodgers, and Boraas 1975; Seale 1980; Lamberti et al. 1992; Kupferberg 1997a; Graham and Vinebrooke 1998; Holomuzki 1998; Mallory and Richardson 2005). In most cases, however, there is little information on the degree to which two or more species in a community actually exploit the same resources.

It also is possible that interference competition occurs in some situations. Faragher and Jaeger (1998) reported that tadpoles of *Rana sphenocephala* inhibited feeding and reduced growth rates of *Hyla cinerea* tadpoles by physically harassing the smaller species in laboratory aquaria. It is not clear from their observations, however, whether such interactions represent aggression by the larger tadpoles or an incidental effect of actively foraging for food in the confines of an aquarium. The behavior of the tadpoles was similar to that interpreted as predatory behavior in interactions between *Rana catesbeiana* and *R. aurora* tadpoles in field enclosures (Kiesecker and Blaustein 1997b). Kupferberg (1997a) reported that she found no evidence of behavioral interactions between bullfrog tadpoles and those of two native species in California. In contrast, Kiesecker, Blaustein, and Miller (2001) reported that interference by *R. catesbeiana* tadpoles decreased survivorship and size at metamorphosis in *R. aurora* tadpoles in ponds in Oregon when food was clumped. The displacement of *Crinia signifera* tadpoles from choice feeding spots in flowing water by *C. riparia* tadpoles is another possible example of interference competition (Odendaal, Bull, and Richards 1984). Overall, however, there is relatively little evidence that behavioral interference is a widespread mechanism of interspecific competition among tadpoles in the field.

Interference competition also could occur through growth inhibition mediated by chemicals released in tadpole waste products, or by organisms such as yeast and algae. The possible role of growth inhibitors in mediating growth of tadpoles crowded together with conspecifics is discussed in chapter 13, and Alford (1999) reviewed the evidence for growth inhibitors being important in interspecific competition. Much of the evidence for interspecific growth inhibition comes from laboratory studies in which tadpoles were raised in crowded conditions (e.g., Beebee 1991). Neither Morin and Johnson (1988) nor Petranka (1989b) found any evidence of such inhibition in artificial or natural ponds. In contrast, workers studying competition between tadpoles of *Bufo calamita* and *Rana temporaria* in England reported significant inhibition of growth in *Bufo* tadpoles that were exposed to *Rana* feces in relatively small artificial ponds (2 meters × 1 meter; Griffiths, Edgar, and Wong 1991; Griffiths, Denton, and Wong 1993) and natural sand dune ponds (Bardsley and Beebee 2001). They identified an unpigmented unicellular alga (*Anurofeca* [= *Prototheca*] *richardsi*) in the tadpole feces that apparently is not toxic to tadpoles (Wong and Beebee 1994). However, when algal cells were abundant in the water, tadpoles fed on them but derived relatively little nutritional benefit. Growth inhibition would then occur because of tadpoles being diverted away from more profitable food (Beebee and Wong 1992). It is not yet clear, however, whether this mechanism of interspecific competition is widespread or important in natural populations of other anurans (Beebee 1995b; Griffiths 1995; Petranka 1995).

Competition Mediated by Other Organisms

In addition to the organisms implicated as growth inhibitors of tadpoles, other types of organisms can have an effect on competition between species of tadpoles. Among the organisms that can have such effects are predators, and these are discussed in a separate, subsequent section. Less is known about the impact of pathogens and parasites on interspecific competition. Kiesecker and Blaustein (1999) reported an example of competition mediated by a pathogenic fungus. In the western United States, the eggs of amphibians are subject to infection by a water mold, *Saprolegnia ferax* (fig. 15.25), and some species are more susceptible to infection than others. The eggs of Cascades frogs (*Rana cascadae*), for example, are highly susceptible to this fungus, whereas those of the Pacific treefrog (*Pseudacris regilla*) are not (Blaustein et al. 1994). The effect of the fungus on *R. cascadae* is exacerbated by high levels of ultraviolet radiation in shallow water (Kiesecker and Blaustein 1995; Kiesecker,

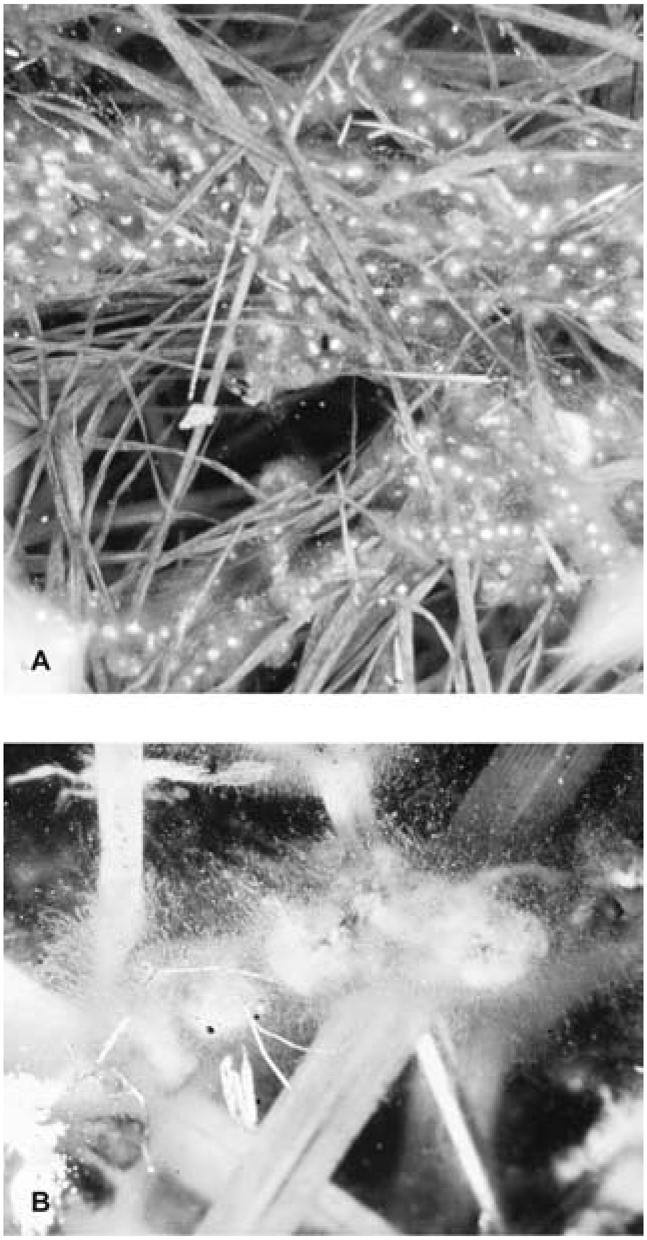

Fig. 15.25. Eggs of *Bufo boreas* infected with a water mold, *Saprolegnia ferax*. (A) Communal mass of toad eggs infected with the mold. (B) Close-up of individual infected embryos. Photos by Joseph M. Kiesecker.

Blaustein, and Belden 2001). Kiesecker and Blaustein (1999) raised eggs and tadpoles of these two species through metamorphosis in experimental ponds with and without the fungus, either alone or in competition with each other. In the absence of the fungus, survivorship and mass at metamorphosis were reduced for *Hyla* tadpoles that were raised with *Rana,* while the time to metamorphosis was increased. When the fungus was present, it killed many *Rana* embryos, and this resulted in much lower densities of *Rana* tadpoles and dramatically reduced survivorship to metamorphosis. The *Hyla* tadpoles in these ponds enjoyed reduced competition from *Rana* and had higher survivorship, larger mass at metamorphosis, and shorter larval periods.

Competition and Pond Hydroperiod

Interspecific competition also can be mediated by physical factors in the environment. Probably the most important of these is pond hydroperiod. Competition among tadpoles generally has the effect of slowing growth rates and increasing the length of the larval period. This can affect survival to metamorphosis if the pond is subject to frequent drying, because tadpoles with long larval periods may not make it out of the pond before the water disappears. Wilbur (1987) investigated the interaction among competition, pond drying, and predation in experimental ponds stocked with four species of tadpoles *(Rana sphenocephala, Scaphiopus holbrookii, Bufo americanus,* and *Hyla chrysoscelis*) at different densities. All species exhibited reduced growth rates, prolonged larval periods, and smaller size at metamorphosis in response to high densities of competitors. Nevertheless, the species differed in their sensitivity to density effects. *Scaphiopus holbrookii,* a species that normally breeds in ephemeral ponds, was the least sensitive, and grew rapidly even at high tadpole densities. Under the pond-drying regime of the experiments, most tadpoles of this species reached metamorphosis before the ponds dried. *Rana* tadpoles, on the other hand, had slow growth rates at all densities and were very sensitive to density effects. These tadpoles never survived in ponds that dried early. *Bufo* tadpoles grew rapidly and could survive in drying ponds, but they tended to be outcompeted by *Scaphiopus* tadpoles. *Hyla* tadpoles did poorly in ponds that did not dry, because of intense interspecific competition. Responses to competition and pond drying were altered when predatory newts were present; that aspect of the study is discussed in more detail in a later section.

Semlitsch and Reyer (1992b) examined the interaction between competition and pond drying in a study of the *Rana esculenta* complex. As mentioned previously, hybrid tadpoles generally are competitively superior to the parental genotypes, and this was especially true when ponds were subjected to a drying treatment. Survivorship of *R. lessonae* tadpoles was considerably lower than that of *R. esculenta* tadpoles in ponds that dried, but the reverse was true for ponds that did not dry. Body size at metamorphosis was smaller for all genotypes for ponds that dried than for those that did not.

Competition and Pond Acidity

Another feature of the physical environment that could affect competition among tadpole species is water acidity (pH). Some anurans live in naturally acidic water, such as that found in bogs or pine barrens, and certain species may be more tolerant of acidic conditions than others. There also is evidence for variation among populations of the same species in the ability of embryos or larvae to tolerate acid conditions (Andrén, Marden, and Nilson 1989; Glos et al. 2003). Human activities have lowered the pH of some bodies of water because of acid rain, and this has the potential to change the species competition of anuran communities. Warner, Dunson, and Travis (1991), and Warner, Travis, and Dunson (1993) studied the effect of pH on competition between tadpoles of *Hyla gratiosa* and *H. femoralis.* The latter tends to be found in more acidic environments. Tadpoles of *H. gratiosa,* the larger species, usually were competitively superior to those of *H. femoralis* and reduced the size of the latter at metamorphosis. When the tadpoles were raised together in moderately acidic water (pH 4.5), the negative effects of *H. gratiosa* on *H. femoralis* were reduced, suggesting that acidity gave *H. femoralis* a slight competitive advantage. These results contrast with those of Pehek (1995), who studied the Pine Barrens treefrog (*Hyla andersonii*), a species restricted to acidic habitats. Competition from tadpoles of *Rana sphenocephala* reduced both survivorship and mass of *H. andersonii,* while competition from *Hyla versicolor* only reduced body mass. Variation in pH did not have any direct effect on the three species, nor did it affect the outcome of interspecific competition. This means that enhanced competitive ability of tadpoles in acidic environments cannot explain the distribution of *H. andersonii.*

Competition and Canopy Cover

Yet another physical factor that could modify competition between species of tadpoles is canopy cover. Certain species of frogs tend to breed in relatively open sites, whereas others often are found in woodland ponds with relatively closed canopies. Natural succession of habitats, such as the growth of woodlands in areas that once were more open, may cause shifts in the relative abundance of different amphibian species (Skelly, Werner, and Cortwright 1999). In particular, species that prefer open habitats may be gradually excluded from ponds as canopy cover and the frequency of drying increase. There are a number of possible reasons for these shifts in species distributions, including changes in the suitability of the ponds for either the eggs or the tadpoles of particular species. For example, differences in canopy cover are likely to be correlated with differences in light availability, water temperature, oxygen content, water pH, algal productivity or species composition, and the type and abundance of predators. Closed-canopy ponds also tend to dry up earlier in the year because of the water demands of the surrounding trees. In general, relatively few North American amphibian species are regularly found in closed-canopy ponds, although some species, such as wood frogs (*Rana sylvatica*) and some species of *Ambystoma* do well in such habitats. Canopy cover may have a strong influence on amphibian species composition in tropical communities as well, but this has not been studied explicitly. There is little overlap in species composition of anuran assemblages in savanna and interior forest ponds in Amazonian Brazil, for example (Gascon 1991; Azevedo-Ramos, Magnusson, and Bayliss 1999), although both types of assemblages include a variety of hylids and leptodactylids. A reasonable hypothesis for future testing is that species distributions are related to relative performance of tadpoles in these very different habitats.

Using the survey of natural ponds by Skelly, Werner, and Cortwright (1999) as background, Werner and Glennemeier (1999) examined the performance of *Rana sylvatica, R. pipiens,* and *Bufo americanus* tadpoles in enclosures placed in open-canopy and closed-canopy ponds. The open-canopy ponds were warmer, had higher levels of dissolved oxygen, and were more productive than the closed-canopy ponds, but did not differ in pH. Closed-canopy ponds provided relatively poor-quality food for tadpoles in the form of leaf detritus and the organisms that break down dead leaves, such as fungi and bacteria, but did not support macrophytes. All three species grew rapidly and had high survivorship in the open-canopy ponds, although leopard frog tadpoles had the highest growth rates. Both leopard frog and toad tadpoles grew slowly and had very low survivorship in closed-canopy ponds. Wood frog tadpoles had high survivorship and slightly higher growth rates than the other two species in closed-canopy ponds. In open-canopy ponds, there was strong asymmetric competition between wood frog and leopard frog tadpoles, with the former being the superior competitors. In closed-canopy ponds, leopard frog tadpoles did so poorly that the presence of wood frog tadpoles had little effect. The growth and survival of leopard frog tadpoles in closed-canopy ponds was increased dramatically by the addition of supplemental food, but food addition had no effect on wood frog performance. These experiments demonstrated that both American toads and leopard frogs are effectively excluded from closed-canopy ponds by the poor performance of their tadpoles, probably because of inadequate food resources. Wood frog tadpoles did well in both types of ponds, and in fact, regularly breed in both types of ponds (Skelly, Werner, and Cortwright 1999). Similar observational and experimental studies have shown that spring peeper (*Pseudacris crucifer*) tadpoles do poorly in closed-canopy ponds and are generally excluded from such habitats, whereas wood frog tadpoles are found in both open- and closed-canopy ponds (Skelly et al. 2002; Halverson et al. 2003).

Interaction between Competition and Predation in Tadpole Communities

The experiments discussed so far were mostly conducted in the absence of major predators, a situation that is unlikely to occur in nature except in the most ephemeral rain pools. Predators can be an important component of any community because they can directly impact the survivorship of prey species and potentially alter their competitive interactions. In addition, predators can have indirect effects on prey species that may affect their competitive ability. For example, some prey species may alter their levels of activity or use of microhabitats in response to predators (see chapter 14), and this in turn can affect the rate at which they acquire food. The direct and indirect effects of predators on prey species can affect the overall diversity of a community by enabling competitively inferior species to prosper at the expense of superior competitors. Predators also can have beneficial effects on individuals lucky enough not to be eaten, because they remove competitors and increase resource availability for the survivors (Wilbur 1997).

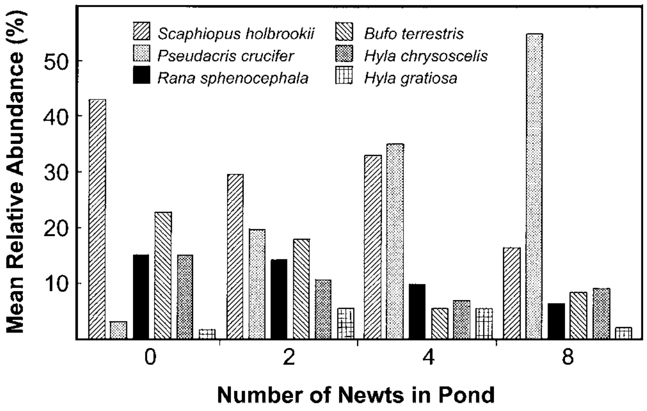

Fig. 15.26. Survival of six species of tadpoles in experimental ponds (cattle tanks) as a function of the density of predatory adult *Notophthalmus viridescens.* Tadpoles of each species were initially stocked at densities designed to reflect those found in natural temporary ponds. After Morin (1983a).

Salamander Predation in Artificial Pond Communities

Starting in the 1980s, Henry Wilbur and his students investigated the role of predators in regulating the structure and dynamics of temporary pond communities, using replicated model communities in cattle tanks to simulate conditions in natural, temporary ponds. These investigators focused on the assemblage of anuran species that occurs on the United States' southeastern coastal plain, with the broken-striped newt (*Notophthalmus viridescens dorsalis*) used as the principal predator (Wilbur 1984, 1987, 1997). A classic series of experiments by Peter Morin set the stage for this line of investigation. In the first set of experiments, six species of tadpoles were introduced into experimental ponds at fixed densities that were thought to reflect typical relative abundance in natural ponds (Morin 1981, 1983a). The tadpoles were introduced in a sequence that preserved the natural phenology of local ponds. Morin varied the intensity of predation by controlling the density of larval salamanders (*Ambystoma tigrinum*) and adult broken-striped newts (*Notophthalmus viridescens dorsalis*). Since the *Ambystoma* larvae eliminated nearly all of the tadpoles from the ponds, only the results with newts as predators were informative.

As expected, the presence of predators greatly reduced overall tadpole survivorship. However, the most dramatic result of the experiments was a reversal in the competitive success of certain species correlated with the density of predators (fig. 15.26). When predators were absent, the species most successful in surviving to metamorphosis were *Scaphiopus holbrookii* and *Bufo terrestris;* these showed dramatic declines with increasing predator density. In contrast, *Pseudacris crucifer* produced almost no metamorphosing young when predators were absent, but showed a dramatic increase in relative success as the numbers of newts increased. Performance of other species, such as *Hyla gratiosa,* was greatest at intermediate predator densities, but was low for all treatments. For several species, size at metamorphosis increased with increasing predator density, while growth rates were inversely related to the density of other tadpole species. This suggested that interspecific competition was occurring. *Pseudacris crucifer* was at a competitive disadvantage compared to other species when predators were absent, but increased predation on the other species enhanced both survivorship and growth in this species. Later experiments showed that *Notophthalmus* did not enhance survivorship of *P. crucifer* tadpoles in the absence of other tadpole species, indicating that the effect of the predator depends on the composition of the tadpole community (Morin 1986). These experiments showed that newts function as keystone predators in the community, because they fundamentally alter the outcome of competition among species of tadpoles. Some species, such as *Pseudacris crucifer,* might not be able to persist with competitively superior species if predators were absent. In other words, the presence of predators is one mechanism that maintains high species diversity in temporary pond communities (Wilbur 1984, 1987, 1997).

In his experiments, Morin (1983a) inferred that competition was occurring by correlating growth performance with final densities of emerging metamorphs. Even stronger evidence for interspecific competition was obtained in another series of experiments, in which both predator density and the density of three tadpole species (*Rana sphenocephala, Bufo terrestris,* and *Scaphiopus holbrookii*) were varied independently (Wilbur, Morin, and Harris 1983). In the absence of predators, *Bufo* tadpoles had strong negative effects on the growth and survivorship of *Scaphiopus* and the growth of *Rana* tadpoles. Predatory newts reduced survivorship in all species, but *Bufo* and *Scaphiopus* tadpoles were virtually eliminated at high newt densities, whereas the larger *Rana* tadpoles were less affected. This freed the *Rana* tadpoles from interspecific competition and resulted in larger sizes at metamorphosis. In fact, the number of newts accounted for nearly two-thirds of the variation in growth rate of *Rana* tadpoles.

The differences in competitive ability and performance in the presence of predators observed in these experiments probably are related mainly to differences in feeding rate and vulnerability to predation. For example, Morin (1983a) found that newts and *Ambystoma* larvae preferred to feed on *Bufo* and *Scaphiopus* tadpoles when they were presented in combination with various hylid and ranid tadpoles, probably because these species are very active and conspicuous when they feed. Most other tadpoles were eaten indiscriminately as they were encountered, but *Rana sphenocephala* tadpoles were actively avoided. This agrees with other observations and experiments indicating that some ranid tadpoles are distasteful to vertebrate predators (Walters 1975; Formanowicz and Brodie 1982; Woodward 1983).

The effects of newts on tadpole communities can be affected by a number of variables, including pond hydroperiod, the phenology of the predator, and interactions with other types of predators. In a rather complex set of experiments, Wilbur (1987) examined competition between *Rana sphenocephala, Bufo americanus, Scaphiopus holbrookii,* and *Hyla chrysoscelis,* at high and low density, with tadpoles subjected to both newt predation and a drying regime. At low density, all species did poorly because of predation. At high density, the competitive dominant, *Scaphiopus,* faired poorly with newts present, while *Bufo* tadpoles did better relative to the other species. *Rana* did relatively poorly as well, because they were the first to be introduced and were subject to predation by newts before alternative prey (zooplankton) were available. When ponds dried at either 50 or 100 days, the two species with short larval periods (*Scaphiopus* and *Bufo*) were the most successful. *Scaphiopus* was the most successful species when newts were absent, but *Bufo* was the most successful when newts were present. Wilbur's experiments showed that pond hydroperiod, competition, and predation all interact to determine the metamorphic success of different species in a community. Rapid pond drying tended to favor species with short larval periods, which also are the most tolerant of high densities (*Scaphiopus* and *Bufo*), but predation determined which species was most successful. *Rana* tadpoles did not survive well in drying ponds because of their slow growth rates, but they also were strongly affected by competition and newt predation. *Hyla* tadpoles also were relatively poor competitors and were highly susceptible to both pond drying and newt predation. Predation can improve the performance of some species, such as *Bufo,* by reducing the density of competitors and increasing growth rates, which would be especially advantageous if ponds dry.

The phenology of predators also can affect tadpole performance. Alford (1989c) examined competitive interactions between the same four species of tadpoles used by Wilbur (1987), with newts present for different periods of time. Some ponds lacked newts, but others had newts present from the beginning of the experiment. Among the latter group, there were ponds from which all newts were removed after nine days or 51 days, and others from which newts were never removed. As in previous experiments, *Scaphiopus* tadpoles tended to dominate ponds that lacked newts. Whenever newts were present early in the larval period of the various anurans the survivorship of the tadpoles was reduced, and the longer newts were present, the greater the effect on tadpole survivorship. Some species, particularly *Rana* and *Scaphiopus,* were virtually eliminated by newt predation when initial tadpole densities were low. At high densities, some tadpoles of each species usually survived when predators were present. The number of *Bufo* and *Hyla* tadpoles was reduced by prolonged exposure to newts, but their relative success increased when predators were present. Later- breeding species (*Bufo, Hyla*) did better when predators were initially present and then removed, because the predators decreased the numbers of tadpoles of earlier-breeding species. Early breeders (*Rana, Scaphiopus*), on the other hand, did better when predators were present throughout the experiment. These species eventually grew to a size at which they were less vulnerable to newt predation, and the continued presence of newts reduced the numbers of their competitors.

Newts are seldom the only predators in temporary ponds, and interactions with other predators could affect the impact of newts on tadpole communities. Fauth and Resetarits (1991) exposed a five-species assemblage of tadpoles (*Rana sphenocephala, Pseudacris crucifer, Bufo americanus, Hyla chrysoscelis,* and *Gastrophryne carolinensis*) to predation from newts at two densities (two or four per tank), either in the presence or absence of one *Siren intermedia.* In this system, *Gastrophryne* and *Rana* tadpoles dominated tanks without any predators, with *Pseudacris* and *Hyla* doing relatively poorly. Even a few newts virtually eliminated *Gastrophryne* tadpoles and greatly increased the relative performance of *Pseudacris.* Sirens were unselective predators on tadpoles, and the presence of one *Siren* in a tank decreased the abundance of all species but did not have a very large impact on the relative proportions of each species (fig. 15.27). Clearly, sirens and newts are not functionally equivalent in their effects on tadpole communities.

A subsequent study by Chalcraft and Resetarits (2003) investigated the effects of three species of fish and three species of salamanders on three species of tadpoles (*Bufo terrestris, Pseudacris crucifer,* and *Rana sphenocephala*). The various types of predators had quite different effects on the

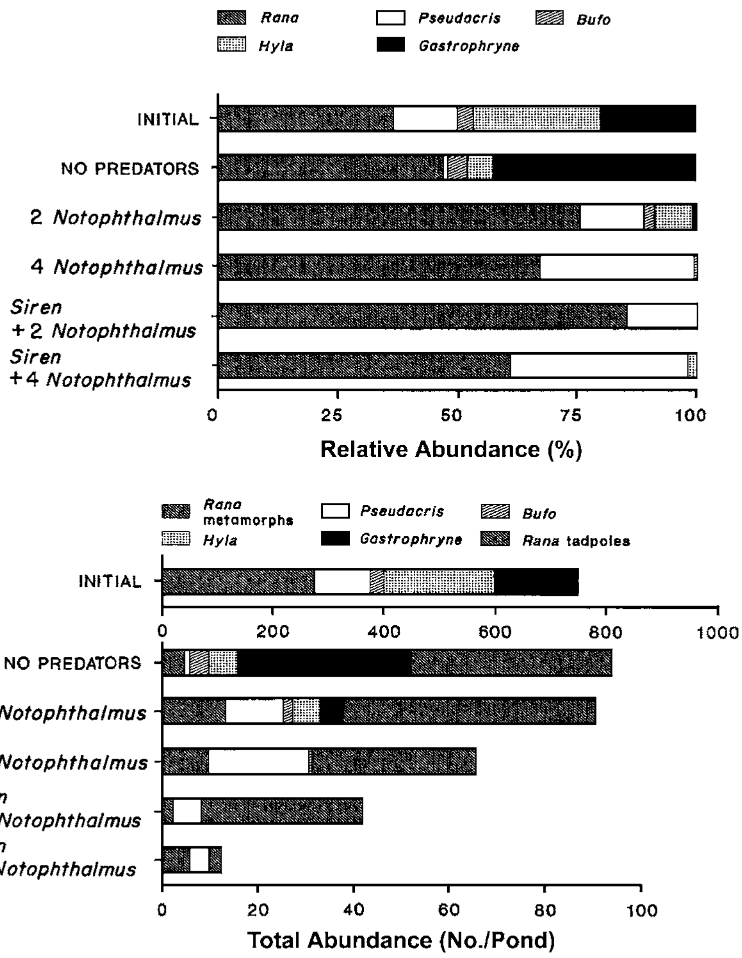

Fig. 15.27. Effect of two predators, broken-striped newts (*Notophthalmus viridescens dorsalis*) and sirens (*Siren intermedia*) on the composition of tadpole communities in artificial ponds (cattle tanks). Tadpole species were introduced on a schedule that reflected natural breeding times and in relative abundances that mirror those of natural ponds. Each bar represents the mean of five replicate populations. Top: Relative initial abundance of each species of tadpole and relative abundance of metamorphs or overwintering tadpoles (*Rana sphenocephala* only) in ponds without predators and those with different combinations of the two predators. Bottom: Total absolute abundance of tadpoles. The presence of predators favored tadpoles of *Rana sphenocephala* and *Pseudacris crucifer,* while total abundance of all tadpoles was progressively reduced with increasing numbers of predators. After Fauth and Resetarits (1991).

survivorship and growth rates of the three species of tadpoles. One fish species, the banded sunfish (*Eneacanthus obesus*), reduced survivorship of all tadpole species dramatically, and one other, the eastern mud minnow (*Umbra pygmaea*) strongly affected both *Rana* and *Pseudacris,* but not *Bufo*. There was little consistency in the effects of the other predator species, however, suggesting that these predators were not functionally equivalent in their effects on tadpole community structure.

Salamander Predation and Tadpole Communities in Natural Ponds

The experiments done with tadpoles and predators in cattle tanks have been designed as model communities to ask basic questions about processes affecting community structure and dynamics. They have not been designed to explain exactly what happens in particular natural ponds (Morin 1998). On the other hand, these experiments are assumed to reflect processes that occur in nature. Resetarits and Fauth (1998) attempted to link studies in experimental ponds with the structure of natural communities by examining correlates of larval species diversity in Carolina bays. Based on previous work in experimental ponds, they made several predictions about the diversity of larval communities in natural ponds. First, when predators are scarce, high larval densities should result in low species diversity, because superior competitors will tend to dominate the ponds. Second, ponds with newts present should have higher species diversity than those without newts, because of the keystone effect of this predator. Third, ponds with sirens should have higher species diversity than those without sirens, because unselective predation will reduce overall competition. Finally, ponds with both predators present should have the highest diversity, because unselective predation by sirens would tend to broaden the range of densities over which the keystone effect of newts could operate. This is because high larval densities will tend to swamp out keystone predators, whereas very low densities could result in the virtual elimination of most species by predators. All of these predictions also should be affected by pond hydroperiod, because species with long larval periods will be excluded from the most temporary ponds.

Resetarits and Fauth (1998) found that pond hydroperiod, the presence of sirens, and the density of tadpoles each explained about a third of the variation in amphibian species diversity. The most surprising result is that the presence of newts had little effect on anuran diversity (fig. 15.28). This is inconsistent with the conclusion from experimental studies that this is a keystone predator in tadpole communities. The reasons for this are not clear. One possibility is that the presence of sirens is necessary for the keystone effect of newts in large ponds like Carolina bays. It also is possible that newts play a keystone role in smaller temporary ponds, which generally lack sirens, and which may be more similar to the conditions in the experimental ponds.

A different subspecies of newt, *N. v. louisianensis,* occurs in Carolina bays and other temporary ponds on the coastal plain of South Carolina. Fauth (1999a) conducted a survey of natural ponds similar to that done by Resetarits and Fauth (1998) in North Carolina, and attempted to identify keystone predators by correlating amphibian species diversity with predator presence or absence. Potential predators in these ponds included newts, which were not very abundant, sirens, and either larvae or paedomorphic adults of another salamander, *Ambystoma talpoideum.* There also were several predatory fishes and insects in some ponds. Only *Ambystoma* had a strong effect on amphibian species diversity, suggesting that this species is a keystone predator, whereas newts and sirens are not. Unfortunately, in the absence of experimental work on this system, any explanations for patterns of species diversity in relation to predators remain somewhat speculative. Fauth's interpretation is consistent with experimental work by Morin (1995) in New Jersey showing that larvae of another ambystomatid, *Ambystoma opacum,* can play a role similar to newts in temporary ponds. The experiments by Chalcraft and Resetarits (2003) showed that both *A. opacum* and *Notophthalmus* had a relatively strong effect on community structure by virtually eliminating *Bufo* tadpoles while increasing the relatively success of the less competitive *Pseudacris crucifer* tadpoles. Other experiments by Kurzava and Morin (1994) suggest that geographic variation in the size of newts of different subspecies can result in somewhat different effects on tadpole communities.

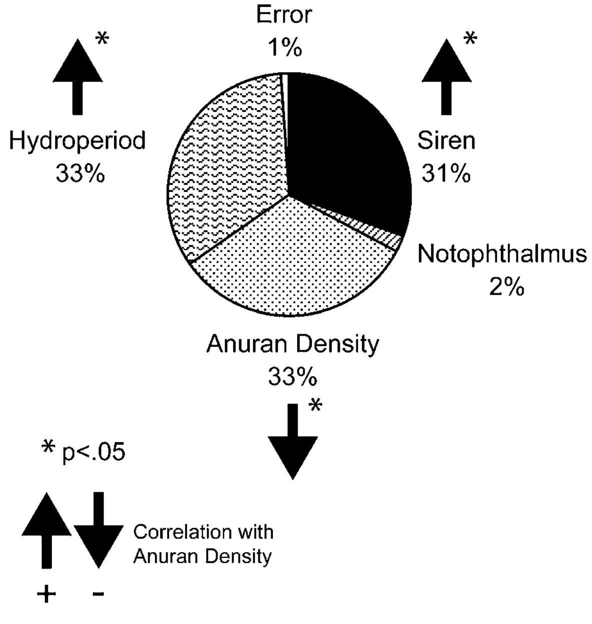

Fig. 15.28. Results of a four-factor regression analysis of tadpole species richness in seven Carolina Bays. Each segment of the pie diagram shows the proportion of variance in number of tadpole species explained by each factor (pond hydroperiod, tadpole density, number of sirens present, and numbers of newts). All factors together explained 99.7% of the variance in number of anuran species inhabiting the ponds. After Resetarits and Fauth (1998).

Insect Predation and Tadpole Communities in Artificial Ponds

The survey of natural ponds by Fauth (1999a) suggested that dragonfly naiads of one species, *Tramea carolina,* play a weak keystone role similar to that of salamander larvae. Indeed, predatory insects are common in many kinds of temporary ponds that lack newts or other salamanders. There have been many studies of the responses of individual amphibian species to insect predators (see chapter 14), but fewer dealing with the role of insect predators in mediating interspecific competition in temporary ponds. Van Buskirk (1988) performed experiments with temporary ponds like those used for the experiments with newts. The ponds were stocked with four species of tadpoles (*Pseudacris triseriata, P. crucifer, Rana sphenocephala,* and *Bufo americanus*), either without predators or with two species of dragonfly naiads (*Tramea carolina* and *Anax junius*), alone or together. The dragonflies reduced the abundance of all species, but relative abundance changed when predators were present. Metamorphosing juveniles were predominantly *Bufo* when predators were present, especially when both predators were present. *Rana* tadpoles seldom reached metamorphosis in the absence of predators, largely because competition from other species slowed their growth rates and they did not reach metamorphosis before the ponds dried. Some *Rana* did reach metamorphosis when one predator species was present, presumably because of reduced competition, but very few survived when both species were present. Survivorship of both species of *Pseudacris* was low when either predator was present, and they were eliminated from ponds with both species present. *Pseudacris triseriata* survived in low numbers when one dragonfly species was present, but *Tramea* eliminated *Pseudacris crucifer.* This result contrasts with the results of experiments with newts, which showed that *P. crucifer* is less susceptible to newt predation than are other species.

Competition, Predation, and the Hydroperiod Gradient

While investigators coming from the Wilbur laboratory have focused most of their attention on competition and predation in artificial pond communities, those from Earl Werner's laboratory in Michigan have used a somewhat different approach. These investigators have focused on differences in the array of predators found in ponds along the gradient from ephemeral vernal pools to permanent ponds and their effects on the structure and dynamics of tadpole communities (Wellborn, Skelly, and Werner 1996; Skelly 1997). Furthermore, the experiments with cattle tanks have been designed to test general predictions about ecological processes and have only secondarily been applied to patterns of species distribution and abundance in natural ponds (Resetarits and Fauth 1998; Fauth 1999a). In contrast, members of the Werner laboratory have started with patterns of species distribution across a gradient of natural ponds and then have designed experiments to determine which factors account for these patterns (Skelly 1997; Werner 1998). Two types of interactions have been investigated in detail: the distribution of two species of *Pseudacris* along the pond permanence gradient, and interactions between green frogs (*Rana clamitans*) and bullfrogs (*R. catesbeiana*) in permanent ponds.

Interactions between Spring Peepers and Chorus Frogs

In southern Michigan, both spring peepers (*Pseudacris crucifer*) and striped chorus frogs (*P. triseriata*) breed in early spring. A survey of 22 natural ponds showed that *P. triseriata* tadpoles were found only in temporary ponds (Skelly 1996). *Pseudacris crucifer* tadpoles were found in all types of ponds, but they were least abundant relative to *P. triseriata* in temporary ponds (fig. 15.29 A). These ponds differed not only in drying regime, but also in the array of predators present. Permanent ponds sometimes contained fish, but dragonfly naiads were the most abundant predators. Fish were never found in temporary or intermediate ponds, but both larval salamanders (*Ambystoma tigrinum, A. laterale*) and adult salamanders (*Notophthalmus viridescens*) were found there, along with a variety of insect predators (fig. 15.29 B). In addition, predators tended to be larger in the more permanent ponds, even within predator categories (beetles, dragonflies, and salamanders).

Skelly (1995a) performed a transplant experiment in which tadpoles of each species were placed in enclosures at natural densities in temporary, intermediate, and permanent ponds, with some enclosures stocked with predators normally found in those ponds. The experiment showed that spring peeper tadpoles were more likely to survive to metamorphosis and reached a larger size at metamorphosis in permanent and intermediate ponds, whereas chorus frogs showed the reverse pattern (fig. 15.30). Chorus frogs had faster growth rates and were more likely to metamorphose from temporary ponds before these dried, whereas the slower-growing spring peepers sometimes were killed by desiccation. On the other hand, chorus frog tadpoles fared poorly in permanent ponds with abundant predators, apparently because their higher level of activity makes them more vulnerable to predation (Skelly 1994). In contrast to most of the experiments done in artificial ponds or in the laboratory, there was little evidence of strong interspecific competition between the two species of tadpoles. Hence, it appears that differential susceptibility to drying ponds and predation combine to determine the distribution of these two species.

Skelly's results are consistent with earlier experiments performed with *P. triseriata* in natural rock pools along the shore of Isle Royale, in Lake Michigan. D. C. Smith (1983) found that pools near the lakeshore were relatively small and most likely to dry quickly, but contained relatively few predators. Those close to the forest edge tended to be larger and more permanent, but also contained predators, including dragonfly naiads (*Anax junius*) and salamander larvae (*Ambystoma laterale*). *Pseudacris triseriata* tadpoles were highly susceptible to predation by dragonflies and were effectively eliminated from permanent ponds by predation. They also did poorly in the most temporary ponds because the ponds often dried up. They were most likely to survive in intermediate ponds that usually did not dry, but were too small to support large populations of predators. A later study (D. C. Smith and Van Buskirk 1995) examined interactions between chorus frog tadpoles in the same population and spring peepers, which occurred at low density in the more permanent ponds with predators. Tadpoles of each species were placed in pools along the permanence gradient. Both species had low survivorship in the permanent ponds with predators, but only chorus frog tadpoles did well in more temporary ponds with few predators. Again, this was mainly due to the faster growth rate and shorter larval period of chorus frog tadpoles. As in Skelly's experiment, there was no evidence of strong competition between the two spe-

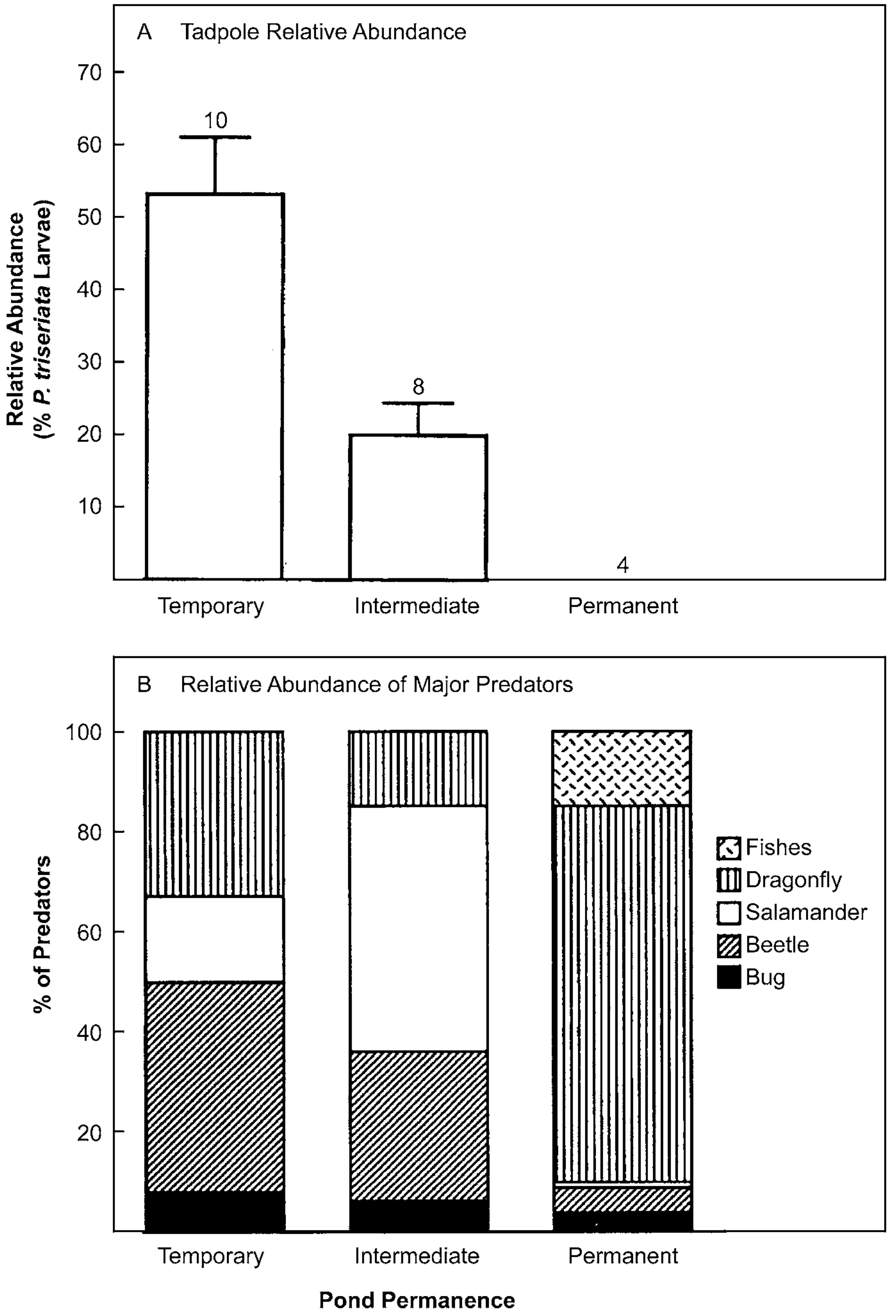

Fig. 15.29. Distribution of *Pseudacris* tadpoles and predators in three types of ponds in Michigan. (A) Percentage of tadpoles that were *Pseudacris triseriata* (the remainder were *P. crucifer*). (B) Relative abundance of major predators in three types of ponds. After Skelly (1996).

cies. Overall, these experiments indicate that *P. triseriata* has life-history traits that are well suited to temporary ponds with few predators, including a high level of activity and fast growth. *Pseudacris crucifer,* on the other hand, is less active and grows more slowly, making it poorly adapted to ponds that dry early, but their lower level of activity makes them less susceptible to predators in more permanent ponds.

Interactions between Bullfrogs and Green Frogs

Interactions between bullfrog (*Rana catesbeiana*) and green frog (*R. clamitans*) tadpoles are different from the interactions between the two species of *Pseudacris.* Both of these species live in permanent and semipermanent ponds, because their long larval periods preclude the use of temporary ponds. Green frogs are more likely than bullfrogs to be

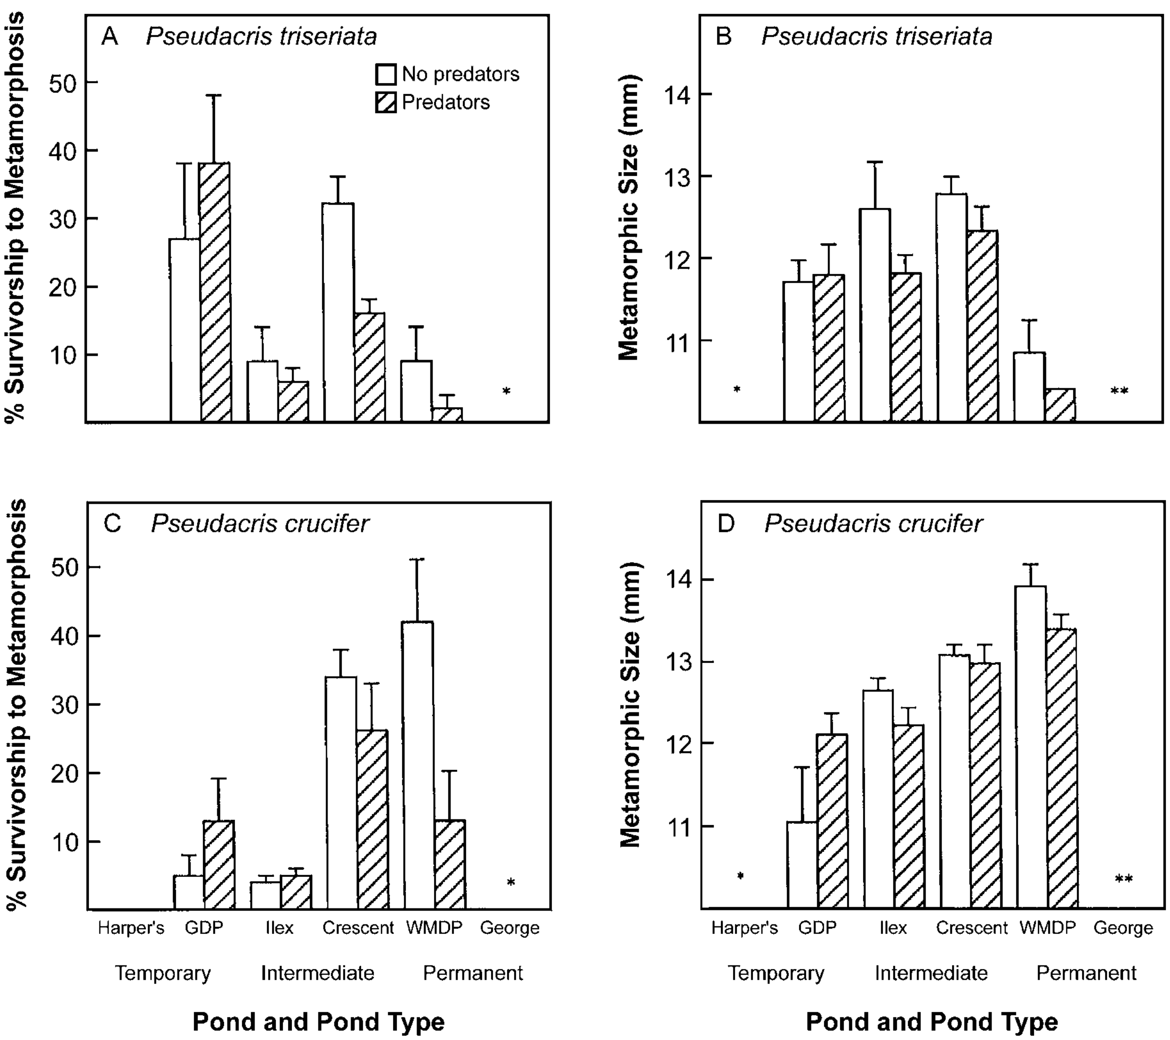

Fig. 15.30. Performance of *Pseudacris triseriata* and *P. crucifer* tadpoles raised in enclosures in temporary, intermediate, or permanent ponds with predators (hatched bars) and without predators (open bars). (A) Percentage of *P. triseriata* tadpoles surviving to metamorphosis. (B) Size of *P. triseriata* at metamorphosis. (C) Percentage of *P. crucifer* tadpoles surviving to metamorphosis. (D) Size of *P. crucifer* at metamorphosis. After Skelly (1995b). Ponds marked * and ** were not included because tadpoles invaded enclosures.

found in ponds that dry periodically, however, because they have a shorter larval period. A major effect of periodic pond drying is to exclude fish from the pond. Green frogs are relatively uncommon in ponds with fish, whereas bullfrogs often are abundant in such ponds (Werner and McPeek 1994). As discussed previously in this chapter, there is evidence of strong competition between the two species, with bullfrog tadpoles tending to be the superior competitor because of their higher level of feeding activity (Werner 1991, 1994).

Interactions between these two species are strongly affected by the assemblage of predators present in each type of pond. Werner and McPeek (1994) conducted experiments in subdivided ponds in which one side of each pond was stocked with bluegill sunfish (*Lepomis macrochirus*) and the other was not. The ponds contained a natural assemblage of invertebrate predators, with dragonfly naiads (*Anax*) being the dominant predator. The two sides of each pond were then stocked with more than 3,000 tadpoles of each of the two species, *R. catesbeiana* and *R. clamitans*. The effect of fish on the tadpole community was dramatic. Bullfrog tadpoles never survived in ponds without fish, but dominated ponds with fish. Green frog tadpole survival was low in all treatments, but their survival relative to bullfrog survival was higher in ponds without fish. Similar results were obtained in an unreplicated experiment in which a large pond was partitioned into sides with and without fish. The fish had a major impact on the abundance of other predators in both the experimental ponds and in natural ponds. In both types of ponds, the dominant insect predator (*Anax*) was greatly reduced by fish predation, as were salamander larvae. In laboratory experiments, fish preferred to feed on green frog tadpoles, but both salamander larvae and

Anax greatly preferred bullfrog tadpoles. Thus, bullfrogs do better than green frogs in ponds with fish for two reasons: because they are less likely to be eaten by the fish, and because the fish reduce the numbers of more significant predators. Because bullfrog tadpoles are superior competitors to green frog tadpoles, bullfrogs might dominate all ponds, but are excluded from those without fish because of heavy predation by dragonfly naiads. They also are excluded from ponds that dry frequently, by having a much longer larval period than do green frogs.

As discussed in chapter 14, bullfrog tadpoles are protected from fish predation by distasteful skin secretions. Such secretions are present in green frog tadpoles as well, but apparently are less effective at repelling fish. Bullfrog tadpoles are more vulnerable to predation by salamander larvae and dragonfly naiads because of their higher levels of activity. The vulnerability of bullfrog tadpoles to dragonfly naiads is likely to increase at high tadpole densities because depletion of food resources can lead to higher levels of feeding activity (Anholt and Werner 1995). In addition to eating tadpoles, predators can have indirect effects on the growth and competitive ability of tadpoles because of the antipredator behavior of the tadpoles (see chapter 14). For example, in cattle tank experiments, both green frog and small bullfrog tadpoles reduced their activity in the presence of caged *Anax* naiads, indicating a response to chemical cues from the predators. This reduction in activity resulted in reduced feeding and slower growth. Large bullfrog tadpoles, on the other hand, were less likely to reduce activity, presumably because they are less vulnerable to dragonfly predation, and actually grew faster in the presence of dragonfly naiads (Werner and Anholt 1996). Small bullfrog tadpoles have a stronger competitive effect on other bullfrog tadpoles and on green frog tadpoles than do large individuals, so the presence of predators produced a greater change in competitive effects of small bullfrog tadpoles. Thus competition and predation interact in complex ways in this system. Increased density of either conspecific or heterospecific tadpoles will tend to reduce growth rates because of competition. This may result in tadpoles becoming more active in their attempts to get enough food, making them more vulnerable to predators. Reduced growth also will increase the amount of time that tadpoles are small and therefore most vulnerable to predators.

These interactions are even more complex when multiple predators are present simultaneously. For example, in laboratory experiments, both green frog tadpoles and small bullfrog tadpoles exhibited large reductions in activity and spatial avoidance of dragonfly naiads. Both species showed little reaction to bluegill sunfish (*Lepomis macrochirus*) and intermediate responses to mud minnows (*Umbra limi*). The strength of behavioral response was directly related to the threat posed by each predator (Relyea and Werner 1999). This means that the most dangerous predator, dragonfly naiads, has two negative effects on tadpole performance. Not only do they reduce survivorship directly by eating the tadpoles, but they also reduce growth rates by reducing feeding activity of tadpoles. Less dangerous predators, such as bluegill sunfish, have only direct negative effects by eating the tadpoles, but they also have indirect benefits by eating the more dangerous predators.

These interactions are further complicated by reactions of predators to each other. For example, when uncaged dragonfly naiads and fish both were simultaneously present with tadpoles, the dragonflies reduced their own activity, apparently in response to the presence of predatory fish. Bullfrog tadpoles, in turn, exhibited less reduction in activity than to dragonflies alone (Eklöv and Werner 2000). Again, bullfrog tadpoles tend to do better when both dragonflies and fish are present than when only dragonflies are present. These changes in behavior can affect competition between bullfrogs and green frogs as well, because green frog tadpoles exhibit greater reductions in activity in response to dragonflies than do bullfrog tadpoles (Werner 1991; Peacor and Werner 1997; Relyea and Werner 1999). Behavioral responses to one type of predator can affect the vulnerability of tadpoles to other types of predators, as well as competitive interactions between tadpoles. For example, when green frog and bullfrog tadpoles in cattle tanks were exposed to free-ranging dragonfly naiads (*Tramea lacerata*) and another type of dragonfly (*Anax*) in cages, the tadpoles showed reduced activity and suffered lower predation than when *Anax* was absent (Peacor and Werner 1997). When large bullfrog tadpoles were present as competitors, these tadpoles depleted resources and caused both green frog and small bullfrog tadpoles to increase their activity. This in turn made these tadpoles more vulnerable to predation by *Tramea*. Taken together, all of these experiments suggest that the distinction between the effects of competition and predation in tadpole communities is somewhat artificial, because each process interacts with the other in complex ways to affect the performance of individual tadpole species (Werner and Anholt 1996).

Competition and Predation in Tropical Pond Communities

Despite the great diversity and abundance of anurans in the tropics, we know almost nothing about how competition and predation affect the structure of tropical tadpole communities. Tropical tadpole communities can be more complex than are those in the temperate zone. They often have more species, with a wider range of trophic adaptations than those of temperate zone tadpoles. In addition, breeding activity may last for months, with different species having very different temporal patterns of reproduction (Aichinger

1987a). Many temporary ponds may fill, dry, and refill continuously throughout the rainy season, resulting in a constantly changing assemblage of tadpole species at any given site (Gascon 1991).

Most studies of tropical communities have been based on surveys of species occurrence in different bodies of water rather than experimental studies of species interactions. Tropical tadpoles can be found in a variety of habitats, from permanent rivers, lakes, and ponds to large temporary ponds, flooded meadows, streamside pools, and animal wallows. The occurrence of tadpole species in different habitats is largely a result of choice of oviposition sites by breeding adults (Magnusson and Hero 1991), but it also could be affected by interactions among tadpoles or their predators. In a study of tadpole distribution in an Amazonian rainforest, many species of tadpoles were widely distributed across a range of habitats from streamside pools to peccary wallows, and physical factors did not explain the composition of tadpole assemblages (Gascon 1991). The presence of fish was correlated with the composition of tadpole assemblages (Hero, Gascon, and Magnusson 1998). In contrast to earlier reports that most Neotropical tadpoles are found in fish-free habitats (Heyer, McDiarmid, and Weigmann 1975), however, many species used habitats containing a variety of fishes. Some species that were found almost exclusively in streams or streamside pools were consistently found with fish. Temporary ponds in the tropics also vary in the amount of vegetative cover available to tadpoles, and this in turn can affect their vulnerability to different kinds of predators (Kopp, Wachlevski, and Eterovick 2006).

Experimental studies of three common species of tadpoles (*Osteocephalus taurinus, Phyllomedusa tomopterna,* and *Allobates femoralis*) showed that fishes were less effective predators of tadpoles than were dragonfly naiads, although both types of predators reduced tadpole survival in small containers (Gascon 1992a). Both types of predators preferred *Phyllomedusa* tadpoles to *Osteocephalus* tadpoles, but it is not clear whether this is due to differences in palatability, habitat selection, activity, or a combination of all three. A survey of savanna habitats in central Amazonia yielded results similar to the rainforest studies, although the diversity of tadpoles was lower and the species composition was different (Azevedo-Ramos, Magnusson, and Bayliss 1999). Tadpoles were more often found in habitats with insect predators than with fishes, but a number of species consistently co-occurred with fishes. There has not been any experimental work with a tropical assemblage to determine how predation affects competition among species, and, indeed, there is relatively little experimental evidence either for or against competition in tropical tadpole communities.

Summary and Conclusions

Most studies of amphibian community ecology have focused on interactions among species in local assemblages. Nevertheless, larger-scale patterns of species diversity and distribution can have an impact on local communities, because these patterns set the stage for interactions among co-occurring species. Amphibians are always imbedded in a larger community of primary producers and various types of consumers, including both predators and prey of amphibians. Investigators usually have defined amphibian communities in terms of guilds of ecologically similar species, such as the frogs of the tropical forest floor or the tadpoles of a temporary pond. There has been relatively little attention given to interactions with other organisms that are potential competitors of amphibians, such as insectivorous lizards. What little work has been done in this area is entirely descriptive. Indeed, there are no experimental studies of interactions between amphibians and other terrestrial vertebrates, other than their predators (see chapter 14). There have been a few experimental studies demonstrating potential competitive interactions between aquatic or larval amphibians and other organisms, including fishes and freshwater invertebrates. Given the potential for even very distantly related organisms to interact as competitors, more attention probably should be given to the broader communities in which amphibians live.

Early studies of amphibian community ecology were largely descriptive, with a focus on patterns of microhabitat use and partitioning of food resources in local assemblages of species. For the last 25 years or so, amphibian community ecology has been heavily experimental. Much of this shift to a more experimental approach reflects a general shift toward more experimental work in ecology in response to criticisms that documenting patterns of resource use tells us little about the processes that have created these patterns.

Despite the enormous diversity of anurans, the community ecology of terrestrial anurans is relatively poorly understood as well. Nearly all studies of terrestrial anuran communities have been descriptive studies of microhabitat use and prey selection in assemblages of species sharing the same habitat. Detailed studies have been conducted with frogs of tropical rainforests, especially in the New World, and those of tropical savannas in Africa. Communities of anurans in the temperate zone are much less diverse than in the tropics, often with less than a half-dozen species living in the same habitat, and their community ecology is poorly studied.

The general pattern that emerges from studies of tropical frogs is that most species are generalist predators on insects and other arthropods. Differences in prey consumed by different species in a community often are based on differences in size of prey rather than prey taxon, and these in turn are related to differences in the body size and foraging modes of the anurans. Some tropical frogs are specialist predators, however, and most of these eat large numbers of ants and termites. Certain clades are most likely to include ant specialists, and all of these have toxic or distasteful skin secretions, derived in part from chemicals acquired by eating ants. These include bufonids, toxic dendrobatids, some mantelline frogs from Madagascar, many terrestrial microhylids, and probably some myobatrachids as well. There also are a few large tropical frogs that have become specialist or opportunistic predators on other frogs, an ecological role largely absent from temperate zone communities. Most temperate zone frogs are generalist predators of invertebrates, although bufonids and microhylids in these regions often are ant specialists. Again, partitioning of food resources usually is related to differences in prey size rather than types of prey. Although the tropic niches of terrestrial anurans have been well documented, experimental studies demonstrating competitive interactions among co-occurring species of frogs are lacking. Indeed, there has not been a single well-designed experimental study of terrestrial anuran communities.

This contrasts with extensive experimental work on terrestrial salamander communities. Classic studies of *Desmognathus* salamanders along Appalachian streams and species of *Plethodon* along elevational gradients have shown that competition for space can be intense and can lead to microhabitat partitioning or exclusion of species from some microhabitats. Competition often takes the form of direct interference and aggressive interactions among species of salamanders, many of which are interspecifically territorial. In some cases, interference competition interacts with differences in physiological tolerances to determine the microhabitat distribution of different species, as in the interaction between the widespread species *Plethodon cinereus* and the very similar *P. shenandoah*. The community ecology of terrestrial salamanders outside of the southern Appalachians is poorly understood. Tropical salamander communities offer interesting opportunities for future research, because species in local assemblages often exhibit sharply defined distributional boundaries along elevational gradients. Unfortunately, the relatively inaccessible locations of many of these populations make long-term field studies and, especially, experimental work difficult.

Relatively few salamanders live in aquatic habitats as adults, and the community ecology of aquatic salamanders has not been investigated in as much detail as that of terrestrial species. Nevertheless, temporary ponds in the southeastern United States often harbor either larvae or adults of several species of aquatic salamanders, including newts (*Notophthalmus*), sirens (*Siren, Pseudobranchus*), amphiumas (*Amphiuma*), and paedomorphic mole salamanders (*Ambystoma*). Surveys of natural ponds and experimental studies in artificial ponds have revealed a complex set of interactions among these species, which often function as both predators and competitors of co-occurring salamanders. In some parts of Europe, up to three species of newts (*Triturus*) live together in the same ponds, and they often are very similar in size and ecology. As with terrestrial salamanders, aquatic newts are generalist predators, with no evidence of differences in taxa of prey consumed. Minor microhabitat partitioning has been reported in some ponds, but not in others, but there has not been any experimental work to determine whether choice of microhabitats is influenced by the presence of other species of newts.

The best-studied amphibian communities are assemblages of larval amphibians, especially those that live in temporary ponds. The small size, abundance, and relatively short larval periods of many species have made them ideal subjects for both laboratory and field experiments. Both competitive interactions and the effect predators on interspecific competition have been studied in a variety of laboratory containers, in artificial mesocosms such as cattle tanks, and in small pens and large enclosures in natural ponds. Laboratory studies provide the greatest control over treatment variables and allow for easily replicated treatments, but they sacrifice much of the realism and complexity of natural environments. Mesocosm experiments, such as those using cattle tanks as artificial ponds, provide a greater degree of realism and complexity, while allowing for replicated treatments. Mesocosm experiments have been criticized by some ecologists as being insufficiently realistic to mimic conditions in natural environments such as real temporary ponds. Some investigators have used enclosures in natural ponds to provide a more realistic experimental environment, but in this case, the size of enclosures often must be traded off against the need for multiple replicates of treatments.

All of these types of experiments have revealed significant competition among species of amphibian larvae. However, a survey of experimental studies by Skelly and Kiesecker (2001) showed that laboratory and mesocosm studies are much more likely to produce evidence of strong interspecific competition than are experiments conducted in natural ponds. In some cases, this may be due to higher larval densities in laboratory experiments and in artificial ponds than in natural ponds. In other cases, it may be that the simplified environments of these experimental settings reduce the diversity of microhabitats and food resources available to larvae in natural ponds.

The structure of larval communities is strongly affected by the permanence of breeding ponds. Some species are typically found only in relatively ephemeral ponds that normally completely dry up every year, whereas others are found only in permanent ponds that never dry up. Some species are intermediate, being found in a wide range of ponds. Temporary ponds often have poorer food resources than do permanent ponds, but usually have fewer predators. They are subject to a variety of physical stresses besides rapid desiccation, including high water temperatures and low oxygen levels. Permanent ponds often have abundant food resources but also abundant predators. The largest and most persistent ponds frequently are inhabited by fish, which exclude many species of amphibians from the ponds.

Amphibian larvae that are adapted to temporary ponds typically have rapid growth and development that enables them to escape from drying ponds, but often at a cost of emerging from ponds at a relatively small size. Permanent pond larvae typically grow and develop more slowly, but tend to emerge from ponds at a relatively large size. Temporary pond larvae often have poorly developed defenses against predators, especially fishes, whereas permanent pond larvae often have a variety of behavioral and chemical defenses against both invertebrate and vertebrate predators. When reared in the same ponds, fast-growing species often outcompete slower-growing species in the absence of predators, presumably because they feed at a much faster rate. The presence of predators can alter or even reverse the outcome of interspecific competition by giving an advantage to slower-growing species that are well protected against predators. Predators often have indirect effects on competitive interactions by causing amphibian larvae to reduce their feeding activity or alter their use of microhabitats in ways that reduce rates of growth and development. Interactions between multiple predators, such as fishes and dragonfly naiads, can affect competitive interactions among amphibian larvae as well, because one predator may prey on both the amphibian larvae and the other predators. In addition, defenses that are effective against one type of predator, such as reducing feeding activity, may not be very effective against another predator with a different foraging mode. Since most natural ponds, especially relatively permanent ones, have a rich assortment of potential predators, the interactions among co-occurring species of amphibian larvae can be complex and vary from one pond to another.

Mechanisms of competition appear to differ between communities of larval salamanders and those of anuran tadpoles. Because all salamander larvae are carnivorous, they can function both as competitors and predators of other species, with their effect being determined largely by differences in body size. Direct interference competition in the form of aggressive attacks, biting of tails, and predation are relatively common among salamander larvae. and may be more important than exploitative competition for food resources in some communities. In contrast, most anuran tadpoles are herbivorous, although some species can be opportunistic predators on the eggs or larvae of other species. In most tadpole communities, exploitative competition for food appears to be more important in structuring the community than is aggressive interference competition. There is evidence from laboratory experiments of chemical interference and growth inhibition in tadpoles, but there is limited evidence for this being an important type of interaction in the field.

Our understanding of the structure and dynamics of larval communities is limited by the difficulty of extrapolating from experiments conducted in cattle tanks and other artificial settings to more natural ponds. Much of the work done with cattle tanks and other mesocosms has been designed to answer general theoretical questions about the nature of competitive interactions among species, but with only secondary reference to the structure of particular pond communities in nature. In some cases, results obtained in experimental studies have not been entirely consistent with observations made in natural ponds. For example, there is abundant evidence from cattle tank studies that newts serve as keystone predators in tadpole communities by altering the outcome of competitive interactions among species. Yet some surveys of natural ponds have failed to reveal a strong effect of newts on the structure of local assemblages. Unfortunately, it is hard to compare these results directly, because one set of studies involves experimental manipulation of predator densities, while the other relies on the correlation between predator abundance and species composition of natural communities. Some workers have addressed this problem by starting with natural patterns of species distribution in different types of ponds and then using experiments to tease out the effects of pond permanence, competition, and predation on community structure.

A general problem with many studies of community ecology in both aquatic and terrestrial communities is that seasonal and year-to-year variations in the intensity of competition are largely ignored. Patterns of community organization often are inferred from point samples collected over a relatively short period, but there is considerable doubt as to whether such data are reliable indicators of community structure (Wiens 1981). Studies of other groups, such as lizards (e.g., Dunham 1980, 1983) have shown that the intensity of competition and the degree of niche overlap between species can vary in response to rainfall and food abundance. Given the substantial variation in population size of some amphibians, even in the tropics (Barbault 1972; Toft, Rand, and Clark 1982), as well the variation in numbers (Levings and Windsor 1982) and availability (Jaeger 1980b) of their prey, it seems likely that the intensity of competition between species of amphibians varies as well.

However, only a few investigators have even attempted to document seasonal changes in abundance and resource use of sympatric species (e.g., Toft 1980b).

Studies of community ecology also would benefit from greater consideration of other aspects of amphibian biology. For example, there are many possibilities for integrating information on the physiological ecology of individual species with information on interactions between species. Jaeger's (1970, 1971a, b) work, showing that the distribution of two species of salamanders is governed by interactions between physiological tolerance to desiccation and competition, provides an excellent example. A number of studies have shown that tolerance of water and temperature stress in anurans is correlated with habitat (Ralin and Rogers 1972; Pough, Stewart, and Thomas 1977; Van Berkum et al. 1982; Beuchat, Pough, and Stewart 1984; see also chapter 2). There also is evidence of differences in temperature responses of tadpoles of closely related species (Negovetic et al. 2001). Nevertheless, there have been few experimental attempts to investigate possible interactions between physiological requirements and interspecific competition. There also are possibilities for integrating community ecology studies with studies of behavioral interactions, as has been done in some of the studies of interference competition in salamanders. Interspecific aggressive behavior also has been described in anurans (see chapter 8), but its importance for habitat segregation between species has not been investigated.

Finally, the relationship between community-level processes in aquatic larvae and those of adults remains to be investigated. While it seems clear that the success of different species in producing new recruits into the population will have a major impact on the distribution and abundance of adults in the community, the connections between the two types of communities have not been explored in detail. Most authors have assumed that individuals metamorphosing at a larger body size will have an advantage in both intra- and interspecific competition as adults, and there is some evidence of this from studies of marked juveniles (see chapter 13). It also is clear that both intra- and interspecific competition among larval amphibians can translate into smaller size at metamorphosis and possibly lower survivorship in the terrestrial environment. We know virtually nothing, however, about how juveniles or adults of pond-breeding amphibians interact with one another, or even if they interact at all.

Chapter 16 Conservation of Amphibians

Hyla crucifer *is what the biologists call him, but most to of us he is simply the Spring Peeper. . . . Everyone who has ever visited the country in the spring has heard him trilling from the marsh at twilight, and though few have ever caught sight of him most must know that he is a little, inch-long frog, who has just awakened from his winter sleep. . . . The peeper seems to realize, rather better than we, the significance of his resurrection, and I wonder if there is any other phenomenon in the heavens above or in the earth below which so simply and so definitely announces that life is resurgent again.*
—Joseph Wood Krutch, *The Twelve Seasons* (1949)

These world-filling, mind-altering choruses of spring peepers have no equal in the northeastern landscape. There is talk now of the silence of the frogs, of their striking diebacks, and declines and the disappearance of species globally. . . . It is a silencing that has taken other voices than those of frogs, as well as voiceless presences, all inevitably vanishing with the disappearance of the places in which they must live.
—David M. Carroll, *Swampwalker's Journal* (1999)

When I began this book, more than 20 years ago, I envisioned a final chapter that might briefly review the highlights of amphibian ecology and behavior discussed in previous chapters, followed by suggestions of critical areas for future research. In the intervening years, however, a greater concern has arisen, a concern that the very animals that amphibian biologists study might be on the verge of extinction. Beginning in the 1980s, amphibian biologists became increasingly convinced that major declines of amphibian populations had occurred in various parts of the world. In some cases, the causes of such declines were clear: destruction of tropical rainforests, drainage of wetlands, conversion of natural habitats to intensive agriculture, urbanization, and other forms of overt habitat destruction. In other cases, the causes were less obvious, with frogs disappearing from seemingly pristine habitats in protected parks and nature reserves and individuals even being found dead or dying in tropical rainforests. Given these alarming developments, it seemed important to use the final chapter to address the issue of declining amphibian populations and what might be done about it.

The literature on declining amphibian populations and amphibian conservation has increased exponentially in recent years. There have been many general reviews (Dodd 1997; Alford and Richards 1999; Corn 2000; Blaustein and Kiesecker 2002; Collins and Storfer 2003; D. Green 2003, 2005a; Storfer 2003; Beebee and Griffiths 2005; Collins and Halliday 2005), regional accounts (D. Green 1997a; Lannoo 1998a; A. Campbell 1999; Minter et al. 2004; Young et al. 2004), and both popular and technical books on the subject (K. Phillips 1994; Beebee 1996; Linder, Krest, and Sparling 2003; Semlitsch 2003a; Lannoo 2005). Given this volume of material, it is fair to ask whether there is anything new to say on the subject. Perhaps not, but I have tried to take a slightly different approach from that of many other authors. Instead of starting with a litany of potential threats to amphibians, I will begin by outlining some features of the basic biology, ecology, and behavior of amphibians that make them either particularly susceptible to environmental perturbations, or not particularly susceptible. Many authors state, almost as a truism, that amphibians are more vulnerable to environmental insults than are other vertebrates and therefore might serve as a kind of "canary in the coal mine," an indicator of environmental degradation (e.g., Carroll 1999). It is therefore worth examining whether this assumption actually is true, or whether there are some features of amphibian biology that make them somewhat less vulnerable to environmental change than are other species and in some instances easier to protect. Whatever the specific causes of decline in a particular population, it is clear that our investigation of these causes and possible solutions to the problem needs to be rooted in a thorough understanding of basic amphibian biology.

What Makes Amphibians Susceptible to Population Declines?

The idea that amphibians as a group are especially susceptible to environmental degradation derives from several basic amphibian characteristics: their relatively small size; their ectothermic physiology, with limited capacity for activity; their highly permeable skin, which seems vulnerable to various biological or chemical agents; and their dependence on aquatic or moist habitats (Vitt et al. 1990; Murphy, Phillips, and Beasley 2000). Many of these characteristics are shared with other groups of animals that have received less attention or concern, especially in the popular press, including freshwater fishes, terrestrial and freshwater mollusks, aquatic insects, and all sorts of other small aquatic and terrestrial invertebrates. Indeed, there is evidence that many of these groups are threatened as well, at least on a regional or local basis, and the decline of amphibian populations should be viewed in the context of a much larger biodiversity crisis (Lydeard and Mayden 1995; Leidy and Moyle 1998; Chapin, Sala, and Huber-Sannwald 2001; Novacek 2001; Saunders, Meeuwig, and Vincent 2002; Halliday 2005). Nonmarine mollusks, for example, account for more than 40% of all recorded extinctions of animal species since 1500, whereas amphibians comprise the smallest proportion of known vertebrate extinctions (Lydeard et al. 2004).

Currently about 35 species of amphibians are thought to have gone extinct since the 1970s, with another 26 species not having been seen by herpetologists for some years (Stuart et al. 2004; see also The AmphibiaWeb Watch List at http://elib.cs.berkeley.edu/aw/declines/extinct.html). About 425 other species are considered critically endangered, but this list is heavily weighted toward regions where herpetologists have noticed major declines, especially Latin America and Australia, and for many species the data are simply insufficient to determine their current status (fig. 16.1). These numbers need to be considered very rough estimates, because new species continue to be described at a faster rate than species disappear, and for a large proportion of amphibian species, we have insufficient data to determine their status (see Pimenta et al. 2005 and Stuart et al. 2005 for an exchange of views on interpreting the data). Furthermore, quantitative data on population status are most deficient in regions with some of the highest species diversity of amphibians (Africa, Asia, and the New World tropics). Nevertheless, recent estimates suggest that for amphibians, at least in the New World, the proportion of threatened species is considerably higher than for either birds or mammals (fig. 16.2; B. Young et al. 2004). The taxonomic distribution of threatened and declining amphibian species is uneven, with some families having a higher proportion of species at risk

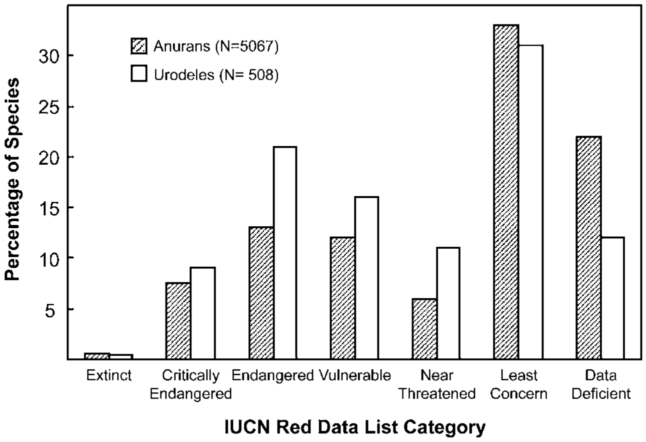

Fig. 16.1. Estimated percentages of anurans and salamanders in different Red List Categories designated by the International Union for the Conservation of Nature (IUCN). Caecilians are not included, because sufficient data to determine their conservation status are lacking for nearly all species. Plotted from data in table S3 of Stuart et al. (2004).

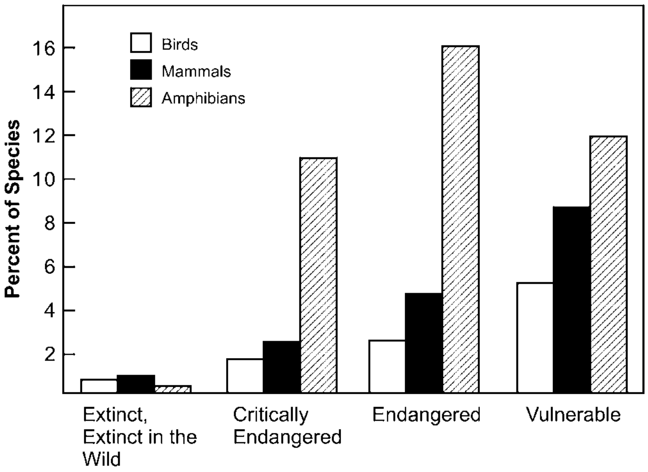

Fig. 16.2. Estimated percentages of New World birds, mammals, and amphibians in different IUCN Red List categories. A higher proportion of amphibians appears to be threatened than either birds or mammals. After Young et al. (2004).

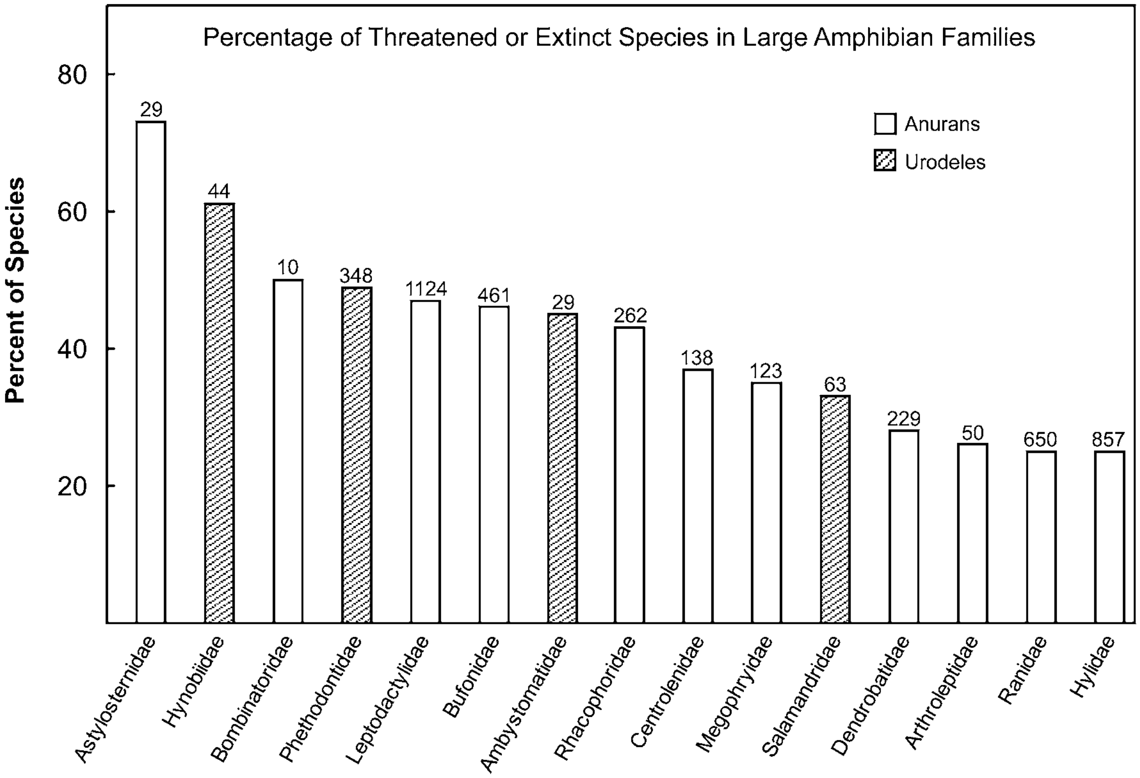

Fig. 16.3. Estimated percentages of threatened or extinct species of amphibians in large families of amphibians. Only those families containing at least 10 species, with at least 25% of species threatened or extinct, are included. Quantitative information on the status of these families is available for only a small fraction of all species, so these estimates are tentative. Numbers above each bar show estimated total number of described species in the family. Plotted from data in table S4 of Stuart et al. (2004).

than others, due to differences in ecological adaptations, accidents of geography, or other factors (fig. 16.3).

Declines of reptile populations have received far less attention in the popular press than have declines of amphibian populations, but these animals appear to be susceptible to many of the same environmental changes that threaten amphibians, and many more reptile species are known to have gone extinct (J. Gibbons et al. 2000; Beebee and Griffiths 2005). Some threats, such as human exploitation of eggs or adults for food, are greater for reptiles than for amphibians because of their larger size. Indeed, many of the largest species of reptiles appear to be at greatest risk, including crocodilians, sea turtles, tortoises, freshwater turtles, and large island lizards (G. Webb, Manolis, and Whitehead 1987; J. Ross 1992; Klemens 2000). In addition, there is abundant evidence for widespread declines of many species of birds and mammals, including widely distributed generalist predators such as the eastern spotted skunk (*Spilogale putorius*) (Gompper and Hackett 2005).

Despite the apparent limitations of amphibians, the group as a whole has been remarkably successful. There currently are more described species of living amphibians than species of mammals (Glaw and Köhler 1998). New species are being described at a rapid rate, especially from poorly explored tropical regions such as New Guinea, Sri Lanka, Southeast Asia, and Madagascar, and previously described species often turn out to be complexes of cryptic species (Hanken, Wake, and Savage 2005). Consequently, current estimates of total amphibian diversity probably are too low (Collins and Halliday 2005).

Amphibians as a group have been around for hundreds of millions of years and have experienced dramatic global changes in climate, habitat structure, and even the arrangement of the continents, sometimes with only modest changes in the assemblage of species present. Indeed, many living species of amphibians are very old, in some cases dating back to the Miocene or earlier (Steele et al. 2005), so they not only have experienced major changes in climate, but have witnessed the rise of major mountain ranges as well. In North America and Europe, amphibian species alive today have moved southward with the expansion of the glaciers and then moved back north as the ice retreated, no doubt experiencing changes in breeding phenology and other aspects of their ecology along the way. In many parts of North America and Europe, the same species of amphibians present today were present during the Pleistocene, even though there have been dramatic changes in the mammal faunas of the same regions (Holman 1995, 1998a, b; Delfino, Rage, and Rook 2003; Delfino 2004, 2005). Over even shorter time scales, such as the last 1,000 years, there have been substantial and often quite rapid changes in temperature (Jones, Osborn, and Briffa 2001; Carey and Alexander 2003). Hence the issue is not whether amphibians can adapt to environmental change, but whether the speed at which such changes are now occurring exceeds the rate at which amphibians can adapt, either through evolutionary change or plastic responses to the environment.

It also is important to keep in mind that the decline of amphibian populations probably is not a new phenomenon. It seems likely that as soon as humans began to occupy the natural landscape, populations of many other animals, including amphibians, began to decline and disappear. This process undoubtedly accelerated with the conversion of large tracts of land to agriculture, and accelerated again with the industrialization and urbanization of much of the human landscape and the conversion to more intensive agricultural methods, including the application of vast quantities of synthetic chemicals. A key question is whether the decline of amphibian populations has now accelerated to a new phase or represents a continuation of an ongoing process that simply failed to capture the attention of biologists and the public. A related issue is whether new types of threats to amphibian populations have emerged in recent years (Collins and Storfer 2003).

Data from Dickinson County, Iowa, in the northwestern part of the state, illustrate decades-long declines of amphibian populations. This area contains many wetlands known as prairie potholes that range in size from small, temporary ponds to large lakes, many of which are used by amphibians for breeding. This area is not considered a hotspot of amphibian population declines, but by the 1990s, two of the seven species (28%) present in the 1920s had disappeared (Lannoo et al. 1994). One of these was Blanchard's cricket frog (*Acris crepitans blanchardi*), a species that once was abundant. Furthermore, the abundance of the most common species, the leopard frog (*Rana pipiens*), had decreased by two to three orders of magnitude since the early 1900s. At that time, this species was extraordinarily abundant, with up to 20 million individuals being commercially harvested each year. The decline of these species probably has been underway for decades. The most likely causes appear to be drainage of more than 90% of the wetlands that existed before human settlement and the more recent introduction of nonnative game fishes and bullfrogs into large wetlands. This sort of long-term decline of amphibian populations undoubtedly has occurred in many parts of the world as human populations have expanded and use of the land has become more intensive. It is possible that the apparent acceleration of this process in the past two or three decades has as much to do with changing rates of environmental degradation as with inherent characteristics of amphibians that make them particularly susceptible to such changes.

In this section, I will briefly review some aspects of amphibian morphology, physiology, behavior, and ecology that may affect their vulnerability to environmental change. All of these aspects of their biology were discussed in much more detail in preceding chapters, so I have not included detailed literature citations here.

Morphological and Physiological Traits

Small Body Size

As a class, the living amphibians are the smallest of terrestrial vertebrates, and miniaturization has been a recurrent theme in amphibian evolution (see chapter 1). Amphibians range in size from roughly the size of a human thumbnail to the size of a cat, but most have a body mass of less than 20 g. Small body size, especially when coupled with a highly permeable skin, can make amphibians vulnerable to any sort of environmental change that results in drying of microhabitats, from local deforestation to global climate change. On the other hand, small body size provides amphibians with some advantages as well. Small-bodied amphibians are able to occupy microhabitats unavailable to most other vertebrates, including root traces and animal tunnels in the soil, spaces under or in rotting logs, moss mats on trees, cracks in rocks, and other sheltered spots. Even degraded habitats may retain some microhabitats, such as fallen logs, required by terrestrial amphibians for survival, so these animals may be able to persist in areas where larger vertebrates have been extirpated. The small body size of amphibians also means that these animals usually exhibit very limited movement. This can be a disadvantage when habitats are fragmented and separated by areas through which amphibians cannot move, although some small amphibians have surprising abilities to move through inhospitable habitat (D. Marsh et al. 2004). It also can be an advantage, because individuals can persist in relatively small patches of suitable habitat (see the following).

Ectothermic Metabolism

The low energy demands of amphibians also provide an advantage by allowing large numbers of individuals to live in relatively small patches of habitat. Indeed, both aquatic and terrestrial amphibians sometimes reach extraordinary population densities not realized by any other group of vertebrates. This means that difficulties in locating mates and other effects of population fragmentation may be minimized by the relatively high densities of some amphibian populations. On the other hand, the ectothermic physiology of amphibians and their heavy reliance on anaerobic metabolism may limit their ability to disperse over long distances to new habitat patches. Rowe, Hopkins, and Bridges (2003) argued that amphibians may be susceptible to any environmental changes that decrease food resources available for energy storage used for reproduction, but it is not clear that they would be any more vulnerable to such changes than any other vertebrates. Indeed, they may do better in resource-limited environments than endothermic birds and mammals.

Permeable Skin

Of all the traits that can make amphibians vulnerable to environmental perturbations, perhaps none is cited more frequently than their permeable skin (e.g., Boone et al. 2003; Rowe, Hopkins, and Bridges 2003). The free flow of water and other materials across the skin is the key to the success of amphibians, enabling them, among other things, to make use of the skin for respiration. It also enables amphibians to rehydrate quickly when water becomes available. On the other hand, a permeable skin makes amphibians highly susceptible to desiccation. This is likely to be especially true for species that normally live in habitats with abundant moisture, such as tropical rainforests. Those that live in habitats with fluctuating water supplies, such as savannas and deserts, are less likely to be eliminated by prolonged drought because they are physiologically and ecologically adapted to variable water supplies.

One might also expect that a permeable skin would make amphibians susceptible to infectious biological agents such as bacteria and fungi. Indeed, as discussed later in this chapter, there is evidence linking some amphibian population declines to fungal infections. On the other hand, under most circumstances, amphibians are seldom encountered in the field with obvious signs of infection, even when they have suffered serious wounds. The principal reason for this is that amphibians produce a host of biologically active peptides in the skin (Erspamer 1994; B. T. Clarke 1997; Rinaldi 2002). Most work has focused on the toxic or distasteful properties of these secretions as defenses against predators (see chapter 14). Many of these compounds also have antibacterial or antifungal properties and have been shown experimentally to eliminate infections by naturally occurring soil bacteria (Simmaco et al. 1998). Indeed, production of antibacterial peptides appears to be induced by contact with microbes in the environment (Mangoni et al. 2001). Some of these compounds are at least partially effective against infectious agents associated with declining amphibian populations (Rollins-Smith et al. 2002, 2003, 2005; Carey et al. 2003). Antimicrobial compounds have been found in the skin of many amphibians that are not especially toxic or distasteful to vertebrate predators, such as *Plethodon cinereus* (Fredericks and Dankert 2000), and it may be that some distasteful or toxic defensive secretions originally evolved as shields against infection (Daly, Garraffo, and Spande 1993). The presence of such compounds may enable amphibians to live in habitats that normally are filled with a great diversity of bacteria and fungi, including eutrophic ponds and moist soil. Selection imposed by the diversity of microbial agents to which amphibians are exposed presumably has led to the diversification of peptides with activity against particular microbes (Duda, Vanhoye, and Nicholas 2002).

Unfortunately, the amphibian skin provides little or no protection against synthetic chemicals, such as pesticides. Most biologists have assumed that amphibians are unusually vulnerable to such compounds. In fact, in standard laboratory tests, amphibians sometimes are less sensitive to some common chemical contaminants than are other groups of organisms (Fontenot, Noblet, and Platt 1996; M. Harris, Bishop, Struger, Ripley and Bogart 1998; M. Harris, Bishop, Struger, van den Heuvel et al. 1998; Glennemeier and Begnoche 2002), although embryos and larvae may be more sensitive to some chemicals than are adults (Boone and Bridges 2003c). There also is considerable variation both within and among species in sensitivity to pesticides and other contaminants (e.g., Bridges and Semlitsch 2000, 2005a, b; Westerman et al. 2003). Nevertheless, chemical contaminants do accumulate in the tissues of amphibians, having been taken up either through the skin or ingested with their food (e.g., Fontenot et al. 2000; Fagotti et al. 2005), and these compounds can have a variety of detrimental effects on the health and survival of individual animals (see reviews in Sparling, Linder, and Bishop 2000 and Linder, Krest, and Sparling 2003). Pesticides and other chemical contaminants also can affect antipredator behavior and other behavioral traits that may influence survivorship (e.g., Boone and Semlitsch 2001). Conversely, exposure to stressors in the environment such as predators or competitors can increase the lethality of relatively low concentrations of some pesticides (Relyea and Mills 2001). Some chemical contaminants can actually enhance growth of tadpoles by eliminating competitors such as zooplankton that also feed on phytoplankton (Boone and Bridges 2003c).

Behavioral Traits

Limited Dispersal Ability

As mentioned previously, the small body size and limited capacity for activity of most amphibians ensures that they lead relatively sedentary lives (see chapter 6). Indeed, in some groups, such as plethodontid salamanders, individuals can spend their entire lives in an area the size of a small room, and they may limit their daily activities to an area the size of a dining room table. Consequently, these animals can persist for years in relatively isolated patches of suitable habitat, with relatively little impact on either population size or the genetic structure of populations. One study of red-backed salamanders (*Plethodon cinereus*), for example, found slightly more genetic differentiation among fragmented populations in a suburban area than among subpopulations in an undisturbed landscape, but the genetic effects were not of the same magnitude as those found in other fragmented amphibian populations (Gibbs 1998c). Furthermore, despite their relatively sedentary habits, red-backed salamanders are able to cross open ground between patches of forest habitat, so their potential for reoccupying habitats after local extinction events is surprisingly high (D. Marsh et al. 2004).

The small home ranges of many terrestrial amphibians (see chapter 6) may make them less sensitive to the effects of habitat fragmentation than are animals with larger home ranges, especially birds and mammals (e.g., Vallan 2000; Bowne and Bowers 2004; Cushman 2006). Several studies have shown that predictions of extinction risk based on the extent of forest habitat reduction or fragmentation tend to yield overestimates of the number of amphibian species at risk compared to larger, more mobile animals such as birds and mammals (Brook, Sodhi, and Ng 2003; Grelle et al. 2005). Aquatic-breeding amphibians distributed in metapopulations consisting of locally isolated patches of aquatic habitat appear to be more susceptible to the effects of habitat fragmentation, such as increased inbreeding and chance extinction of local populations. Often the ability of aquatic amphibians to reoccupy habitat patches after a local extinction event is constrained by their limited abilities to disperse across the intervening terrestrial habitat and their fidelity to breeding sites (Storfer 2003; L. Andersen, Fog, and Damgaard 2004; Cushman 2006). Nevertheless, some amphibians with relatively poor dispersal abilities do manage to colonize suitable habitats relatively quickly (e.g., *Ambystoma macrodactylum;* Funk and Dunlap 1999). Furthermore, even when dispersal by adults is uncommon, long-distance dispersal by juvenile amphibians probably is much common than generally recognized (Rothermel 2004). Indeed, many amphibian populations inhabiting networks of ponds probably have too much juvenile dispersal between ponds to be considered true metapopulations (M. A. Smith and Green 2005).

Antipredator Behavior

Various types of antipredator behavior can affect the vulnerability of amphibian populations to decline or extinction. Many amphibians, especially aquatic larvae, have evolved a remarkable ability to detect and identify potential predators and alter their behavior and even their morphology accordingly (see chapter 14). In many cases, these responses are predator-specific, which means that amphibians often do not respond appropriately to exotic predators such as fish to which they have not been previously exposed. Consequently, introduced predators can have a rapid impact on amphibian populations, although there is some evidence that some amphibian species eventually can acquire some capacity to recognize and escape from such predators. Some types of habitat management may interfere with antipredator behavior. For example, removal of aquatic vegetation from ponds, either mechanically or chemically, can remove vital cover into which amphibian larvae normally retreat when exposed to predators (J. E. Murphy, Phillips, and Beasley 2000).

Life Histories and Reproduction

Dependence on Water

All amphibians, even those with nonaquatic eggs, depend to some extent on the availability of water for reproduction (see chapter 10), and species that breed in standing or flowing water may be particularly vulnerable to environmental degradation and change. In many parts of the world, freshwater habitats are among the most threatened of all ecosystems, being highly susceptible to biological or chemical pollution, acidification, changes in temperature, silt deposition, and other physical alterations brought about by deforestation and changes to the surrounding terrestrial landscape. Freshwater ecosystems also are among the most heavily impacted by introduced predators and other exotic organisms. The result is an unusually high risk of extinction among freshwater organisms, from plants and invertebrates to fishes and amphibians (Lydeard and Mayden 1995; Benz and Collins 1997; Ricciardi, Neves, and Rasmussen 1999; Dudgeon 2000, 2002; Loh 2000; Warren et al. 2000; Brönmark and Hansson 2002; Saunders, Meeuwig, and Vincent 2002).

Changes in aquatic habitats have the potential to eliminate whole assemblages of amphibians that depend on them for breeding, even when the surrounding landscape appears more or less intact. Probably at high risk are species that breed in clear, cold streams with low nutrient input, because these species are likely to have the narrowest tolerance limits for changes in temperature, nutrient input, or silt load associated with forest clearing, pollution, and other habitat alteration (Corn and Bury 1989; Welsh and Ollivier 1998; Gillespie 2002). Stream-breeding amphibians have declined in several parts of the world (Lips 1998; S. Williams and Hero 1998; Corn, Bury, and Hyde 2003; Young et al. 2004), although it is not clear that these declines all can be attributed to a common cause. Amphibians that inhabit unpolluted, nutrient-poor ponds and lakes, like those found in many montane regions, also are vulnerable because of low tolerance for habitat alteration. For example, stream and lake-dwelling frogs of the genus *Telmatobius* from high altitudes in the Andes are declining, although not necessarily from a single cause (Young et al. 2004). Also at risk are amphibians that depend on vernal pools and other temporary bodies of water. These pools not only provide breeding sites for many amphibians that are intolerant of predators that live in more permanent water, but they also provide important habitats for amphibians moving between larger wetlands. Temporary wetlands often are not afforded the same level of legal protection as more persistent bodies of water and have been disappearing in many parts of the world. They also are highly susceptible to any changes in climate that decrease the amount of time that such pools hold water (Semlitsch and Bodie 1998; Snodgrass, Komorowski et al. 2000; Semlitsch 2002, 2003c; Jakob et al. 2003; R. Brooks 2004). This is especially true for very small vernal pools (< 0.5 hectare), which can be important breeding sites for many amphibians (Egan and Paton 2004).

If freshwater habitats are especially endangered, then amphibians that spend most of their lives on land, particularly those with terrestrial reproduction, might be expected to derive some advantage from their lack of exposure to degraded aquatic habitats. In the rainforests of northern Australia, for example, terrestrial-breeding microhylids and other largely terrestrial frogs have not experienced the declines seen in stream-breeding frogs in the same area (S. Richards, McDonald, and Alford 1993; S. Williams and Hero 1998). A similar trend was seen at Monteverde in Costa Rica, where half the anuran species disappeared in 1987. Species of *Eleutherodactylus* appeared to be less affected than were aquatic-breeding frogs, although three species closely associated with streams did disappear. The only anuran species to reappear in large numbers by 1994 was a species of *Eleutherodactylus,* and several species that had not declined appeared to be increasing in abundance (Pounds et al. 1997). On the other hand, the spectacular golden toad (*Bufo periglenes*) also disappeared, and this was not a stream breeder, although it did lay aquatic eggs. In Puerto Rico and elsewhere in Latin America, there have been declines in some species of *Eleutherodactylus* and other frogs with nonaquatic reproduction, while other species, such as *E. coqui,* have flourished (Woolbright 1997; Lips 1999; Stallard 2001; Young et al. 2001). In Latin America as a whole, anurans with nonaquatic reproduction appear to be more at risk than are aquatic breeders (Young et al. 2004), but this pattern may be confounded by the fact that most terrestrial breeders are forest-interior specialists and therefore are vulnerable to deforestation and habitat fragmentation.

In some areas, pond-breeding and terrestrial-breeding species appear to be somewhat less affected than are stream-breeding species, but the data are not sufficiently robust to allow rigorous statistical analysis (Crump 2003). The picture for terrestrial plethodontid salamanders with direct development is mixed. Hairston and Wiley (1993) failed to find evidence of population declines in six species monitored for 15–20 years in North Carolina. In contrast, Highton (2005) reported that many species were less abundant in the 1990s at sites where they were common in the 1970s. Because most terrestrial plethodontids live in forests, they may be particularly susceptible to destructive forestry practices that eliminate or fragment local populations (Wyman 2003).

Terrestrial amphibians, especially those with nonaquatic reproduction, also are susceptible to any climate changes or habitat alterations that produce changes in temperature, length of the dry season, amount of rainfall in the wet season, soil moisture content, and other environmental variables that directly impact amphibians (Boone et al. 2003). Indeed, amphibians with nonaquatic reproduction generally are confined to moist forest habitats, and may be even more sensitive to habitat disturbance or degradation than are amphibians adapted to more open habitats (Pearman 1997; Wyman 2003). Not only can terrestrial amphibians be affected directly by dry conditions, but they also may experience changes in their food resources that affect population size (Donnelly and Crump 1998). The terrestrial embryos of amphibians with direct development may be especially vulnerable if they are laid in relatively shallow, unprotected sites in leaf litter, or have low tolerance for desiccation (e.g., N. Mitchell 2002a).

Use of Multiple Habitats

Many amphibians make use of distinctly different habitats, either at different stages of the life cycle, or at different times of year (fig. 16.4). The most common situation is for amphibians to breed in aquatic habitats, but spend the rest

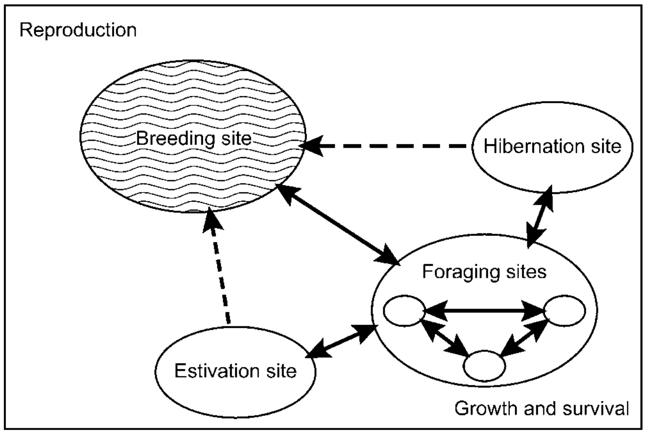

Fig. 16.4. Diagram of habitat use by an amphibian that breeds in water, but spends at least part of the year on land. Some species move from aquatic breeding sites to terrestrial foraging areas, where they may spend most of the year and may even hibernate or estivate, making a return trip to water the following year. Other species use distinct terrestrial or aquatic habitats for hibernation and may move directly from these sites to breeding ponds in the spring. Desert-dwelling amphibians often estivate underground and emerge after heavy rains to move directly to temporary water for breeding, followed by a short period of foraging activity. Two-way movements are shown as two-headed, solid arrows. One-way movements are shown as single-headed, dashed arrows. After Semlitsch (2003c).

of the year in surrounding terrestrial habitats (Dodd 1996; S. Pope, Fahrig, and Merriam 2000; Richter et al. 2001; Trenham 2001). Other species move between different types of habitats for reproduction, feeding, and hibernation (Lamoureux and Madison 1999; Matthews and Pope 1999; Pilliod, Peterson, and Ritson 2002; Semlitsch 2003b). In either case, amphibians using multiple habitats are vulnerable to habitat degradation in one type of habitat, even if another remains intact. If wetland management plans fail to include protection of sufficient surrounding terrestrial habitat, then amphibian populations may decline (Semlitsch 1998, 2003b). Deforestation and other forms of habitat degradation may eliminate aquatic-breeding amphibians even if the aquatic habitat appears unaltered. This is much the same problem faced by migratory birds that move from tropical habitats in the winter to temperate habitats during the breeding season, but on a much smaller spatial scale (T. Martin and Finch 1995). Consequently, the problem probably is easier to address from a conservation perspective than is habitat preservation for migratory birds.

Complex Life Cycles

In most amphibians, movement between habitats is accompanied by metamorphosis from an aquatic larva to a terrestrial adult (see chapter 13). The transition period during metamorphosis is a particular vulnerable one for many species, because they are exposed to predators in two different habitats and exhibit reduced locomotory ability in both habitats (see chapter 14). Most amphibian ecologists have focused on the aquatic stages of the life history and the importance of egg and larval mortality in driving local population dynamics. This is especially true for amphibians that breed in temporary ponds that fluctuate in hydroperiod from year to year. Nevertheless, for some species, mortality of terrestrial juveniles may be at least as important as larval mortality in determining population dynamics and the vulnerability of a population to extinction (Biek et al. 2002; Conroy and Brook 2003), and in long-lived species, adult mortality may be important as well (B. Schmidt, Feldmann, and Schaub 2005). This means that we need to pay close attention to preservation of terrestrial habitats that are essential to juveniles and adults once they leave a pond.

There is evidence that immune responses of amphibians are suppressed during metamorphosis as the larval immune system transitions to the adult immune system. High levels of stress hormones, which are associated with metamorphosis (see chapter 13), also suppress immune responses, so any additional environmental stresses that increase production of these hormones could adversely affect immunity to disease (Rollins-Smith 1998, 2001). Some immune responses, such as the production of antimicrobial peptides in the skin, do not even begin until after metamorphosis is complete.

Any environmental changes that prolong or disrupt the process of metamorphosis are likely to have detrimental effects on amphibian populations. Metamorphosis is regulated by complex hormonal interactions, and there is evidence that some types of chemicals, including certain pesticides, can disrupt or alter hormone action, resulting in retardation of growth and development, incomplete or premature metamorphosis, developmental abnormalities, and altered sexual maturation, all of which are likely to negatively impact survival and reproduction (Carey and Bryant 1995; T. Hayes 2000, 2004; Ouellet 2000; T. Hayes, Collins, Lee, Mendoza, Noriega, Stuart, and Vonk 2002). Because of their complex life cycles, amphibians could be more vulnerable to such endocrine disruptors than are other vertebrates such as reptiles, birds, and mammals (Kloas 2002). Nevertheless, all vertebrates, including humans, share common endocrine controls of reproduction and are potentially at risk of serious endocrine disruption by chemical contaminants, so amphibians are not unique in this regard (D. Kime 1998; Guillette 2000; Fossi and Marsili 2003; Gies 2003; Kawai, Kobayashi, and Kaneko 2003; Hayes 2005).

Boom and Bust Population Cycles

Many amphibians, especially those that breed in temporary ponds, experience boom or bust population cycles, with a few good years of reproduction often followed by several bad years (Pechmann et al. 1989; Semlitsch et al. 1996; Alford and Richards 1999; Richter and Seigel 2002; Pechmann 2003; Richter et al. 2003). In amphibians with this type of population ecology, the number of breeding adults and the number of eggs produced often are poor predictors of the number of metamorphs emerging from the pond (see also chapter 15). Large fluctuations in population size, which sometimes can result in the complete disappearance of a local population, complicate the task of distinguishing natural population fluctuations from sustained population declines (Pechmann et al. 1991; Pechmann and Wilbur 1994; Pounds et al. 1997; Alford, Dixon and Pechmann 2001; Pechmann 2003; Halliday 2005). In general, one can expect that populations that undergo frequent and dramatic fluctuations in size will be susceptible to chance extinction events during particularly bad years (D. Green 2003). When habitats are fragmented and populations are isolated from one another, the potential for extinction resulting from stochastic events increases. For example, the single known breeding population of the dusky gopher frog (*Rana sevosa*) in Mississippi is vulnerable to extinction because of large year-to-year fluctuations in population size, number of eggs produced, and embryonic and larval survivorship (Richter and Seigel 2002; Richter et al. 2003).

On the other hand, amphibians that experience boom or bust population cycles typically reach sexual maturity relatively quickly and usually produce large numbers of eggs, life-history traits that allow them to take advantage of favorable breeding conditions that occur unpredictably. It also is likely that juveniles of such species tend to disperse more readily from natal ponds than do species with more stable population dynamics, although juvenile dispersal is poorly studied for most amphibians (see chapter 6). Hence, these species may have a greater capacity to recover from events such as droughts than do species with slow growth and development and low reproductive output, especially if dispersal results in recolonization of breeding ponds. Many pond-breeding amphibians also exhibit considerable plasticity in growth and development in response to rapid pond drying and other environmental variables (see chapter 13). Amphibians that do not normally experience major fluctuations in temperature, rainfall, or the persistence of standing water may be less likely to survive prolonged drought or even subtle changes in yearly rainfall patterns or soil moisture that result from deforestation or global climate change.

Distribution and Ecology

Limited Geographic Range

Perhaps the single most important ecological factor that can make a species vulnerable to extinction is a limited geographic range. Because of the limited dispersal abilities of amphibians, many species have very small geographic ranges (Beebee 1996; Duellman 1999c). Although they may be locally abundant, species with limited ranges usually exist in relatively few discrete populations. It is the rate at which populations disappear and new ones are founded that ultimately determines the likelihood that a species will go extinct (D. Green 1997b, 2003, 2005a). If a local population of a species with a limited range disappears, it is less likely to be replaced by colonization from other populations than are populations of more widespread species. Consequently, species with limited ranges often receive disproportionate attention from conservation biologists. For example, many of the North American amphibians currently listed or being considered for listing as threatened or endangered species by the federal government are those with historically small ranges, while others have undergone dramatic reductions in range size. Because listing criteria are largely based on the number of viable populations of a given species, species with limited ranges are more likely to receive government protection.

Members of certain clades of amphibians may be particularly vulnerable to extinction because of small geographic ranges. For example, terrestrial salamanders tend to have much smaller geographic ranges than do anurans in the same regions (Beebee 1996). Many plethodontid salamanders in both North America (Highton 1971; Petranka 1998) and Central America (D. Wake and Lynch 1976; García-París et al. 2000) are confined to single mountains or small mountain ranges. Only a few species in the United States, such as *Plethodon nettingi* and *P. shenandoah* (fig. 16.5 A), currently are listed as threatened or endangered. *Plethodon nettingi* occurs in several dozen disjunct populations, and in some places is abundant, but probably always has had a very small geographic range (Pauley et al. 2005). *Plethodon shenandoah* is found in isolated patches of habitat largely surrounded by more competitive species, especially *P. cinereus,* which prevent *P. shenandoah* from extending its range (Jaeger 1971a, b, 1980a). Many other plethodontids have similar small ranges and also may be vulnerable, but have not received federal protection. For example, the Peaks of Otter salamander, *Plethodon hubrichti* (fig. 16.5 B), has a range only about 20 km long in the Blue Ridge Mountains of Virginia, much of it in forest subjected to periodic timber harvesting (Kramer et al. 1993). Although locally abundant in some populations, this species undergoes dramatic population declines after logging (Sattler and Reichenbach 1998).

Small geographic ranges sometimes result from use of specialized habitats that are naturally limited or patchy in their distribution. For example, salamanders in the genus *Eurycea* have undergone extensive evolutionary divergence in caves and springs on the Edwards Plateau of Texas (see fig. 13.24 in chapter 13). Some species are relatively widespread, but others, such as the Barton Springs salamander (*E. sosorum*) and the San Marcos salamander (*E. nana*), are limited to single springs and therefore are highly vulnerable to local extinction (Chippindale 2000; Chippindale et al. 2000). In the case of the Barton Springs salamander, the only known population lives in and around a popular local swimming area, so its habitat is heavily impacted by human use. In Europe, all of the cave- and crevice-dwelling salamanders of the genus *Hydromantes* (sometimes called *Speleomantes*) have small geographic ranges and are considered vulnerable, while the blind cave salamander *Proteus anguinus* (fig. 1.33 B in chapter 1), with a slightly larger range, is endangered (Corbett 1989). Also at risk are populations of European amphibians that live on offshore islands, some of which are endemic and all of which have inherently limited ranges (Corbett 1989; Gibson and Freeman 1997; Andreone and Luiselli 2000).

Small geographic ranges often reflect patterns of climate change during the last few million years that have resulted in advances and retreats of glaciers, alteration of rainfall patterns, and contractions and expansion of forest and grassland habitats that have influenced the current distribution and genetic divergence of amphibian populations. The size and location of a species' current geographic range often reflects a past history of range expansion and contraction. For example, phylogeographic studies of Western Palearctic brown frogs of the genus *Rana* have shown that the re-

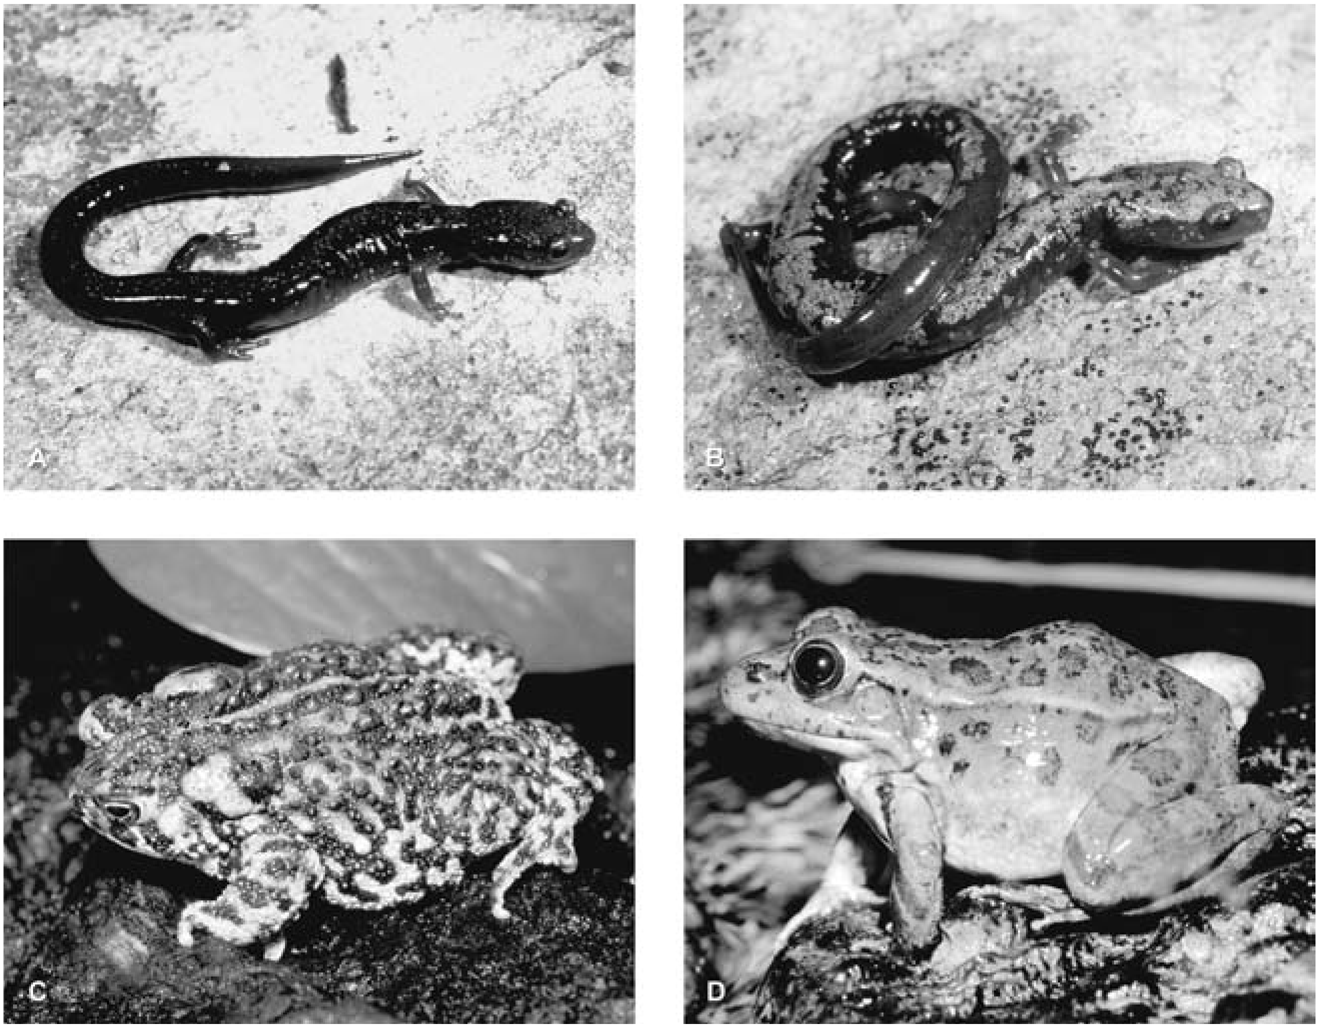

Fig. 16.5. Many threatened or endangered North American amphibians have small geographic ranges. (A) The Shenandoah salamander, *Plethodon shenandoah,* is found in three isolated populations in Shenandoah National Park. This species is ecologically similar to the more widespread red-backed salamander, *Plethodon cinereus,* and is confined to dry talus slopes by competition from that generalist species. (B) The Peaks of Otter salamander, *Plethodon hubrichti,* probably always had a very small geographic range and is confined to a 16-kilometer section of the Blue Ridge Mountains of Virginia. Populations currently are stable, but are vulnerable to habitat fragmentation and degradation from logging and defoliation of the forest canopy by gypsy moth caterpillars. (C) The Wyoming toad, *Bufo baxteri,* once was abundant along river floodplains of the Laramie Basin of Wyoming. Populations experienced precipitous declines in the 1970s from unknown causes, and the species has not been seen in the wild since 1987. A captive breeding and reindroduction project so far has not been very successful. (D) The relict leopard frog, *Rana onca,* once was considered to be extinct, but survives in small numbers in southern Nevada. Much of its natural habitat has been destroyed by conversion to agriculture, draining of marshes, large-scale dam projects, and invasion of aquatic habitats by introduced bullfrogs (*Rana catesbeiana*) and other alien predators. Photos by Wayne Van Devender (A–C) and Richard D. Bartlett (D).

stricted ranges of many species in southern Europe result from populations being isloated in southern refugia during glacial periods and undergoing subsequent speciation (Veith, Kosuch, and Vences 2003). Similarly, populations of frogs that inhabit the wet tropical forests of northeastern Australia have experienced repeated range expansions and contractions, with populations being restricted to isolated refugia during glacial periods (C. Schneider, Cunningham, and Moritz 1998). In southeastern Brazil, some forest-interior frogs are found in isolated remnants of the Atlantic forest, surrounded by more arid Caatinga habitats. These populations exhibit considerable genetic divergence resulting from contraction of forest habitats that occurred long before the more recent human destruction and fragmentation of the remaining areas of forest (Carnaval 2002). While the processes that resulted in some amphibian populations having small or fragmented ranges are natural parts of the evolution of these species, the resulting patterns of distribution may make such species especially vulnerable to local extinction when isolated habitat patches are destroyed or severely altered.

Many endangered amphibian species with very small geographic ranges represent relict populations that diverged or became isolated from ancestral populations that were more widespread. The Houston toad (*Bufo houstonensis*) is closely related to the American toad (*Bufo americanus*) and is thought to be a Pleistocene relict that became isolated from a more widespread ancestral population because of increasing aridity. Its historic range has always been small, and it currently is found in only a few isolated populations, most of which are in decline (L. E. Brown and Mesrobian 2005). Similarly, the Wyoming toad (*Bufo baxteri;* fig. 16.5 C) is a close relative of the Canadian toad (*Bufo hemiophrys*) and represents another Pleistocene relict population that became isolated in the Laramie Basin and more recently was reduced to a population in a single lake. It now appears to be extinct in the wild, although captive breeding and reintroduction efforts continue (Odum and Corn 2005). Yet another Pleistocene relict is the black toad (*Bufo exsul;* fig. 16.8 A), found only in Deep Springs Valley, California (J. F. Murphy, Simandle, and Becker 2003). The Vegas Valley leopard frog (*Rana fisheri*) was found only in the wetlands in and around what is now the city of Las Vegas, Nevada, and probably has been extinct since the 1940s (R. Jennings 2005). It is a close relative of the aptly named relict leopard frog (*Rana onca;* fig. 16.5 D), which once was considered to be extinct (J. Jaeger et al. 2001). It had a very limited distribution in Arizona, Utah, and Nevada, and the range has recently contracted to a few sites in Nevada (Bradford, Jaeger, Jennings 2004). In Europe, the Mallorcan midwife toad (*Alytes muletensis*) was isolated from ancestral *Alytes* populations on the Balearic Islands. It now is confined to only a few mountain torrents on part of the island of Mallorca, and is therefore highly vulnerable to extinction (Corbett 1989). The European salamanders in the genera *Euproctus* and *Calotriton* all have very small ranges restricted to high elevations, and are thought to be Pleistocene relicts (Beebee 1996; Carranza and Amat 2005).

Hot Spots for Range-Limited Amphibians

It seems likely that hundreds of species of amphibians around the world are similarly imperiled by very small geographic ranges, but in most cases, the status of these populations is poorly known. Of particular concern to conservation biologists are regions of the world in which severely endangered habitats contain a large number of endemic amphibian species with limited ranges. Indeed, areas of high species diversity and high levels of endemism often contain a high percentage of range-limited species (Duellman 1999b; C. Seymour et al. 2001), many of which also tend to be habitat specialists (Wijesinghe and Brooke 2004). In such situations, habitat destruction has the potential to eliminate whole assemblages of unique amphibians simply because they are found nowhere else. Many areas of the world where concentrations of endemic or range-limited amphibian species occur are relatively small geographically, so protection of a very small proportion of the earth's terrestrial habitats has the potential to protect a large percentage of amphibian species. Some, but not all, of these areas have been designated as biodiversity "hot spots," based largely on analysis of species diversity and endemism of other organisms, especially plant species (N. Myers 1988, 1990, 1996; T. Brooks et al. 2002).

Unfortunately, areas that currently are protected do not always correspond to areas of high species diversity or endemism for amphibians or for other organisms (Prendergast et al. 1993; Young et al. 2004). In subequatorial Africa, for example, where parks and reserves have tended to focus on large, charismatic mammals, most regions with concentrations of endemic or range-limited amphibian species are not currently protected (C. Seymour et al. 2001). In Namibia, which has few endemic amphibian species, but surprisingly high species diversity for a desert region, most of the human population is concentrated near wetlands, which also harbor most of the amphibian species. Most such wetlands are not protected (B. Curtis et al. 1998). In South Africa, on the other hand, the picture is somewhat brighter, with an estimated 96% of amphibian species occurring on protected lands (Drinkrow and Cherry 1995). In general, for sub-Saharan Africa, proposals for land conservation that focus on centers of high species diversity rather than areas already protected or areas chosen to represent particular biomes appear to be most likely to protect the largest proportion of amphibian species (Burgess et al. 2002).

Duellman (1999b) identified over 40 relatively small regions of the world with high amphibian species diversity, a high percentage of endemic species, or both (fig. 16.6). Not all of these regions are equally threatened, but many are in tropical countries where deforestation and other forms of habitat destruction continue at a rapid pace. Of particular concern are montane tropical forests, which are threatened throughout the world. These forests tend to have high amphibian species diversity and large numbers of endemic species. Furthermore, the geographic ranges of many montane amphibian species are quite limited because of physical and altitudinal barriers to dispersal.

High on the list of areas of special concern to amphibian biologists is Madagascar, a very poor country with a high population growth rate (Andreone and Luiselli 2003). Nearly all amphibian species in Madagascar are endemic, and species diversity is high. The total ranges of most species are poorly known, but many are known from only a few localities, in some cases only the type locality where the species was first collected. With increasing fragmentation of the remaining forested regions of Madagascar, there is the potential for a large assemblage of unique amphibians to disappear (Andreone and Luiselli 2003; Lehtinen, Ramanamanjato, and Raveloarison 2003). The amphibian fauna of continental

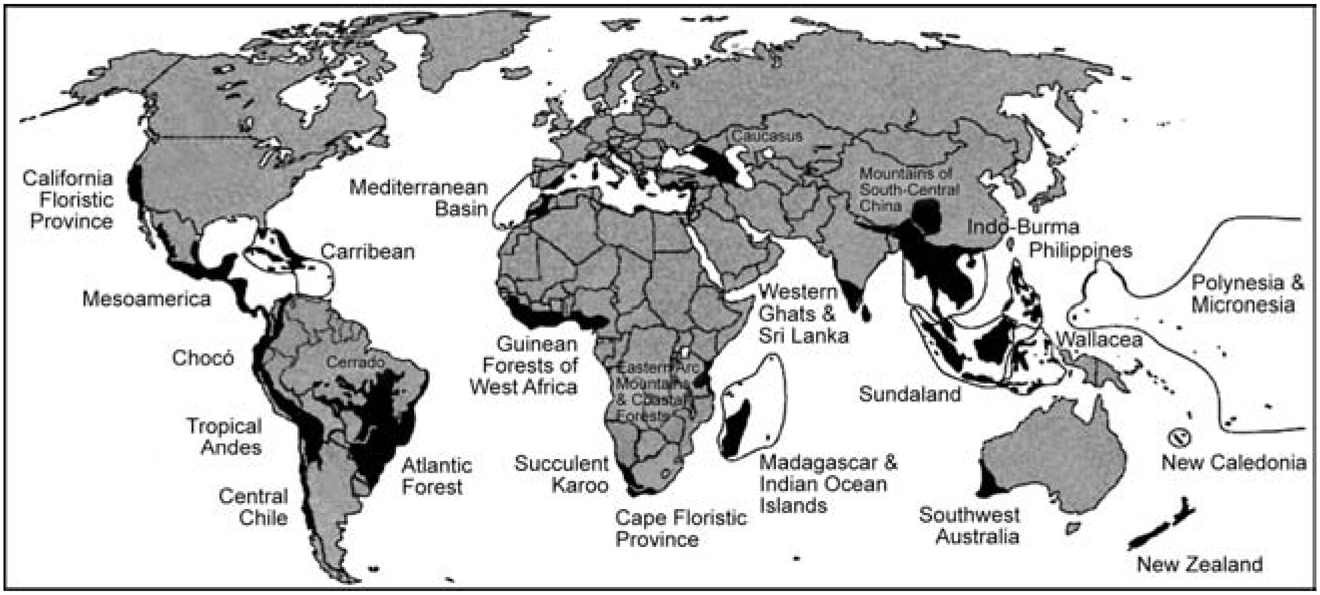

Fig. 16.6. Major hotspots of amphibian species diversity or endemism. Names and areas in black show regions with unusually large numbers of amphibian species, a large proportion of endemic species, or both. Species diversity tends to be especially rich in tropical montane regions and in moist forested coastal areas in both the temperate zone and the tropics. Many of these areas also have high proportions of endemic species. Some of these amphibian hotspots unfortunately are located in regions with poor and growing human populations and rapid rates of deforestation and habitat fragmentation. After Hero and Shoo (2003).

Africa has received less attention than that of most parts of the world, but there are a number of relatively small montane regions in subequatorial Africa that are rich in amphibian species, most of them endemic and most with limited ranges. These include highland areas of Tanzania, Kenya, Ethiopia, Zaire and surrounding countries, Cameroon, Malawi, Zimbabwe, Mozambique, Zambia, and South Africa (Poynton 1998, 1999, 2003; Channing 2001; C. Seymour et al. 2001; T. Brooks et al. 2002).

Other tropical or subtropical montane regions with unique assemblages of amphibian species, many with limited ranges, include the Andes of northern South America (Ecuador, Venezuela, and Colombia), the tropical southern Andes (Bolivia and Peru), the Guiana Highlands of Venezuela and the Guianas, the highlands of southern Mexico and Central America from Guatemala to western Panama, the highlands of Haiti, the highlands of Borneo and New Guinea, the highlands of Burma, Thailand, and Vietnam, and the Western Ghats and southern Himalayan Mountains of India (Duellman 1999b; Bossuyt et al. 2004; Dutta et al. 2004; Young et al. 2004).

A recent addition to the list is Sri Lanka, a small island with more than 200 species of amphibians, including many endemics, most of which are concentrated in montane rainforests. This is comparable to the diversity of much larger areas such as Madagascar, Borneo, and the Philippines (Pethiyagoda and Manamendra-Arachchi 1998; Meegaskumbura et al. 2002; Bossuyt et al. 2004). In fact, Sri Lanka may have the highest diversity of amphibian species per unit area of any site in the world. The status of amphibian populations in many of these regions is poorly known, although most are vulnerable to deforestation and other forms of habitat destruction. Sri Lanka already has lost more than 90% of its original rainforest.

Certain coastal regions of the world have unusual combinations of temperature, rainfall, and vegetation that create unique and geographically limited habitats for amphibians. As in many montane regions, these areas tend to have high amphibian species diversity and a large proportion of endemic and range-restricted species. One of the most severely threatened assemblages of amphibians is found in the remaining patches of Atlantic Coastal Forest in Brazil (Morellato and Haddad 2000; Saatchi et al. 2001; Grelle et al. 2005), where 93% of the amphibian species are endemic (Duellman 1999b) and many have quite limited ranges. A number of frog species in this region have declined or disappeared altogether in the last 20 years, and increasing destruction and fragmentation of the forest threatens a unique assemblage of species (Heyer et al. 1988, 1990; Weygoldt 1989a; Young et al. 2004). Also threatened are the many endemic amphibians of the unique Southwestern Cape Region of South Africa, which is subjected to increasing urbanization (Drinkrow and Cherry 1995; C. Seymour et al. 2001; Minter et al. 2004). In Australia, a number of frog species have small ranges limited to acidic habitats such as heathland, *Melaleuca* swamps, sedgeland, and *Banksia* woodlands along the coast of southeastern Queensland and northeastern New South Wales, an area with the fastest growing human population in the country. Other frogs in this region are limited to upland mesic forests that also are under pressure from development. While some species are doing well, others have declined dramatically (Hines, Mahony, and McDonald 1999). Coastal habitats in Australia with somewhat smaller numbers of amphibian species, but with a higher percentage of endemic species, some with limited ranges, are found on the southwestern and southeastern coasts of the continent. Other coastal habitats with relatively large proportions of endemic or range-limited amphibians include the temperate forests of southern Chile and the northwest coast of North America (Duellman 1999b).

Habitat Specialization

Some amphibians have generalized habitat requirements, while others are quite specialized. All else being equal, one can expect species with specialized habitat requirements to be more vulnerable to extinction, especially if suitable habitats are scarce, patchy in their distribution, or limited geographically. An example of an extreme habitat specialist is the North American green salamander (*Aneides aeneus;* fig. 14.25 D in chapter 14). This species inhabits crevices in rock outcrops in mature forests. Populations tend to be small and widely separated from one another, so are highly vulnerable to local extinction. Consequently, this species is listed as threatened or endangered in most of the states encompassed by its range (Madej 1998). Populations in the southern parts of the species' range, especially in North Carolina, experienced catastrophic declines in the late 1970s, with further declines and some local extinctions recorded in the 1990s (J. Mitchell et al. 1999; Corser 2001; Pauley and Watson 2005). Some local populations were eliminated by housing developments and other forms of habitat destruction, but the causes of declines in other populations are unknown. Because of the patchy distribution of suitable habitat, recolonization of local populations is likely to be extremely slow, so the status of this species, at least in parts of its range, is of major concern. Conservation of these salamanders is further complicated by the likelihood that the single named species actually is a complex of up to four cryptic species. If so, then the geographic ranges of these highly specialized species are even smaller than currently recognized (Pauley and Watson 2005).

Not all habitat specialists have limited ranges. For example, the eastern spadefoot toad (*Scaphiopus holbrookii;* fig. 16.7) can be considered a habitat specialist in that it requires sandy or loamy soils and temporary ponds for reproduction, but it has a wide distribution in the eastern and southern United States (Palis 2005). In regions where such habitats are common, such as the southeastern states, this species can be locally abundant, but at the periphery of its range, where such habitats are rare, it is threatened or endangered. In Connecticut, for example, spadefoot toads historically inhabited areas that mostly have been converted to sand and gravel operations or developed into shopping malls or housing developments. The species is listed as endangered in the state, but it remains relatively common on nearby eastern Long Island and Cape Cod, where sandy habitats are plentiful (Klemens 1993). In Europe, the natterjack toad (*Bufo calamita*) is similarly specialized for sandy habitats. Although it has a wide distribution on the continent, its favored habitats tend to be patchily distributed and increasingly threatened by human activities. Consequently, the number of viable populations has declined over much of the northern part of its range, even though the overall size of the range has not changed very much (Beebee 1977, 1983; Banks, Beebee, and Cooke 1994; Beebee 1996; Sinsch 1998; Buckley and Beebee 2004).

Fig. 16.7. The eastern spadefoot toad, *Scaphiopus holbrookii,* requires sandy or loamy soils and temporary ponds for reproduction. It has a large geographic range, extending from southern New England to Florida and Louisiana. It remains abundant in the southeastern United States, but has become rare at the periphery of its range, as in Connecticut, where habitat destruction has eliminated most historic populations. Photo by Wayne Van Devender.

Extreme habitat specialization can make some species vulnerable to natural environmental changes that can lead to the decline or extinction of local populations. For example, a tiny marsupial hylid frog from the Atlantic Coastal Forest of Brazil, *Fritziana ohausi,* was common in the area around Boracéia through the 1970s. Females of this species carry eggs on their backs and deposit tadpoles in small bodies of water, especially in hollow bamboo stems. During the 1970s, the species of bamboo used by this frog flowered synchronously and died, and the frog disappeared from the area, although it may still persist in lower numbers in tree holes and similar breeding sites (Heyer et al. 1990). In a nearby area dominated by ground bromeliads (*Vriesea neoglutinosa*), a fire of unknown origin in 1995 caused a crash in a population of a hylid frog, *Phyllodytes luteolus,* which lives entirely in the bromeliads (Papp and Papp 2000). Such population crashes probably have minimal impact on the survival of a species when that species is relatively widespread, but as populations become increasingly fragmented and the ranges of species are reduced, such events can be catastrophic.

Use of specialized habitats also could make amphibians vulnerable to the secondary effects of selective harvesting of key plant species in the habitat. For example, many species of bolitoglossine salamanders in Mexico and Central America live in bromeliads that grow on the branches of oaks and other trees (D. Wake 1987). Some species of bromeliads in the genus *Tillandsia* are heavily harvested for the home decoration market. A regulated, sustainable commercial harvest of bromeliads has been proposed as a strategy to reduce deforestation by providing a source of income for local people derived from the forest (Wolf and Konings 2001). This seems like an innovative proposal from the standpoint of sustaining populations of bromeliads and protecting the forest, but we have no information on the number, density, or spatial distribution of bromeliads required to sustain populations of animals that depend on them, including salamanders. While any regulated harvest is likely to provide more protection for salamanders and other inhabitants of bromeliads than unregulated harvesting and forest destruction, it may be possible to devise a management plan that is most favorable for populations of both bromeliads and their associated fauna. Cloud forest amphibians also are vulnerable to other kinds of habitat alteration, such as conversion of forested habitats to ornamental fern production (Mendelson et al. 2004).

Natural Habitat Disturbance and Succession

In considering the effect of habitat alteration on amphibian populations, we must keep in mind that relatively few habitats are completely stable over long periods of time, even in the absence of obvious changes caused by humans. Most habitats are subjected to periodic natural disturbance and alteration. Some changes occur over relatively short time scales, on the order of a few years or decades, whereas others occur over longer time scales, on the order of thousands or tens of thousands of years. Short-term habitat changes can alter the distribution and abundance of amphibian species over relatively small spatial scales. Some short-term changes can be catastrophic, such as hurricanes or fires that cause major damage to habitats, or droughts that temporarily alter soil moisture regimes and eliminate breeding habitat for amphibians. Dry conditions coupled with unusually cold winters may kill some amphibians in terrestrial hibernation sites, even if breeding sites remain intact (Irwin 2005). Such disturbances can alter the species composition and abundance of amphibians in an area, and are likely to impact habitat specialists more than habitat generalists. Eventually, given enough time, an assemblage of amphibian species may return to predisturbance conditions, but there is the potential for rare species to be eliminated altogether by such events. Unfortunately, there has been relatively little research on the long-term effects of natural disturbances such as fire, drought, unusually cold winters, or hurricanes on amphibian populations (Boone et al. 2003; Pilliod et al. 2003).

In Puerto Rico, Hurricane Hugo caused major damage in the Luquillo Experimental Forest in 1989, toppling many trees and opening up the forest canopy. The largest and most common frog, *Eleutherodactylus coqui,* actually increased in abundance following the hurricane, apparently in response to an enormous increase in the abundance of insects feeding on decaying vegetation and new undergrowth (Woolbright 1991, 1996). In contrast, a number of other species either disappeared or became much less common in the immediate aftermath of the hurricane. These included *E. portoricensis, E. wightmanae, E. richmondi,* and *E. eneidae,* which may have suffered from increased dryness of the forest floor following the opening of the canopy and a period of decreased rainfall after the hurricane (Joglar and Burrowes 1996; Woolbright 1997; Joglar 1998). All of these species are smaller and have somewhat more specialized habitat requirements than the habitat generalist, *E. coqui,* and some already were in decline before the hurricane, possibly as a result of increased numbers of days without significant rain in the mid-1980s (M. Stewart 1995). At the same time, populations of a number of species, including *E. coqui,* were declining at higher elevations, not all of which were equally impacted by the hurricane, perhaps in response to other as yet unidentified environmental changes (Stallard 2001).

Other natural environmental changes occur more gradually and can result in changes in the species composition of amphibian assemblages. For example, Skelly, Werner, and Cortwright (1999) examined long-term changes in the distribution of amphibian species in ponds on the Edwin S. George Reserve in Michigan. They found that increased forest growth had resulted in closure of the canopy over some ponds, which in turn shortened the hydroperiod of the ponds. Many of these closed-canopy ponds were abandoned by breeding amphibians, and no new colonization of these ponds occurred. In more open-canopy ponds, on the other hand, the diversity of amphibian species either remained stable or increased. Over the entire mosaic of ponds in the area, new colonization events roughly balanced population extinctions, so the number of breeding populations of most species showed little net change. Beavers may be important in this type of system, because they can reverse the trend toward canopy closure, providing more open habitats for amphibians (Skelly and Friedenburg 2000). Other studies have shown that natural habitat succession can alter the composition of local amphibian assemblages (e.g., Brodman, Cortwright, and Resetar 2002), but where habitat change has been minimal, there has been little change in amphibian populations (e.g., Busby and Parmelee 1996; Crochet et al. 2004; Hossack, Corn, and Pilliod 2005). Changes in regional climatic conditions or other environmental changes also can result in some species in a local assemblage becoming more common while others decline, even as species composition remains stable (Martínez-Solano, Bosch, and García-París 2003).

For some amphibians, populations may be threatened by a combination of human-induced and natural habitat changes. In Britain, for example, the natterjack toad (*Bufo calamita*) originally was a specialist inhabitant of heathland habitats. Most such habitats have been destroyed or fragmented by conversion to intensive agriculture, planting of conifer forests, or urban development. The natterjack toad was largely extirpated from heathland habitats (Beebee 1977, 1983). The remaining patches of heathland are threatened by natural succession to overgrown scrub. Some low-intensity livestock grazing may be required to preserve a more open habitat for natterjack toads and other heathland species (Beebee 1996), which do not appear to be well adapted to moving through complex, enclosed habitats (Stevens et al. 2004). In a similar vein, cattle grazing appears to be important in maintaining temporary wetlands in the Central Valley in a relatively unvegetated state, required by California tiger salamanders (*Ambystoma californiense*) and their principal prey (fairy shrimp; Pyke and Marty 2005). This was due in part to shorter hydroperiods in ungrazed pools.

Habitat Isolation and Population Structure

Amphibians that require specific habitats for breeding often use interconnected patches of suitable habitat, and maintenance of stable populations may require continued access to a variety of habitat patches. Many pond-breeding amphibians, for example, exist in metapopulations in which dispersal between breeding sites is relatively rare, but occurs frequently enough to enable recolonization of local ponds after extinction events (see chapter 6). In this type of population, certain highly productive breeding sites may send emigrants to other less productive sites, thereby maintaining populations over the entire area. Amphibians with this type of population structure may be especially vulnerable to habitat fragmentation and artificial barriers to dispersal, such as roads or agricultural land that is unsuitable for amphibians. Such barriers may prevent recolonization of habitat patches following local extinction events. Dispersal among habitat patches also may be essential for maintaining the genetic diversity of populations, and increased barriers to dispersal may result in increased inbreeding and decreased genetic variation. These effects of habitat fragmentation are discussed in more detail in a later section.

For pond-breeding amphibians that live in networks of ponds in relatively close proxmity, extinction of local populations and colonization of habitats by new populations are relatively common events, even in the absence of major habitat changes (Sjögren 1991a; Sjögren-Gulve 1994; Hecnar and M'Closkey 1996, 1997c; Carlson and Edenhamn 2000; D. Green 2003; Trenham et al. 2003). Small populations, in particular, are susceptible to chance extinction due to short-term events such as drought (Jaeger 1980a; Dodd 1993, 1995), killing frosts (Heyer et al. 1988), floods, fires, or disease. For widespread species with generalized habitat requirements, such changes in populations are unlikely to impact the overall status of a species as long as a suitable mosaic of habitats is available and colonization of new habitats roughly balances local extinction events. For species with more specialized requirements, alteration, fragmentation, or isolation of habitats may result in permanent population declines or extinction. The frequency of natural extinction of local populations means that information on the status of a given species at a single locality is of little relevance in establishing whether the species is declining. Only information at larger spatial scales will be useful in determining the long-term prospects for species survival (Hecnar and M'Closkey 1996, 1997c; Bosch, Boyero, and Martínez-Solano 2004).

How Can We Tell If Amphibian Populations Have Declined or Disappeared?

One difficulty in identifying the causes of declining amphibian populations is actually demonstrating that such declines have taken place. When scientists first became concerned about declining amphibian populations, there was some debate about the quality of the data available to show that widespread declines had occurred. Initially much of the information was anecdotal, with amphibian biologists noting that many species seemed not to be as abundant in areas where they once were common, or had disappeared altogether. In some instances, such as the disappearance of the spectacular *Bufo periglenes* from Monte Verde in Costa Rica, the evidence of decline seemed irrefutable, although even in this case, there was reluctance to concede that the species was permanently gone (M. Crump, Hensley, and Clark 1992).

Several investigators who worked on temporary pond amphibians that exhibit large annual fluctuations in population size argued that the data available for most populations could not be distinguished statistically from random population fluctuations (Pechmann et al. 1991; Pechmann and Wilbur 1994). Others argued that the accumulated weight of such evidence argued for immediate attention to the problem, even if much of the evidence was anecdotal

(Blaustein 1994), or questioned the statistical basis for concluding that populations were not declining (Blaustein et al. 1994). One immediate response to this debate was a call for more long-term monitoring of amphibian populations, to improve the quality of the available data. Since then, through the efforts of the Declining Amphibian Populations Task Force and other organizations, monitoring efforts have been initiated throughout the world (Storfer 2003; Stuart et al. 2004; Young et al. 2004; Heyer and Murphy 2005), and considerable attention has been given to the proper design of monitoring studies (Heyer et al. 1994; Lips et al. 2001; Weir and Mossman 2005).

There really are two ways to go about monitoring amphibian populations (D. Green 1997b). The first is to follow numbers of individuals in particular populations over long periods of time in the hope of discerning long-term trends in population size. The second is to monitor the number of viable populations of a given species over time. The first approach is useful in providing basic information about the demography of amphibian populations and the factors that normally regulate population size, and therefore is important for a complete understanding of amphibian ecology. It is not, however, a very useful approach for determining whether widespread declines of amphibian populations are occurring.

The difficulty is that many years of accumulated data will be required for each population before definitive trends can be identified. Even the few relatively long time-series data sets on amphibian populations may be inadequate to reveal real population declines. In a study of three data sets for the European common frog (*Rana temporaria*), spanning periods of 23–28 years, only one of three populations showed a clear decline, and that was attributable to the introduction of fish into the breeding habitat (Meyer, Schmidt, and Grossenbacher 1998). Some monitoring programs have shown clear population declines when the monitoring effort happened to correspond to a major population crash (e.g., Corn and Fogelman 1984; Semb-Johansson 1991; Bradford 1991; Kagarise Sherman and Morton 1993), but others showed large but nondirectional changes in population size (e.g., Pechmann et al. 1991; D. Green 1997c). One difficulty with most such studies is that population estimates are based on raw counts of numbers of individuals seen, but are not adjusted for the probability that individuals will be detected. Accurate estimates of year-to-year fluctuation in population size require the use of statistical methods to estimate total population size from the number of marked individuals recaptured over time (B. Schmidt 2003). For most amphibian populations, it is simply not possible to obtain accurate estimates of total population size, either because of logistical difficulties, or because characteristics of the species make accurate censuses impossible. As D. Green (1997b, 297) stated, "There is little chance within a human lifetime to identify what is the normal range of fluctuation in population size for many species of amphibians, and therefore no way to know if a population has deviated from this norm."

The second approach is to monitor the occurrence of populations through repeated sampling over long periods of time. All populations, given enough time, are expected to go extinct, but often are replaced relatively quickly by colonists from nearby populations. Consequently, it is the rate at which populations disappear and become reestablished that determines the likelihood of species extinction (D. Green 1997b; Carlson and Edenhamn 2000). An important consideration in monitoring the occurrence of populations over time is the frequency with which sampling is conducted. Long-term studies of amphibian populations in a large number of ponds on the Edwin S. George Reserve in Michigan revealed that infrequent sampling or long intervals between samples are likely to greatly overestimate the number of local population extinctions (Skelly et al. 2003). Comparative surveys of collecting success after intervals of 20 years or more may be useful in documenting the complete disappearance of populations (e.g., Drost and Fellers 1996; Lips et al. 2004), but are less likely to provide reliable estimates of population declines (e.g., Hairston and Wiley 1993; Highton 2005). This is especially true when only two sampling periods are being compared (e.g., Münch and Schröer 1994; Martínez-Solano, Bosch, and García-París 2003), because it is nearly impossible to distinguish between long-term population declines or disappearances and the short-term effects of variation in rainfall or other conditions that affect breeding success.

Where Are Amphibian Populations Declining?

Declines of amphibian populations have been reported from throughout the world (Stuart et al. 2004), but the data for some areas are better than for others. Information on population size and numbers of viable populations is most reliable for amphibians in North America, Europe, and Australia, where large numbers of biologists are available to monitor population trends. Monitoring efforts are just beginning in some parts of Asia and Latin America and are virtually nonexistent in most of Africa. There are many reports from around the world of apparent declines of individual species or populations of amphibians in *Froglog*, the newsletter of the Declining Amphibian Populations Task Force (DAPTF), but much of this information remains anecdotal and often is based on visits to sites that were studied several decades earlier. The data also are better for some taxonomic groups than for others. Most attention has been given to declines of anuran populations, in part because there are many more of them than other types of amphibians, and because they often are conspicuous and therefore easily monitored. We have much less quantitative information on salamander populations. What we do know often is based on collecting trips 15 or 20 years apart at the same locality, rather than continuous monitoring of populations (e.g., Highton 2005). We have little information on typical population densities of caecilians, although they can be surprisingly abundant, even in human-altered habitats (Oommen et al. 2000; Measey and Di-Bernardo 2003; Measey et al. 2003a, b; Gower et al. 2004; Measy 2004). Although there are some reports of declines in caecilian populations, we lack reliable quantitative data on population trends for these animals (Stuart et al. 2004; Gower and Wilkinson 2005).

In the past 20 years or so, a number of "hot spots" for amphibian population declines have been identified, including montane regions of western North America, Central and South America, and Australia. Amphibian population declines appear to be less severe in other parts of these continents, such as lowland rainforest in South America or eastern deciduous forest in North America. Nevertheless, it is clear that amphibians are vulnerable to declines in any habitat that is under severe pressure, and virtually any amphibian population could be affected by long-term global climate changes. The following sections provide a brief overview of what is known about amphibian declines on all of the major continents and islands.

North America

The West

The pattern of amphibian population declines in North America is somewhat paradoxical in that the most dramatic declines have occurred in the West, the least populated part of the continent, while relatively few species have declined in the Northeast, the most densely populated region. Declines of amphibians in the western United States have been of particular concern because many populations have disappeared from apparently pristine and largely uninhabited areas, including national parks. Ranids and bufonids have been most affected, with declines or disappearances of populations reported in Yosemite, Sequoia, Kings Canyon, and Lassen National Parks in California (Bradford 1991; Fellers and Drost 1993; Kagarise Sherman and Morton 1993; Bradford, Graber, and Tabatabai 1994; Drost and Fellers 1996). Populations of native ranids and bufonids have declined elsewhere in the West as well, including the Pacific Northwest, the mountains of Colorado (including Rocky Mountain National Park), Yellowstone National Park in Wyoming, the Central Valley of California, and the desert Southwest (Corn and Fogleman 1984; Clarkson and Rorabaugh 1989; A. Blaustein and Olson 1991; Olson 1992; Carey 1993; Corn 1994, 2003; M. Jennings and Hayes 1994; Fisher and Shaffer 1996; Corn, Jennings and Muths 1997; Patla and Peterson 1999). In Canada, a number of ranids and at least one species of *Bufo* have declined in western Canada (British Columbia and Alberta), but not in eastern provinces. As in the United States, *Rana pipiens* has nearly disappeared from western Canada (D. Green 1997b). M. Hayes and Jennings (1986) estimated that every native ranid species in western North America had experienced either local or regional population declines. A variety of causes have been implicated in these declines, including destruction of breeding habitat, the introduction of exotic predators such as fishes and bullfrogs (*Rana catesbeiana*), use of pesticides and other agricultural chemicals, increased UV radiation, and fungal infections and other diseases. These are discussed in more detail in later sections.

Several of the most severely threatened species of frogs and toads in the West, including those now thought to be extinct, are those with historically limited ranges in specialized habitats, such as canyon streams and springs in otherwise arid environments. These include the Wyoming toad (*Bufo baxteri*), Amargosa toad (*Bufo nelsoni*), Vegas Valley leopard frog (*Rana fisheri*), and relict leopard frog (*Rana onca*). Other species, including *Bufo boreas* (fig. 16.8 C), *B. canorus, Rana pipiens, R. yavapaiensis, R. chiricahuensis, R. pretiosa, R. luteiventris, R. tarahumarae, R. muscosa, R. cascadae,* and *R. draytonii,* were once more widespread, and in some cases were very abundant. All have suffered local or regional population declines, although some species are secure in parts of their ranges (Corn 1994, 2003; M. Jennings and Hayes 1994; Pearl and Hayes 2005). Other western anurans, including hylid treefrogs, the largely fossorial spadefoot toads, and the tailed frogs (*Ascaphus*) apparently have not suffered widespread population declines, although populations of all of these groups are vulnerable to habitat destruction and some have been eliminated from parts of their historic ranges (e.g., *Spea hammondii* in the Central Valley of California; Fisher and Shaffer 1996).

There is little evidence for widespread declines of western species of salamanders, although some species with very small ranges, such as *Batrachoseps aridis,* are endangered (Corn 1994). Some populations of *Ambystoma tigrinum, A. californiense* (fig. 16.8 B), and *A. macrodactylum* have declined or disappeared, in many cases because of habitat destruction or the introduction of predatory fishes (Collins, Jones, and Berna 1988; Ruth 1988; Harte and Hoffman 1989; Corn 1994; Barry and Shaffer 1994). Some of these populations subsequently recovered (Wissinger and Whiteman 1992). *Ambystoma tigrinum* has declined in British Columbia, but not elsewhere in Canada (Weller and Green 1997). Logging and other habitat alteration may threaten local populations of terrestrial and stream-dwelling salamanders, but populations may eventually recover in areas

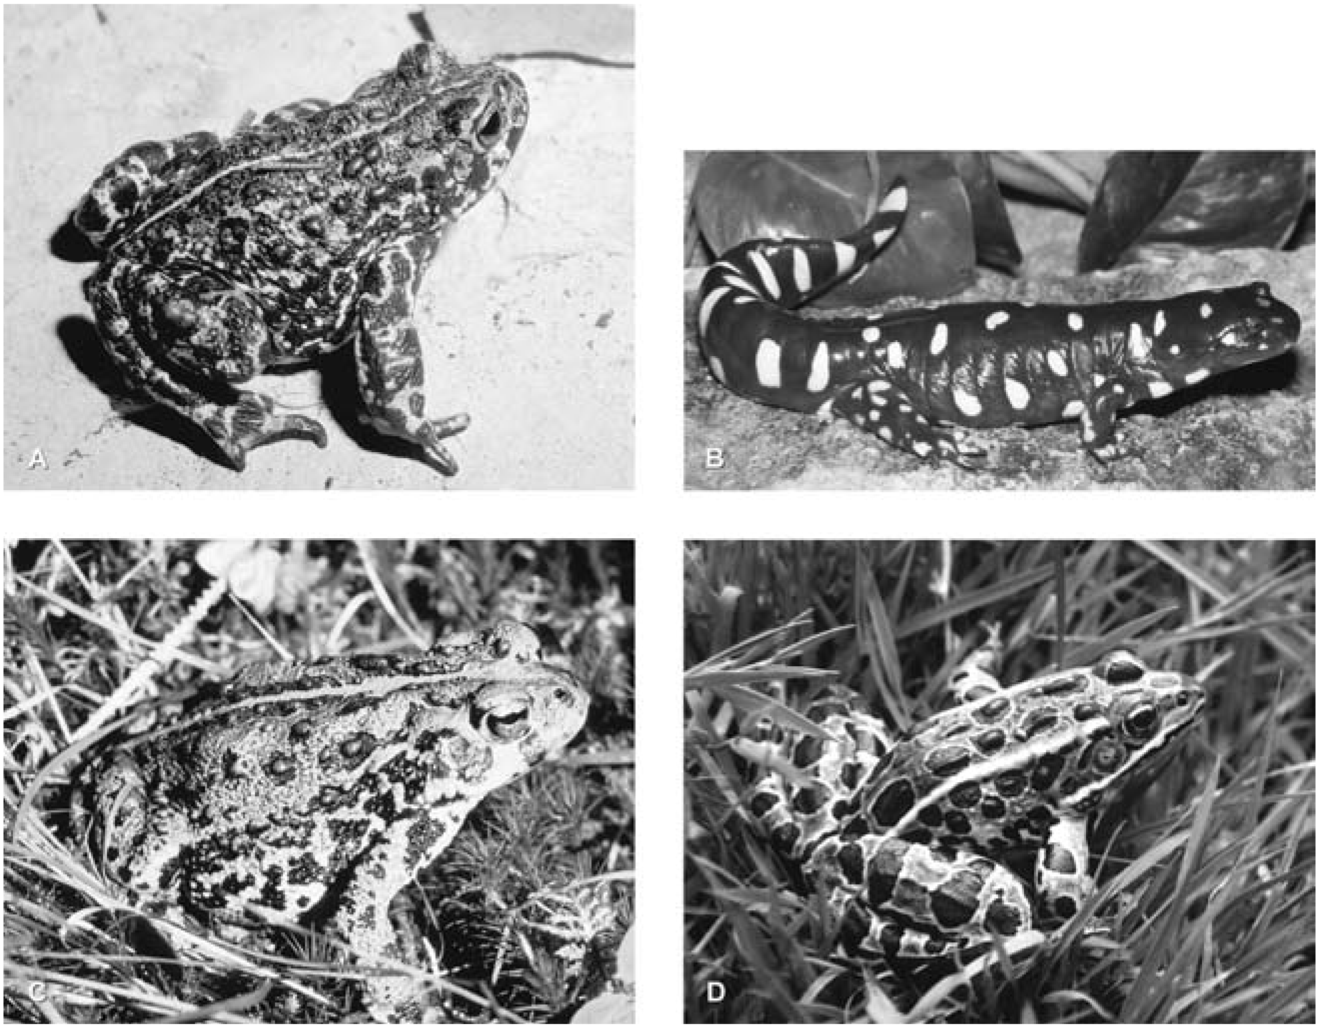

Fig. 16.8. Populations of amphibians in western North America are vulnerable for a number of reasons. (A) The black toad, *Bufo exsul,* has one of the smallest geographic ranges of any North American anuran, being limited to an area of about 15 hectares around four spring systems in Deep Springs Valley, Inyo County, California. The population currently appears to be stable, but is highly vulnerable to habitat alteration. (B) The California tiger salamander, *Ambystoma californiense,* is a California endemic with a range centered on the Central Valley, an area heavily impacted by agriculture, habitat degradation, and chemical pollution. Many populations are considered endangered and others have disappeared. (C) The western toad, *Bufo boreas,* has a wide distribution in western North America and once was very abundant. Some populations have suffered catastrophic declines, especially at high altitudes, but others remain stable. (D) The northern leopard frog, *Rana pipiens,* has one of the largest geographic ranges of any North American anuran. Populations have virtually disappeared from western North America and have suffered major declines in the Midwest, but are relatively secure in eastern North America. Possible factors contributing to the decline of this species include wetland destruction, habitat fragmentation, conversion of natural habitats to agriculture, pollution from pesticides and other chemicals, and introduction of nonnative predators. Photos by Wayne Van Devender (A, B), Carl W. Rettenmeyer (C), and Kentwood D. Wells (D).

that are not completely clearcut (Bury and Corn 1988a, b; A. Blaustein et al. 1995; Diller and Wallace 1996; Grialou, West, and Wilkins 2000; Aubry 2000; Naughton et al. 2000; Wilkins and Peterson 2000).

The Midwest

The status of midwestern amphibians was reviewed in detail in Lannoo (1998a). Much of this region lacks the vast tracts of national parks and forests and other protected lands that dominate the West, although the Upper Midwest (northern Minnesota, Michigan, and Wisconsin) is heavily forested, as are parts of Indiana, Illinois, and Ohio. Many midwestern amphibians exist in a mosaic of forests, wetlands, and other natural habitats, intensive agricultural lands, and urban and suburban development (Porej, Micacchion, and Hetherington 2004). Major threats to midwestern amphibians appear to be habitat destruction and fragmentation, the intensive use of pesticides, fertilizers, and other agricultural chemicals, and widespread introduction of predatory game fishes and bullfrogs into ponds and lakes. None of the species of amphibians in the Midwest appears to be immediately threatened with extinction, but the abundance of many species, such as the northern leopard frog (*Rana pipiens;* fig. 16.8 D) undoubtedly is a small fraction of what was present before the advent of modern agriculture.

Several of the midwestern states are among those with the greatest loss of original wetland habitat, with estimated losses of at least 90% in Ohio, 89% in Iowa, 87% in Indiana, and 85% in Illinois, and this is likely to have impacted populations of amphibians more than those of some other vertebrates (Leja 1998). Beginning in the Dust Bowl years of the 1930s, many natural wetlands in the Midwest were replaced by hundreds of thousands of artificial farm ponds, many of them stocked with fish. Most of these provide poor habitat for amphibians other than bullfrogs, which can coexist with fish (Lannoo 1996, 1998b). Similar patterns of wetland loss or conversion have occurred in the Great Plains states, including Nebraska (McLeod 2005) and South Dakota (Naugle et al. 2005), with concomitant reductions in the abundance of amphibian species that depend on fish-free temporary ponds for breeding. In some states, loss of amphibian habitats probably has accelerated in recent decades with the decline of cattle grazing and the rise of row crop agriculture. Not only does this tend to eliminate many seasonal wetlands that make planting of crops inconvenient, but it also leads to increased application of fertilizers and pesticides that leach into the remaining wetland habitats (R. Gray and Brown 2005).

In contrast to the western United States, the Midwest has not experienced recent synchronous declines of many species of amphibians in particular regions, nor has there been a differential impact on certain taxa, such as ranids and bufonids. Currently about 30% of the salamanders species and 26% of the anuran species in this region are listed as endangered, threatened, or of special concern in at least one midwestern state, but only a few species are listed in many different states (Lannoo 1998c). Most of these tend to be species with relatively limited ranges or specialized habitat requirements. For example, the four-toed salamander (*Hemidactylim scutatum*) is rare in much of the Midwest and is limited to sphagnum bogs; it is listed in all of the states where it occurs. Similarly, the green salamander (*Aneides aeneus*), a habitat specialist, is at the periphery of its range in this region and occurs in only two states, where it is listed as endangered. The hellbender (*Cryptobranchus alleganiensis*), which requires unpolluted river habitats, is listed as endangered in three of the four midwestern states where it occurs.

Among the anurans, the Illinois chorus frog (*Pseudacris illinoensis*) has perhaps the most specialized habitat requirements, and is limited to isolated patches of once plentiful sand prairie wetlands that mostly have been converted to agriculture (Brandon and Ballard 1998; L. Brown and Cima 1998; Tucker 1998). It is considered rare or threatened in the states where it occurs. An exception to this pattern is the northern cricket frog (*Acris crepitans*), which occurs throughout the Midwest and is abundant in some areas, but has experienced pronounced declines since the 1950s in the upper Midwest (Hay 1998; Lannoo 1998c; R. Gray and Brown 2005). The causes of these declines are unclear, but probably include changes in wetland management that have reduced the availability of fish-free permanent wetlands suitable for cricket frogs, changes in cattle grazing practices that have altered the vegetation on the banks of ponds, and other human-induced habitat alterations. R. Gray and Brown (2005) listed more than 50 possible human-induced environmental changes that may negatively impact cricket frog populations. While many of these factors are likely to affect other amphibians as well, they speculated that cricket frogs are especially vulnerable because of their short adult lifespans and relatively small effective population sizes, which make populations especially vulnerable to events such as prolonged droughts (D. Green 2003).

The East and South

Less detailed information has been published on the overall status of amphibians in the eastern and southern states than in the West and Midwest, but population monitoring efforts are now underway in most states. These regions have not experienced recent widespread population declines like those in the West and in some species in the Midwest, although local declines have occurred due to habitat alteration or changes in rainfall regimes and pond hydroperiods (Daszak et al. 2005). Many anurans in the eastern United States have large geographic ranges, and many tend to be habitat generalists that can adapt to a variety of breeding sites and terrestrial environments. Some species do well in human-altered environments or are relatively tolerant of the proximity of humans. For example, Fowler's toads (*Bufo fowleri*) favor more open habitats than do American toads (*Bufo americanus*), which share much of their range, and may actually benefit from land clearing (D. Green 2005b). Bullfrogs (*Rana catesbeiana*) do well in fish hatcheries, farm ponds, and other artificial bodies of water that contain fish. In Florida, the introduced Cuban treefrog (*Osteopilus septentrionalis*) has expanded its range, taking advantage of human-altered habitats not used by many other anurans (Meshaka 2001).

Some widespread anuran species that have declined elsewhere remain common in the eastern part of the country. Most notable is the northern leopard frog (*Rana pipiens*), which has disappeared from much of the western part of its range in both the United States and Canada, and has experienced pronounced declines in abundance in the Midwest, but remains common in much of the East (Rorabaugh 2005). For most widespread anuran species in the East and South, local populations remain threatened by habitat destruction and the relentless development of land for housing, shopping centers, roads, golf courses, and other human activities that are detrimental to amphibians, but none appears to be threatened with extinction.

Some eastern anurans have more specialized habitat requirements and may be more sensitive to habitat alteration by human activities. The disappearance of many historical populations of the eastern spadefoot toad (*Scaphiopus holbrookii*) at the periphery of its range in Connecticut has already been mentioned (Klemens 1993). Another habitat specialist is the Pine Barrens treefrog (*Hyla andersonii;* fig. 7.23 D in chapter 7), which is limited to pine barrens habitats and is distributed in a number of disjunct populations in New Jersey, the Carolinas, the Florida Panhandle, and Alabama (Means 2005). While this frog can be locally abundant, populations undoubtedly have been reduced by widespread destruction of suitable habitat. Current populations remain at risk because their habitat often is considered unattractive wasteland and therefore prime land for industrial, commercial, or residential development.

The gopher frogs (*Rana capito* and *R. sevosa*) were once widespread in longleaf pine forests of the Atlantic and Gulf coastal plains, but 95% of this habitat has disappeared, having been replaced by pine plantations or development. These frogs are considered threatened or endangered in all of the states where they occur, and *R. sevosa* currently is known from only a single pond in Mississippi (Richter et al. 2003; Jensen and Richter 2005; Richter and Jensen 2005). Gopher frogs share their specialized habitat with the flatwoods salamander (*Ambystoma cingulatum;* fig. 16.9), which has undergone a similar drastic decline in breeding populations (Dodd 1995; Means, Palis, and Baggett 1996; Palis and Means 2005).

Fig. 16.9. The Flatwoods Salamander, *Ambystoma cingulatum,* is endemic to longleaf pine flatwoods habitats in the southeastern United States. This species is threatened by the conversion of most such habitats to managed pine plantations, which often lack the seasonal flooding required by this species for reproduction, as well as herbaceous cover in the terrestrial habitats of adults. Photo by Wayne Van Devender.

Most other eastern and southern species of *Ambystoma* have more generalized habitat requirements and remain relatively common in most areas (Lannoo 2005). Most of these species prefer or require fish-free temporary wetlands for reproduction, so are potentially vulnerable to the introduction of fishes and the usual array of habitat degradation and destruction that affects temporary wetlands throughout the country. Most of the aquatic salamanders of the East and South also appear to be secure (*Necturus, Cryptobranchus, Siren, Pseudobranchus,* and *Amphiuma*), although species with relatively restricted ranges are likely to be at some risk (e.g., *Necturus alabamensis;* Bailey 2005). Local populations of many of these species remain vulnerable to all sorts of habitat degradation that affect aquatic environments, but widespread population declines have not been reported.

Mexico, Central and South America, and the Caribbean

Much of the recent concern over declining amphibian populations has focused on Latin America, especially montane regions of Mexico, Central America, and South America (Young et al. 2001; Crump 2003; Lips et al. 2004; Young et al. 2004; Lips and Donnelly 2005). Until recently, most information on amphibian populations in this region came from collecting efforts of systematists, not from detailed ecological studies, so quantitative information on the status of populations is scarce. Many parts of Latin America have been poorly studied, and efforts to monitor amphibian populations have only recently begun (Lips et al. 2001). Monitoring efforts will have to continue for many years if long-term population trends are to be detected, but in the meantime, efforts to preserve critical habitats are needed (Young et al. 2001; Lips et al. 2005). Throughout much of this region, amphibian populations are threatened by widespread deforestation and other forms of habitat destruction and degradation associated with rapidly growing human populations. A typical example is Honduras, which has a rich amphibian fauna, but also a poor and expanding human population. Widespread environmental degradation threatens more than half of the amphibian species, some of which already are extinct (McCranie and Wilson 2002; L. Wilson and McCranie 2003).

There also have been disturbing accounts of amphibian species declining or disappearing in apparently pristine protected habitats, such as the cloud forests around Monte Verde in Costa Rica (Pounds and Crump 1994; Pounds et al. 1997), as well as dramatic observations of dead and dying frogs in forests elsewhere in Costa Rica, Panama, and Colombia (Lips 1998, 1999; J. D. Lynch and Grant 1998). Similar declines have occurred elsewhere in Mexico and Central and South America, especially in montane regions above 500–800 meters in Mexico and Central America and 1,000 meters in the Andes of South America (Young et al. 2001; Lips et al. 2004; Lips and Donnelly 2005; Young et al. 2004). Ecuador has been particularly hard hit, with both species diversity and abundance having been reduced at many localities in the Andes (Bustamante, Ron, and Coloma 2005). As mentioned earlier, the Atlantic Coastal Forest of Brazil (fig. 16.10 A, B), which includes some montane habitats, has been especially hard hit (Heyer et al. 1988; Weygoldt 1989a; Guix et al. 1998; Eterovick et al. 2005). Population declines have been less evident in lowland rainforest, including the Amazon Basin (e.g., Duellman 1995; Salas et al. 1999; Azevedo-Ramos and Galatti 2002), but have occurred in some areas where the forest has been destroyed or fragmented (Tocher, Gascon, and Zimmerman 1997; Funk and Mills 2003; Eterovick et al. 2005). Population declines in tropical montane regions are of particular concern, because these areas tend to have the highest species diversity of amphibians, the largest proportion of endemic species, and a high proportion of species with limited ranges (Duellman 1999a; Lips et al. 2004; Lips and Donnelly 2005; Young et al. 2004).

Attention has focused mostly on anurans, which are far more conspicuous and more easily monitored than are urodeles. A wide variety of anuran genera have been affected, but certain groups appear to be particular vulnerable, especially those closely associated with streams. These include bufonids

Fig. 16.10. Parts of the Neotropics are considered hotspots for amphibian population declines. The Atlantic Rainforest of Brazil harbors a large number of unusual endemic species of anurans, especially in the family Leptodactylidae. Some of these, including *Paratelmatobius lutzi* (A) and *Holoaden bradei* (B), have not been seen in the wild for many years. Major population declines also have occurred in the cloud forest of Monte Verde in Costa Rica, where the spectacular bright orange toad *Bufo periglenes* (C) apparently has gone extinct. In Puerto Rico, three endemic species of *Eleutherodactylus* appear to be extinct. Other species, including the tiny forest floor frog *E. wightmanae* (D), have declined in some parts of the island, especially at high altitudes. Possible causes for declines of these and other Neotropical species include disease, habitat destruction and fragmentation, and climate change. Photos by Ivan Sazima (A, B), Wayne Van Devender (C), and Kentwood D. Wells (D).

of the genus *Atelopus* (with up to a third of all known species having disappeared and most populations endangered), dendrobatids of the genus *Colostethus,* centrolenids, and several genera of stream-breeding hylids (Coloma 1995; Lötters 1996; Pounds et al. 1997; Young et al. 2001; Lips et al. 2004; La Marca et al. 2005). Anurans with direct development, including some species of *Eleutherodactylus,* have declined in some areas (e.g., southern Mexico; Lips et al. 2004), as have some species that breed in small bodies of water, such as *Bufo periglenes* in Costa Rica, which is thought to be extinct (fig. 16.10 C). In general, however, species that lack aquatic larvae appear to have been less affected than have stream-breeding frogs (Bustamante, Ron, and Coloma 2005; Lips et al. 2005). Most anurans that depend on permanent or temporary ponds for reproduction do not appear to have suffered widespread declines. Nevertheless, there have been localized declines of some species (e.g., *Hyla pseudopuma* at Monte Verde, Costa Rica; Pounds et al. 1997), and whole assemblages of amphibians have been eliminated in areas affected by habitat destruction (Duellman 1978). Although salamander populations in Latin America have not been studied as intensively as have anuran populations, there is evidence for localized declines of some species (e.g., *Bolitoglossa pesrubra* at Cerro de la Muerte, Costa Rica; Lips and Donnelly 2005; *Lineatriton lineolus* in the mountains of southern Mexico; Lips et al. 2004). Because many Neotropical salamanders have narrow altitudinal distributions, future changes in climate may reduce the ranges of many species (Parra-Olea, Martínez-Meyer, and Pérez-Ponce de Leon 2005).

The anuran fauna of most Caribbean islands (except for Trinidad and Tobago) differs from that of mainland South and Central America in being dominated by the genus *Eleutherodactylus,* which has direct development of terrestrial eggs. There also are a few species of hylids, dendrobatids, and bufonids, which include riparian, fossorial, and semiarboreal species. Some species of *Eleutherodactylus* also are riparian, although they do not breed in water. Many of these amphibians are associated with forested habitats, although some occur in more open areas. Islands of the Caribbean have suffered enormous reductions in their original forests, with remaining forest cover estimated from a high of about 13% for Cuba to a low of < 1% for Haiti. It therefore seems likely that many Caribbean amphibians are vulnerable to population declines or extinction (Young et al. 2004). Nevertheless, definitive evidence of such declines is limited, largely because of a scarcity of herpetologists searching for rare species in suitable habitats (Hedges 1993).

The best-studied region is Puerto Rico, where there is clear evidence of the decline and possible extinction of some species of *Eleutherodactylus,* while other species have prospered. The largest species on the island, *E. karlschmidti,* has not been found since 1974. It was a conspicuous frog closely associated with stream habitats and is unlikely to be missed by experienced herpetologists, so is presumed to be extinct (Burrowes and Joglar 1991; Hedges 1993; Joglar and Burrowes 1996; Joglar 1998; Burrowes, Joglar, and Green 2004). The cause of the disappearance of this species is unknown, but other species of *Eleutherodactylus* associated with streams have declined elsewhere in the Caribbean (Hedges 1993) and in Mexico and Central America (Lips et al. 2004). Also generally considered to be extinct is the unique ovoviviparous frog *E. jasperi,* last seen in 1981. This species is a bromeliad specialist and therefore more difficult to detect, especially at low population levels. Some of the limited known habitat of this species has been destroyed (Burrowes and Joglar 1991), but definitive evidence that it is extinct is lacking (Hedges 1993). A third species, with more generalized habitat requirements and a wider distribution on the island, *E. eneidae,* also has disappeared. Several other species, including *E. coqui, E. portoricensis, E. wightmanae* (fig. 16.10 D), *E. richmondi, E. locustus,* and *E. gryllus,* have suffered localized population extinctions or declines, especially at higher altitudes, even in protected forests (Joglar and Burrowes 1996; Woolbright 1997; Burrowes, Joglar, and Green 2004). On the other hand, most species found in lowland habitats have not declined, perhaps because they are better able to adapt to human-altered landscapes. *Eleutherodactylus coqui,* in particular, is an extreme habitat generalist and is found at both low and high elevations in Puerto Rico and does well even in plantations of introduced *Eucalyptus* trees (Joglar 1998; Beard et al. 2003; Fogarty and Vilella 2003).

The diversity of habitats used by the declining species in Puerto Rico, and the persistence of some species in areas where others have declined, suggests that there is not a single cause of population declines in this region. Stallard (2001) examined long-term data on environmental variables such as forest cover, temperature, precipitation, rain and stream chemistry, and atmospheric dust transport for eastern Puerto Rico, where high-elevation populations of some frogs have declined. He found significant levels of air pollution in the area, but could not definitively tie pollution to anuran declines, nor were changes in rainfall and temperature thought to be significant enough to contribute to the observed declines. An analysis of remote-sensing data for a number of regions that have experienced amphibian declines, including Puerto Rico, also failed to show definitive correlations between environmental variables and population declines (Carey et al. 2001). Temperatures in Puerto Rico were somewhat higher than normal and precipitation somewhat lower during the periods when some declines of frogs occurred (M. Alexander and Eischeid 2001; Burrowes, Joglar, and Green 2004). Prolonged periods with relatively little rainfall, even when annual rainfall is near normal, can decrease population size in these frogs and could lead to local extinction of rare species (M. Stewart 1995). Stress associated with drought also could weaken defenses of frogs against disease, and there is some evidence for chytrid fungus infections in two species of *Eleutherodactylus* in Puerto Rico in the 1970s, although one of these, *E. coqui,* remains abundant today (Burrowes, Joglar, and Green 2004).

Australia and New Zealand

For a continent dominated by arid habits, Australia has a remarkably rich anuran fauna (over 200 species), but lacks both caecilians and salamanders. Family-level diversity is low, with the fauna dominated by the families Hylidae and Myobatrachidae. Members of these families have adapted to many different habitats, from extreme deserts to tropical rainforests. A few microhylids and ranids are found in tropical regions of far northern Australia, and one introduced bufonid, *Bufo marinus,* has spread over much of the northeastern part of the country (Lever 2001). Australia has a low human population density over much of the continent, with most of the population concentrated in coastal areas where development may threaten some anurans. The country has a relatively large community of herpetologists, so the status of Australian frogs is reasonably well known compared to some other continents (A. Campbell 1999).

Declines of anuran populations have been reported in several regions of Australia. Some of these clearly seem to be related to human encroachment on natural habitats, as has occurred along the east coast of Queensland and New South Wales (Hines, Mahony, and McDonald 1999) and for some species in areas around Sydney (Thumm and Mahony 1999). Logging and cattle grazing in state and private forests threatens some species in northern New South Wales and southern Queensland (Lemckert and Morse 1999; K. Parris 2001), while human alteration of natural streams has reduced frog habitats on the Southern Tablelands of New South Wales (Hazell, Osborne, and Lindenmayer 2003). Some species also have declined in upland and montane habitats in more protected areas of New South Wales and Victoria (Gillespie and Hines 1999; W. Osborne, Hunter, and Hollis 1999). Many of these species have restricted ranges or utilize specialized habitats (Murray and Hose 2005). The status of anurans in Western Australia is poorly known because relatively few people have worked in this vast, arid region. Three species, *Geocrinia alba, G. vitellina,* and *Spicospina flammocaerulea,* all of which have very small or fragmented ranges, are considered to be endangered (D. Roberts, Conroy, and Williams 1999; Conroy and Brook 2003).

The declines that have received the most attention have occurred in rainforest populations of hylids and myobatrachids in Queensland (K. McDonald 1990; S. S, Richards, McDonald, and Alford 1993; Trennery, Laurance, and McDonald 1993; K. McDonald and Alford 1999). Many of these populations were in national parks and other protected areas, and appear to have undergone relatively synchronous declines starting in the late 1970s. Nearly all of these species were stream breeders, as has been the case for declines in South and Central America (S. Williams and Hero 1998). The relatively rapid declines of many species living in the same habitat suggested the possibility of unusual weather connected with El Niño events or epidemic disease as a major cause of decline (Laurance 1996; Laurance, McDonald, and Speare 1996). Although the latter idea initially was controversial (Alford and Richards 1997; Hero and Gillespie 1997), there is increasing evidence that chrytrid fungal infections were involved in at least some anuran declines in this area (Berger et al. 1998; Berger, Speare, and Hyatt 1999). This issue is discussed in more detail in a later section. A number of frogs, including two species of *Taudactylus* (fig. 16.11 A), the two unique gastric-brooding frogs of the genus *Rheobatrachus* (fig. 16.11 B), and several treefrogs in the genus *Litoria* appear to be extinct (A. Campbell 1999). Some others, such as the cascade treefrog (*Litoria pearsoniana*), seem to have recovered from earlier population declines, although some of the evidence for dramatic declines of this species in the 1970s and 1980s is questionable (K. Parris 2001).

In contrast to Australia, New Zealand has very few frogs. The only native frogs are four species of *Leiopelma* (fig. 1.14 E in chapter 1). Some Australian hylids (*Litoria*) have been introduced, and some populations of these species declined in the 1990s (P. Bishop 1999; B. Bell et al. 2004). This genus *Leiopelma* is now restricted to the northern part of the country and some offshore islands, but probably was once found throughout New Zealand (B. Bell 1994; Holyoake, Waldman, and Gemmell 2001). Several species appear to have gone extinct after the arrival of humans and their associated animals, especially rats (Towns and Daugherty 1994). A number of features of the biology of these frogs make them vulnerable to population declines or extinctions. Most have restricted ranges and limited dispersal abilities. They appear to be unusually long-lived (perhaps more than 30 years; B. Bell, Pledger, and Dewhurst 2004), but have very low reproductive rates. They also are vulnerable to introduced predators, including rats and Australian treefrogs (*Litoria;* Thurley and Bell 1994).

The most widely distributed species is *L. hochstetteri,* but it is found in isolated small populations. *Leiopelma archeyi* has a smaller geographic range, and some populations have experienced significant declines, possibly due to infection by chytrid fungus (B. Bell 1999; B. Bell et al. 2004). This species is now considered critically endangered. Several populations of *Leiopelma* are restricted to two small off-

Fig. 16.11. Montane rainforests of Queensland, Australia are hotspots of amphibian population declines. Among the frogs that have disappeared are several stream-dwelling myobatrachid frogs, such as *Taudactylus diurnus* (A) and the unique gastric-brooding frogs of the genus *Rheobatrachus,* including *R. silus* (B). The fungal disease chytridiomycosis has been implicated in the declines of these species. Photos by Harold Cogger.

shore islands, Stephens and Maud Islands. The Stephens Island frogs (*L. hamiltoni*) are very rare, with perhaps no more than 200 individuals (D. Newman 1990). They have been the subject of transplantation efforts to establish a population in a new habitat (D. Brown 1994). The Maud Island population consists of several thousand individuals in a remnant of forest (E. Bell and Bell 1994). In the 1980s, one hundred of these frogs were introduced into a new location on Maud Island and appear to have established a stable population (B. Bell, Pledger, and Dewhurst 2004). The Maud Island frogs were considered conspecific with the Stephens Island *L. hamiltoni* until B. Bell, Daugherty, and Hay (1998) described this population as a new species, *L. pakeka.* More recent DNA sequence data indicated that these two populations are genetically similar and probably should not be considered different species (Holyoake, Waldman, and Gemmell 2001), but the issue remains controversial (B. Bell, Pledger, and Dewhurst 2004). The taxonomic status of the frogs is important for their conservation status, because without the Maud Island population, *L. hamiltoni* has been considered one of the world's rarest and most endangered anuran species. Whatever the taxonomic status of these populations, it is clear that the Stephens Island population cannot survive without active protection and management.

Europe

Europe has been densely populated by humans for thousands of years and has been heavily altered by agriculture, industrialization, and urbanization. To make matters worse, the species diversity of amphibians in Europe is positively correlated with human population density (Araújo 2003). Partly this reflects a latitudinal effect, with amphibian diversity and human population density both decreasing in the colder northern parts of Europe. Habitats that most North Americans would consider pristine natural areas are scarce; most European amphibians live in a mosaic landscape consisting of small patches of relatively natural habitat interspersed with agricultural land, small towns, suburbs, cities, industrial areas, and roads. Even many national parks and reserves in Europe include human-altered habitats and do not resemble the large tracts of wilderness found in the western parts of North America, or even those in parts of eastern North America such as the Adirondack Mountains in New York, Algonquin Park in Ontario, and the largely uninhabited forests of northern Maine. There are a few exceptions, such as the Białowieża Primeval Forest in Poland, which supports dense populations of amphibians (Pikulik et al. 2001) that provide an essential source of food for the abundant carnivorous mammals in the area (see chapter 14). Unfortunately, only a small portion of this forest is currently protected as a national park, with the remainder subject to logging that may leave the protected forest as an isolated island habitat (Tomiałojć and Wesołowski 2004).

The amphibian fauna of Europe is relatively depauperate, due in large part to Pleistocene glaciation and the east-west orientation of several major mountain ranges that probably blocked movement of some amphibians into southern refugia during glacial periods. Borkin (1999) listed 77 species of amphibians in Europe, from Spain to Russia and Turkey (32 urodeles, 45 anurans), but the number found north of the Mediterranean region is less than half of the total (about 35 species). This means that all of Central and Northern Europe has fewer species of amphibians than the state of North Carolina. Even regions whose local species diversity is relatively high have only 15–20 species of amphibians, fewer

Fig. 16.12. Europe has a relatively impoverished amphibian fauna, with the greatest diversity found in southern Europe. The Mediterranean treefrog, *Hyla meridionalis,* shown here, is abundant in southern Europe and is not a major conservation concern. The closely related and morphologically similar northern species, *Hyla arborea,* has suffered declines in many parts of Europe, due mainly to habitat destruction and fragmentation. Habitat protection and restoration have increased population sizes in some countries. Photo by Walter Hödl.

than are found in a small northeastern state like Connecticut. The Mediterranean region, which includes the area from the Iberian Peninsula to Turkey and the northern fringe of Africa, has the most diverse amphibian fauna (fig. 16.12), as well as the largest proportion of endemic species (69% of urodeles and 56% of anurans). Many of these endemics have small geographic ranges resulting from fragmentation of ancestral populations in Pleistocene refugia, and therefore may be at greater risk than are the more widespread species found in northern and central Europe. Northwestern Italy has among the highest local diversity because this is where Italian endemics meet more widespread European species and those found further east in the Iberian Peninsula (Andreone and Sindaco 1998; Andreone and Luiselli 2000). There also are isolated populations of more widespread species, such as *Rana lessonae* in Britain and Sweden, that probably are the result of Pleistocene colonization events at the margins of the species' range (Beebee et al. 2005; Snell, Tetter, and Evans 2005). These peripheral populations are vulnerable to extinction, even if the species is not threatened elsewhere (indeed, the last individual of *R. lessonae* from Britain died in 1999).

The highly altered landscape of Europe, with its mosaic of natural and human-altered landscapes, as well as the large number of species with restricted ranges, has resulted in Europeans having a somewhat different perspective toward amphibian conservation than one finds in North America or in the tropics. North American conservationists tend to focus first on protection of natural habitats and buffer zones around breeding sites and minimizing the impact of human activities on amphibians in mosaic landscapes (Calhoun and Hunter 2003; Semlitsch and Rothermel 2003). European conservationists have been somewhat more focused on active management of landscapes for amphibians, restoration of degraded habitats, creation of new habitats such as breeding ponds, mitigation of wetland loss, and transfer of amphibian populations to newly created wetlands, and captive rearing and release programs to increase the number and size of amphibian populations (Thielcke et al. 1985; Zvirgzds, Stašuls, and Vilnītis 1995; Beebee 1996; Buley and Garcia 1997; Hödl, Jehle, and Gollmann 1997; Directorate of Culture and Cultural and Natural Heritage, Council of Europe 2003; Buckley and Beebee 2004; Edgar, Griffiths, and Foster 2005; Snell, Tetter, and Evans 2005). They have devoted considerable effort to identifying potential amphibian breeding sites in disturbed habitats, such as urban and suburban areas (Beebee 1979c; Dalbeck et al. 1997). European conservationists also have focused attention on individual species that appear to be at elevated risk because of specialized habitat requirements (e.g., the moor frog, *Rana arvalis,* and the natterjack toad, *Bufo calamita;* Beebee 1983, Glandt and Podloucky 1987; Banks, Beebee, and Denton 1993; Sinsch 1998; Buckley and Beebee 2004), fragmented habitats (e.g., *Hyla arborea*) (Stumpel and Tester 1993; L. Andersen, Fog, and Damgaard 2004), or naturally restricted ranges (e.g., island populations; Buley and Garcia 1997; Gibson and Freeman1997; Andreone and Luiselli 2000; Lecis and Norris 2003, 2004).

Most European amphibian species, even those that are not endangered, receive some legal protection (Corbett 1989; Beebee 1996; Beebee and Griffiths 2000; Spellerberg 2002; Directorate of Culture and Cultural and Natural Heritage, Council of Europe 2003). Such laws are aimed primarily at regulating or prohibiting the collection and commercial trading of amphibians. In some cases, there also is some protection against destruction or degradation of critical amphibian habitats, but legal protections are not always effective in protecting amphibians against habitat destruction and fragmentation (McLean, Wight, and Williams 1999). Unfortunately, some European governments have been slow to draft or implement action plans for threatened and endangered species of amphibians that have been identified as priorities by experts in amphibian conservation. Furthermore, despite the large number of herpetologists in Europe and increasing interest in conservation issues, information on the status of many European amphibians is fragmentary (Directorate of Culture and Cultural and Natural Heritage, Council of Europe 2003). There also is considerable variation among European countries in the extent to which natural habitats remain available to amphibians. In Eastern Europe, for example, some countries, such as Romania, have suffered major environmental degradation and undisturbed habitats are scarce. Others, such as Croatia, have many natural areas intact and a large network of protected sites.

The European amphibians at greatest risk for population declines or extinction are mostly those with limited ranges, as discussed previously. These include island endemics such as *Alytes muletensis,* restricted to small habitats on Mallorca, and *Discoglossus sardus, Hyla sarda,* and *Euproctus platycephalus,* which are endemic to Sardinia. Also at risk are habitat specialists such as cave salamanders (*Proteus, Speleomantes* [= *Hydromantes*]), brook salamanders (*Euproctus*), the natterjack toad (*Bufo calamita*), and the moor frog (*Rana arvalis*). Mainland species with relatively small natural ranges are at risk, although not all are currently declining. Many of these species are found in southern Europe, especially the Mediterranean region, including a number of species largely or completely restricted to Italy (*Pelobates fuscus insubricus, Rana italica, R. latastei, Triturus italicus, T. carnifex*) or the Iberian peninsula (*Alytes cisternasii, Rana iberica, Triturus boscai*).

Some relatively widespread European species with generalized habitat requirements have undergone declines in some regions, while remaining stable in others. For example, the common frog (*Rana temporaria*) is found throughout Europe, and has adapted well to human-inhabited landscapes, using garden ponds and other man-made sites for breeding. In Britain, this species declined in the 1960s and 1970s due to intensification of agriculture, but it has rebounded with the increasing popularity of garden ponds in urban and suburban areas and efforts to provide new breeding sites (Beebee 1979c, 1996, 1997; J. M. R. Baker and Halliday 1999; Beebee and Griffiths 2000; Robinson and Sutherland 2002). In Sweden, moderate agricultural land use in the northern part of the country actually provides more favorable habitat for this species than does undisturbed forest. Conversely, in the more intensively used agricultural land of southern Sweden, there is greater fragmentation of forest habitat and poorer quality habitat for common frogs, resulting in lower population densities and lower genetic diversity within populations (Johansson et al. 2005). In Switzerland, long-term population records from the area near Bern indicated that two populations have remained relatively stable, while a third has declined, probabably due to the introduction of predatory fish into the breeding site (Meyer, Schmidt, and Grossenbacher 1998). The common toad (*Bufo bufo*) also is found over much of Europe and is abundant over most of its range, where it has adapted well to human landscapes and often breeds in garden ponds. Nevertheless, recent population declines have occurred for unknown reasons in lowland areas of southeastern England, even in sites where *Rana temporaria* is doing well (J-A. Carrier and Beebee 2003).

Surveys of larval amphibians in a national park in central Spain in the mid-1980s and in 1999 showed that the same overall assemblage of species was present in both surveys, but the relative abundances of species had changed. The population of *Alytes obstetricans* crashed, apparently due to disease, while that of *Rana perezi* increased and most other species remained relatively stable or showed modest declines (Bosch, Martínez-Solano, and García-París 2001; Martínez-Solano, Bosch, and García-París 2003). The reason for the increase in *Rana perezi* is unclear, although the authors suggested that warmer temperatures at higher altitudes enabled this species to expand its range out of the lowlands. Unfortunately, with only two population surveys, it is impossible to determine whether this is a permanent range expansion or a temporary range shift. A resurvey of 56 ponds in southern France originally studied in the 1970s showed little evidence of decline in amphibian populations. There were numerous instances of species disappearing from ponds, but these local extinctions were roughly balanced by colonization of new ponds (Crochet et al. 2004).

In the mosaic landscape of modern Europe, continued habitat destruction and fragmentation are key issues for the conservation of amphibian populations (P. Joly, Morand, and Cohas 2003). Even in widespread species that are not in danger of extinction, there is evidence for negative effects on populations in fragmented landscapes. Most European amphibians breed in ponds, and breeding sites often become surrounded by inhospitable habitat such as agricultural fields, roads, and housing developments that restrict movements between ponds. This type of habitat fragmentation can result in increased mortality from road traffic (A. Cooke 1995; Fahrig et al. 1995; Hels and Buchwald 2001) and increased likelihood of extinction of small populations that are not replenished by migrants from nearby ponds (Balletto and Giacoma 1993; Halley, Oldham, and Arntzen 1996; Vos and Chardon 1998; Joly et al. 2001; Hels and Nachman 2002). There also can be negative genetic effects of fragmented landscapes leading to isolation of populations, including increased inbreeding and decreased heterozygosity (Hitchings and Beebee 1997, 1998; G. Rowe et al. 1999; Garner et al. 2003; Lesbarrères et al. 2003; G. Rowe and Beebee 2003; L. Andersen, Fog, and Damgaard 2004; Johansson et al. 2005), which may or may not result in decreased fitness (Edenhamn, Hoggren, and Carlson 2000; G. Rowe and Beebee 2005).

Many declines of European amphibian populations have been attributed to destruction of essential breeding habitat, fragmentation of habitats, or both. Many widespread European species exist in local metapopulations that depend on a network of breeding ponds in which periodic extinctions of small populations are balanced by recolonization from larger populations nearby (Sjögren 1991a; Sinsch 1992b;

Miaud, Joly, and Castanet 1993; Sjögren Gulve 1994; Sinsch and Seidel 1995; Vos and Stumpel 1996; Carlson and Edenhamn 2000; Ebisuno and Gentilli 2002). Some of these species appear to be particularly susceptible to habitat fragmentation, incuding *Hyla arborea, Bombina bombina,* and several species of *Triturus*. Local or regional declines of these species have been reported in some parts of Europe, while other populations have remained stable.

Several European countries have had considerable success in increasing amphibian populations through a combination of habitat restoration, construction of new breeding ponds, development of habitat corridors to connect breeding sites, and reintroduction of captive-reared animals. In Sweden, for example, habitat restoration and construction of new breeding ponds for *Hyla arborea* has been underway since the 1980s, resulting in an increase in the estimated number of breeding males from about 3,500 to more than 20,000 at more than 500 different sites (J. Baker 1997; Directorate of Culture and Cultural and Natural Heritage, Council of Europe 2003). Similar restoration efforts have increased populations in Denmark as well (L. Andersen, Fog, and Damgaard 2004). Tree frogs collected in Sweden have been used in a program to reintroduce *Hyla arborea* to nearby Latvia, and there is now a stable population in that country (Zvirgzds, Stašuls, and Vilnī 1995). Sweden also has reintroduced *Bombina bombina,* which went extinct in the 1960s, and the current population numbers several thousand individuals in more than 70 breeding ponds. Unfortunately, a reintroduction effort for this species in Latvia in 1988 was not successful (Directorate of Culture and Cultural and Natural Heritage, Council of Europe 2003). The number of populations of natterjack toads (*Bufo calamita*) in Britain has increased by about 10% since 1970, in part because the number of successful translocations to new breeding sites exceeded the number of population extinctions (Buckley and Beebee 2004). Transfers of great crested newts (*Triturus cristatus*) from ponds destroyed by development to newly created wetlands has been used in Britain as a method to mitigate the negative effects of development. Unfortunately, transfers of animals have not been done in a systematic manner, and monitoring of new populations has been spotty and insufficient to determine whether such populations are sustainable (Edgar, Griffiths, and Foster 2005).

Europe has been plagued by the introduction of all sorts of nonnative animals that have the potential to alter the composition of local assemblages of amphibians, as well as intentional or accidental movement of European amphibians to new parts of the continent. Britain, for example, has about as many introduced species of amphibians as native species, but the ecological impact of most of these introductions is not known (Bell and Bell 1995; Beebee and Griffiths 2000). Multiple introductions of some species, such as *Rana lessonae,* have made it difficult to determine whether certain species are entirely introduced or also include native populations (Beebee et al. 2005). Recent research suggests that once a species is introduced into Europe, it has a relatively high probability of becoming established and even expanding its range (Jeschke and Strayer 2005). Some types of introductions clearly have had negative consequences for amphibians. For example, predatory game fish have been widely introduced into previously fish-free habitats. Most European amphibians cannot breed in habitats with fish, and populations often are eliminated when fish are introduced (Brönmark and Edenhamn 1994; Aronsson and Stenson 1995; Braña, Frechilla, and Orizaola 1996; Reshetnikov and Manteifel 1997; Nyström et al. 2002; Böll 2003; Martínez-Solano, Barbadillo, and Lapena 2003; Martínez-Solano, Bosch, and García-París 2003; Reshetnikov 2003; Crochet et al. 2004).

Some large ranids, such as *Rana ridibunda,* do well in permanent lakes, ponds, and rivers inhabited by fish (Teplitsky, Plénet, and Joly 2003). This species was introduced to southeastern England in 1935 and has established large breeding populations in marshes and pasture ditches that are not used by most native amphibian species (Beebee and Griffiths 2000). Throughout Europe, this species tends to be a very successful colonizer of permanent water habitats, whether through natural dispersal or human introduction. Because of its ability to survive in habitats with fish, it can use large rivers as dispersal corridors. Introduced or invasive populations of *R. ridibunda* have been reported in France (Neveu 1997; Pagano, Crochet et al. 2001; Pagano, Joly et al. 2001; Pagano, Lode, and Crochet 2001), Spain (Arano et al. 1995), Switzerland (Vorburger and Reyer 2003), Russia, Ukraine, Kazakhstan, and Kirgizia (Kuzmin 1999). Introduced populations have become established in various parts of Siberia and on the Kamchatka Peninsula in the Russian Far East, aided in part by warming of lake waters by discharges from power plants (Kuzmin and Maslova 2003). In addition to predation and other negative ecological effects on local native species, there is concern that interbreeding between *R. ridibunda* and other European water frogs may result in genetic displacement of other phenotypes by *R. ridibunda* (Arano et al. 1995; Pagano et al. 2003; Vorburger and Reyer 2003).

The North American bullfrog (*Rana catesbeiana*), another fish-tolerant species, also has been introduced into Britain, but populations have not spread as widely as those of *R. ridibunda.* This species has been introduced into parts of Belgium, France, Italy, Germany, the Netherlands, and Greece as well, and some breeding populations have become established (Stumpel 1992; Neveu 1997; Andreone and Marocco 1998). This species is likely to do well in permanent ponds and lakes inhabited by fish, but also could move into other habitats and displace native species. The ecological impact of introduced bullfrogs on native European amphibians has scarcely been studied (Haffner 1997; see http://www.zavod-symbiosis.si/3_en_bullfrog.htm).

Asia

Because of its enormous size and diversity of climates, Asia has the greatest variety of habitats of any continent, ranging from extreme deserts to tropical rainforests and the highest mountains on Earth. Asia also has a very diverse amphibian fauna, because it represents a contact zone between Palearctic species, Oriental species, and Gondwanan amphibians that entered Asia when India drifted northward and contacted the Asian mainland. With more than 650 species of amphibians, southern Asia has by far the greatest diversity (this area includes Sri Lanka, India, Bangladesh, the countries on the southern flank of the Himalayas, Southeast Asia, Indonesia, and the Philippines; Inger 1999). In contrast, the Palearctic regions of Asia have far fewer species of amphibians, with about 42 species in Western Asia, nine species in Siberia, 20 species in Central Asia, and 55 species in Palearctic Eastern Asia (Borkin 1999). If we consider only the temperate parts of Eastern Asia (China, Taiwan, Korea, the main islands of Japan, Hainan, and the Ryukyu Islands), there are more than 300 species, with far greater diversity in the Oriental realm (southern China, Taiwan, and the Ryukyu Islands) than in the much larger Palearctic realm (Asian Russia, Mongolia, northern China, Korea, and the main islands of Japan; Zhao 1999; Kuzmin and Maslova 2003).

In addition to lowland tropical rainforest areas, which are rich in amphibians, both tropical and temperate montane regions tend to have high species diversity and large numbers of endemic species. Amphibian hot spots of particular interest to conservation biologists, because of high species diversity or large numbers of endemic species with limited ranges, include Sri Lanka, the Western Ghats of India, the Eastern Himalayan region of India, the mountains of southwestern China, montane regions of Southeast Asia, and tropical rainforests of Malaysia and Indonesia. Many of these regions remain poorly explored by herpetologists, and many new species of amphibians continue to be described from Sri Lanka, India, Southeast Asia, and China. In addition, the main islands of Japan and the Ryukyu Islands, while having modest numbers of amphibian species, have a high proportion of endemic species (Zhao 1999; Bossuyt et al. 2004). Several other parts of Asia have relatively low species diversity, but often harbor unique endemic species of amphibians. These include the Caucasus region of Georgia and Russia and several montane areas of Iran, Iraq, Turkey, Afghanistan, Kyrgyzstan, Kazakhstan, and China (Borkin 1999; Tarkhnishvili and Gokhelashvii 1999; Zhao 1999).

As in Europe, human population density in Asia tends to be greatest in the areas of high amphibian species diversity, particularly in India, Sri Lanka, China, and Indonesia. Areas of low amphibian diversity, including Asian Russia, northwestern China, Mongolia, and Central Asia, generally have lower human population densities. This means that deforestation and other human alteration of natural habitats are the chief threats to many species of Asian amphibians. For much of Asia, there is surprisingly little information on the status of amphibian species and almost no quantitative data on declines of amphibian populations, although there have not been reports of large population declines in most regions. There also is wide variation among Asian countries in the level of protection afforded to amphibians or critical amphibian habitats, but in many cases, amphibians are poorly protected in this region and conservation efforts are just beginning.

An appreciation of nature has long been a part of Japanese culture, and Japanese conservationists have paid considerable attention to protecting endangered species of amphibians, despite a shortage of scientists working on the systematics and ecology of amphibians (Matsui 2000). Approximately 83% of the amphibian species or subspecies on the main islands of Japan are endemic, as are 77% of the amphibians of the Ryukyu Islands (Zhao 1999; Matsui 2000; Ota 2000). These include a number of species of hynobiid salamanders, the giant salamander, *Andrias japonicus,* and eleven anuran species. The number of endemic species probably is higher than currently recognized, because genetic studies have revealed hidden taxonomic diversity, especially in the genus *Hynobius* (Matsui et al. 2000, 2001; Nishikawa et al. 2001; Tominaga et al. 2003). Many Japanese species are widespread, but some species with limited habitats are threatened or endangered, especially in the Ryukyu Islands, where deforestation is a major threat (Ota 2000).

On the main islands of Japan, some ranid frogs have declined, including *Rana porosa brevipoda.* The main cause of decline appears to be reduction in natural wetlands due to conversion to agriculture or housing developments, as well as changing agricultural practices in rice fields that provide the main habitat for many species. The traditional method of growing rice involved irrigation of rice paddies by shallow ditches, which provided essential habitat for a variety of aquatic organisms, including frogs. In the last 30 years, most rice field have converted to irrigation by underground pipes that feed deep concrete ditches, which lack the shallow vegetated habitats used by frogs (Fujioka and Lane 1997). The resulting decline in frog populations may impact predators that prey on frogs, such as snakes and wading birds. Also potentially at risk are invertebrate predators that depend heavily on frogs, such as the endangered giant water bug (*Lethocerus deyrollei;* Hirai and Hidaka 2002). The American bullfrog (*Rana catesbeiana*), which was introduced as a source of food in the early twentieth century, is now widespread in Japan and is a potential threat to some native amphibians (Inger 2001). Nevertheless, the only detailed study of the diet of bullfrogs in Japan showed that adults ate mostly crayfish and juveniles ate mostly smaller invertebrates, with little evidence of predation on native anurans (Hirai 2004). Bullfrogs may be competitors of native anurans in this location and may impact populations of other aquatic organisms, but the impact on amphibian populations is unclear.

Taiwan straddles the Tropic of Cancer and has a subtropical climate. Its dense human population is concentrated in the lowland plains of western Taiwan, with the center of the island dominated by high mountains. Amphibian species diversity is modest, with about 30 species, representing a combination of tropical species and temperate zone species that reached the island from mainland China (Zhao 1999). About one third of the species are endemic to Taiwan. Others not currently recognized as endemic, such as Taiwanese populations of *Limnonectes kuhlii,* probably are distinct from populations assigned to the same species on mainland Asia (Emerson, Inger, and Iskander 2000). As many as 20 species have been found in one location in the mountains (Hsu et al. 2003). There is little published information on the status of amphibians on Taiwan, but amphibian numbers have declined and amphibians are threatened by industrialization and deforestation (http://www.tesri.gov.tw/english/content/animal/ani-amphibians). About 12% of Taiwan has been set aside as national parks, nature reserves, and protected areas, mostly in the mountains, and about a third of the amphibian species are protected by law (Hsu and Agoramoorthy 1997). One salamander, *Echinotriton andersoni,* is considered extinct on Taiwan (Zhao 1998).

There is little information published in English on the status of amphibian populations in mainland China, although the status of a few species is discussed on Amphibia Web (http://elib.cs.berkeley.edu/aw/index.html) and in some Chinese publications (Ye, Fei, and Hu 1993; Zhao 1998). This enormous country has a rich and diverse amphibian fauna, particularly in southern China and the southwestern mountains (Zhao and Adler 1993; Fei 1999; Zhao 1999). With the world's largest human population, China also has suffered from enormous environmental degradation (Li et al. 2004), including industrial pollution, extensive deforestation, and loss of wetlands, all of which are likely to have a negative impact on amphibian populations. About 5% of the country has been set aside for parks and nature reserves, although none was specifically designed to protect amphibians (Zhao 1999).

Few detailed surveys of amphibian populations have been conducted in China, but Yiming and Wilcove (2005) estimated that at least 31 species of amphibians in China are threatened or endangered, with two thought to have gone extinct. The major threats to Chinese amphibians are habitat destruction, especially deforestation, pollution, and overexpoitation for food and medicine. Fellers, Yuezhao, and Shaoyin (2003) reported on surveys of three species of amphibians in the Zoige Wetlands at the headwaters of the Yellow River, conducted in 1997 and 2000–2002. All three species showed a reduction in population size, but the number of sites surveyed was too small and the time period too short to demonstrate a significant decline. Anecdotal evidence from local people suggested that these wetlands had decreased in size over the last 20 years and that amphibians had become less common. Currently a number of species of hynobiid and salamandrid salamanders are considered vulnerable or endangered in China, as is the giant cryptobranchid salamander *Andrias davidianus* (R. Murphy et al. 2000; Stuart et al. 2004). At least one salamander, *Cynops wolterstorffi,* is considered extinct in China. Less than a dozen species of anurans in the families Ranidae and Megophryidae are considered endangered or vulnerable, including several very unusual frogs in the genus *Vibrissaphora* (Zhao 1998).

Widespread collection of common ranid species for food and medicine probably threatens some local Chinese populations of amphibians, although not all species are threatened throughout their ranges. According to a recent global assessment of amphibian declines (Stuart et al. 2004), overexploited amphibian species are heavily concentrated in China and Southeast Asia, with ranid frogs being the most frequently overexploited. Yiming and Wilcove (2005) estimated that 40% of the 25 species of Chinese amphibians for which data are available are threatened by overexploitation for food, and 20% are threatened by medicinal use. Illegal harvesting of frogs (*Rana dybowskii*) by Chinese immigrants also is reported to threaten some populations in Far Eastern Russia. Nevertheless, this species and the other ten species of amphibians in this sparsely populated region appear to be secure, and many remain very abundant. The most vulnerable species are forest specialists such as the hynobiid salamander *Onychodactylus fischeri,* but even for this species, threats are largely local. A major threat to some local amphibian populations in both the Russian Far East and in China is the constuction of hydroelectric dams that flood forested gorges. On the other hand, many lowland species that favor open habitats may even increase in human-altered habitats. Potential threats to local populations of amphibians in Asian Russia include the deliberate introduction of nonnative mustelid predators such as mink (*Mustela vison*) and otters (*Lutra lutra*), as well as the European frog *Rana ridibunda,* but the ecological impact of these invasive species has not been well studied (Kuzmin and Maslova 2003). Only a few species of Chinese amphibians are thought to be threatened by alien species, but the problem has been little studied in China (Yiming and Wilcove 2005).

Hong Kong has a surprisingly rich amphibian fauna for such a densely populated area, with 23 species (8% of all Chinese amphibians; Lau and Dudgeon 1999). Despite its large human population, 38% of the land area of Hong Kong is protected. Montane forests are the best-protected habitats, and many amphibians are associated with montane streams. Lowland wetlands, on the other hand, are poorly protected (Yip, Corlett, and Dudgeon 2004). Several anurans closely associated with rice paddies have undergone drastic declines with the disappearance of rice cultivation in Hong Kong, and several other species have quite restricted ranges.

Southeast Asia, including Mayanmar (Burma), Thailand, Laos, Cambodia, Vietnam, Malaysia, Singapore, Indonesia, Brunei, and the Philippines, has an extraordinarily rich amphibian fauna. The greatest species diversity, with a high level of endemism, occurs in Sundaland, which encompasses Sumatra, Java, Borneo, and surrounding smaller islands, as well as the Palawan Islands of the Philippines. This region harbors at least 200 species of amphibians, of which about 60% are endemic. Only about a quarter of the species occur on more than one of the larger islands, although many species are broadly distributed within islands (Inger 1999). The amphibians of Malaysian Borneo have been studied most intensively (Inger and Stuebing 1989, 1997). Those of the other islands are not as well known, although there is a recent guide to amphibians of Java and Bali (Iskandar 1998). Some bufonids, ranids, microhylids, and rhacophorids that favor open habitats have adapted well to rice paddies and other human-altered habitats and often are more common in such habitats than in forests (Inger 1999).

Forest specialists, many of which breed in streams, presumably are at greatest risk because of widespread deforestation, leading to habitat degradation and fragmentation. In some countries, such as Singapore, most of the original forest is gone (Brook, Sodhi, and Ng 2003). In others, large tracts of forest remain, but most Asian forests are at risk from both legal and illegal logging activities. Voris and Inger (1995) found that frog populations were stable from the 1960s through the 1990s along streams in undisturbed forest in two regions of Malaysian Borneo, Sarawak and Sabah, with no evidence of major declines in any species. Nevertheless, stream-dwelling frogs are susceptible to logging that destroys terrestrial habitat and increases silt loads in streams, because most tadpoles of these species cannot survive high silt loads (Inger 1999). Species with very restricted ranges obviously are at risk from logging and other forms of habitat destruction as well. In contrast to the relatively well-protected forests of Malaysian Borneo, deforestation in Indonesian Borneo and Sumatra is proceeding at an alarming rate, even in legally protected forests (Jepson et al. 2001; Curran et al. 2004; Fuller, Jessup, and Salim 2004). This destruction poses an immediate risk to all forest-dwelling amphibians in the region, as well as most of the other wildlife in one of the world's true biodiversity hotspots.

A potential threat to some of the most common ranid frogs in Indonesia is the export of frog legs, mostly to Europe and China. Indonesia has replaced India and Bangladesh as the major source of frog legs after those countries banned frog exports. Nearly all of the frogs being shipped into Europe appear to be crab-eating frogs (*Fejervarya cancrivora*), even though some shipments were declared to be other species, including the introduced American bullfrog (*Rana catesbeiana;* Veith et al. 2000). Estimates of the number of frogs exported from Indonesia range up to a million frogs per year. It seems likely that such numbers will adversely impact frog populations, and marked declines of large ranids in both India and Bangladesh were attributed to overexploitation. Nevertheless, I am not aware of any detailed ecological studies on the impact of frog leg exploitation on anuran populations, the level of harvest that can be sustained, or the amount of time required for a population to recover from overexploitation. Decreases in anuran numbers have been blamed for increased populations of pest insects in India, Bangladesh, and Indonesia, with a concomittant increase in use of chemical pesticides that itself could be harmful to amphibians (Abdulali 1985; Barfield 1986; Oza 1990; Bazilescu 1996; Jacques 1999). Again, I do not know of any rigorous studies designed to demonstrate a causal relationship between anuran declines, insect populations, and pesticide use.

On mainland Southeast Asia, the amphibian fauna of peninsular Malaysia and Thailand is relatively well known (Chan-ard et al. 1999), although a recent guide to amphibians of Thailand (Nutphund 2001) uses outdated taxonomy and has many misidentified photographs (Ohler 2003a). The amphibian fauna of Myanmar (Burma), Laos, Cambodia, and Vietnam is poorly studied. Recent exploration in Vietnam and Laos has resulted in the description of a number of new species of amphibians (Inger, Orlov, and Darevsky 1999; Ohler 2003b; B. Stuart 2005), and there is hidden diversity among those species already described (Bain et al. 2003). Of over 112 species known from Vietnam, only about 10 are officially listed as endangered, threatened, rare, or vulnerable, but there is anecdotal evidence that some species have declined. Some amphibians are at risk from overexploitation for food, medicine, and the pet trade (Nguyen 2000). Others are at risk from forest exploitation that degrades amphibian habitats. In one survey, twice as many species of amphibians were found in undisturbed montane forest as in exploited forest (Nguyen 1998). The amphibian fauna of other Southeast Asian countries is so poorly known that a survey of amphibians from a single mountain range in Cambodia doubled the number of anuran species known from that country (Ohler, Swan, and Daltry 2002), and more than 35 undescribed species of anurans have been discovered in recent surveys in Mayanmar (see http://www.calacademy.org/research/herpetology/mayanmar). As in Vietnam, there appears to be hidden diversity among species already described for Mayanmar, such as the *Fejervarya limnocharis* complex (this group probably contains many cryptic species throughout southern Asia; Toda et al. 1998). Quantitative information on the status or possible decline of amphibian populations is not available for any of these countries.

The countries of South Asia vary in the diversity of their amphibian faunas. The island nation of Sri Lanka is a remarkable amphibian hotspot, with more than 250 species, including more than 100 species of rhacophorid frogs, many still undescribed (Pethiyagoda and Manamendra-Arachchi 1998; Meegaskumbura et al. 2002; Bossuyt et al. 2004). Most of these species are concentrated into about 15,000 km^2 of wet forest, giving Sri Lanka the highest density of amphibian species per unit area in the world. Over 220 species of amphibians are found in India and the southern Himalayas, including Nepal and Bhutan, with a number of endemic lineages and especially high diversity in the wet forests of the Western Ghats region and the southern Himalayas (Inger 1999; Bossuyt et al. 2004). New species are regularly described from these areas, and many taxonomic problems remain, so the actual amphibian fauna probably is considerably larger (Dubois 1998). Indeed, the total amphibian fauna of the Western Ghats may be nearly twice as large as currently recognized (Daniels 2003). The region not only harbors a large number of endemic species of frogs, but also at least 14 species of endemic caecilians (Bjatta 1997). Nepal has about 55 species of amphibians, nearly all of which are anurans, with only one caecilian (*Ichthyophis sikkimensis*) and one salamander (*Tylototriton verrucosus;* Schleich, Anders, and Kästle 2002). The amphibian fauna of Bangladesh, much of which is low and wet, is less diverse, probably with fewer than 50 species. The amphibian fauna of relatively arid Pakistan is even smaller, with only about 25 species, mostly bufonids and ranids (Khan 2005).

The status of amphibian populations in these countries is only beginning to be studied (Gupta 1998; Molur and Walker 1998; Daniels 1999). Because the highest species diversity and nearly all of the endemic species in this region occur in wet montane forests, deforestation and forest fragmentation almost certainly are the major threats to amphibian populations. In Sri Lanka, many of the endemic rhacophorid frogs appear to have extremely small geographic ranges, so they are likely to be vulnerable to even relatively localized deforestation. At least 80% of the original wet-zone forests of Sri Lanka are now gone, and the remaining forests are highly fragmented. Museum records from the nineteenth century indicate that at least 15 species of amphibians formerly known from Sri Lanka are now extinct. Given the recent discovery of many new species of frogs, it seems likely that many other species probably went extinct before being described. Along with the direct effects of deforestation, other potential threats to forest-dwelling amphibians in Sri Lanka include increased temperatures and decreased rainfall caused by deforestation, acid rain, and heavy use of pesticides and herbicides in tea plantations that occupy most of the montane regions of the country. In addition, most of the areas of high amphibian diversity are not included in the country's system of parks and nature reserves, which have focused on protecting large mammals in the lower, drier parts of the country (Wijeyamohan, da Silva, and Santiapillai 1994; Pethiyagoda and Manamendra-Arachchi 1998).

Forest-dwelling amphibians face similar threats in other countries with dense human populations, especially India and Nepal. The Western Ghats region of India is a major center of amphibian diversity, where nearly 80% of the amphibians are endemic (Daniels 1992, 1997a, b, c, d; Bhatta 1997; Krishnamurthy 1999, 2003; Krishnamurthy and Hussain 2000; Vasudevan, Kumar, and Chellam 2001; Bossuyt et al. 2004). It also accounts for about 20% of all the tea cultivation in the country. Tea cultivation not only results in removal and fragmentation of natural forest habitats, but it also typically involves heavy application of chemical pesticides that may end up in streams outside of the plantations. Tea plantations can support a surprisingly high diversity of amphibian species (Daniels 2003), but there has not been a carefully designed study to compare the abundance and diversity of amphibians in tea plantations and in nearby natural forests. Amphibians may be threatened even in protected lands, because such parks often include a mosaic of disturbed and undisturbed habitats. A potentially serious threat to amphibians and other animals of the Western Ghats is the increasing frequency of forest fires, even in protected reserves (Kodandapani, Cochrane, and Sukumar 2004). The reason for the increase in fires is not entirely clear, but may result from a combination of land use changes, habitat fragmentation, and climate change, as well as increased human activity in and around forested areas.

In Kudremukh National Park in the Western Ghats, iron mining continues despite the lack of human settlement in most of the park, and this has disturbed and fragmented parts of the natural forest. Of the 42 species of amphibians reported from the park, 22 occurred only in undisturbed habitats, while another 20 occurred in both disturbed and undisturbed habitats (Krishnamurthy 2003). Consequently, species richness was higher in undisturbed sites, and population densities were higher as well. Nepal also has suffered extensive deforestation, despite having a relatively large network of protected areas. Serious habitat degradation in the uplands of Nepal undoubtedly poses a threat to forest-dwelling amphibians, but there is little specific information on the status of amphibian populations in the country (Maskey, Schleich, and Kästle 2002).

A number of South Asian anurans tend to favor open habitats and often occur at higher densities in disturbed habitats around human settlements than in undisturbed forest (Maskey, Schleich, and Kästle 2002; Krishnamurthy 2003). These include the widely distributed toad *Bufo melanostictus* and several pond-breeding microhylids, ranids, and rhacophorids. This appears to be a general pattern in much of Asia, with species that adapt well to agricultural landscapes and other human-altered habitats often becoming very common, while total amphibian species diversity declines as natural forested habitats disappear (Gillespie et al. 2005). Ironically, the abundance of amphibians such as large ranid frogs in human-altered habitats often makes them vulnerable to overexploitation for food or commercial export of frog legs. This apparently occurred in both India and Bangladesh in the 1980s, where *Hoplobatrachus tigerinus* has been the most commercially important frog species. Both countries eventually banned commercial export of frog legs. The large ranid frog *Paa liebigii* is widely collected for food in Nepal (Schleich and Kästle 2002). The ecological impact of harvesting on populations of this species has not been studied in detail, but several members of the genus *Paa* from the Himalayan region are considered to be overexploited (Stuart et al. 2004).

Africa

Less is known about the amphibian fauna of Africa and the current status of amphibian populations than that of any other continent. Much of the continent remains poorly explored herpetologically, but undescribed species are frequently discovered as new areas are explored. Political instability and lack of basic infrastructure such as roads has limited access of biologists to many parts of Africa. Indeed, only two areas have received much attention in terms of amphibian conservation, southern Africa and Madagascar, although the amphibians of East Africa are beginning to receive more attention (Channing and Howell 2006). Although individual species are known to be at risk elsewhere in Africa, often because of limited geographic ranges (e.g., *Nectophrynoides asperginius* in Tanzania; Weldon and du Preez 2004), there has been little systematic work on the status of African amphibian populations or their even basic habitat requirements (Behangana 2004; Behangana and Arusi 2004). The montane forests of Africa are particularly rich in endemic species of amphibians, many of which have very limited ranges and specialized habitat requirements (Gartshore 1986; Hofer, Bersier, and Borcard 1999, 2000; Poynton 1998, 1999; Channing 2001; J. M. Lea, Luiselli, and Politano 2005; Channing and Howell 2006). We can expect forest-dwelling amphibians, especially stream-breeders and those with nonaquatic reproduction, to be at risk anywhere in Africa where deforestation is proceeding at a rapid rate. Anurans that breed in ponds are more likely to adapt to human-altered habitats than are forest-floor or stream-breeding species (Andreone 1994; J. M. Lea, Luiselli, and Politano 2005). As in Asia, African anurans that adapt well to agricultural landscapes and other human-altered habitats, especially ranids, bufonids, and hyperoliids, are likely to thrive even as forest-dwelling species disappear (e.g., Lawson 1993; S. Lynn and Lindle 2002). In some cases, overall species diversity actually increases in disturbed habitats, even as species' composition changes dramatically (J. M. Lea et al. 2003, 2005).

Civil wars and the movement of large numbers of refugees in various parts of Africa can render even relatively recent work on amphibian populations obsolete and makes the status of protected areas in many parts of the continent uncertain. For example, the Comoé National Park in the Ivory Coast, where extensive studies of amphibian populations have been conducted (Rödel 2000), was invaded by thousands of refugees during the recent civil war and breakdown of government authority in that country. This park is now considered one of the most endangered protected natural areas on the list of UNESCO World Heritage Sites (http://whc.unesco.org/danglist.htm), but the specific effect of recent habitat degradation on amphibian populations is not known. Similar problems afflict several national parks in the Democratic Republic of the Congo and Uganda, and these parks also appear on the list of endangered World Heritage Sites. Other countries simply lack the resources to adequately manage protected areas. The Central African Republic, for example, has about 11% of its land area designated as protected areas. Unfortunately, these areas do not adequately represent all of the ecoregions of the country. Savanna habitats are overrepresented among the protected areas, whereas lowland forests that are likely to harbor many species of amphibians are poorly protected. Furthermore, many areas have little or no active management or protection because of inadequate resources in this very poor country. Poaching of mammals is widespread, but amphibians are more likely to be affected by habitat destruction, and their status is unknown (Blom, Yamindou, and Prins 2004).

By far the best-studied African amphibian fauna is that of southern Africa. The composition of the fauna is well known (Passmore and Carruthers 1995; Channing 2001). This region has a high proportion of endemic species, with about 55% of the species in South Africa, Lesotho, and Swaziland being endemic, and about 66% of all southern African species (J. A. Harrison et al. 2001). A project to compile a detailed atlas of the distribution and status of amphibian species in the region has been underway for a number of years and has now been completed (Minter et al.

2004). In contrast to the heavily forested habitats of the equatorial and montane regions of Africa, much of southern Africa is relatively arid, and amphibians are heavily dependent on wetland habitats for breeding, with temporary wetlands being especially important (Channing and van Dijk 1995). South Africa has lost roughly a third of its original wetlands, and many of the remaining wetland habitats are found in areas of high human population density (J. A. Harrison et al. 2001). Consequently, protection of wetland habitats, especially seasonal wetlands, is a high priority for conservation of southern African amphibians.

Fortunately, a large proportion of amphibian species in South Africa (96%) is represented in protected areas (Drinkow and Cherry 1995), but a much smaller proportion is in protected areas in southern Africa as a whole (C. Seymour et al. 2001). About 72% of the anurans of South Africa, Lesotho, and Swaziland are not threatened or endangered (Minter et al. 2004). Nevertheless, a number of South African species are endangered because of habitat destruction and development. These include several species of *Heleophryne* (see fig. 1.14 C in chapter 1), inhabitants of mountain streams that are found only in this region. Many of the other endangered anurans in South Africa are found in the Southwestern Cape region, where agricultural, urban, and suburban development threaten critical habitats. One highly endangered species is *Xenopus gilli,* which is endemic to fynbos habitats. Most of the known breeding sites of this species have been disturbed or destroyed by agricultural or urban development, and the species also is threatened by hybridization by the much more widespread species *X. laevis* (Picker and de Villiers 1989; Harrison et al. 2001). Other species in the same habitats that have declined due to habitat loss include *Bufo pantherinus, Microbatrachella capensis, Cacosternum capense,* and *Capensibufo rosei* (Harrison et al. 2001; C. Seymour et al. 2001; Minter et al. 2004). There have been local declines of some widespread species, such as *Pyxicephalus adspersus,* due to habitat destruction, but it remains common in much of southern Africa. Because many southern African amphibians breed in seasonal wetlands in savanna or fynbos habitats, a particular threat is the widespread conversion of such habitats to plantations of introduced pine and *Eucalyptus* trees, as well as invasion of wetland habitats by alien plants such as *Acacia* trees, all of which alter the water table and often eliminate breeding sites (Minter et al. 2004).

The importance of Madagascar as a center of amphibian diversity and endemism already has been mentioned. Some species of frogs are widespread in open areas and human-altered habitats, including hyperoliids in the genus *Heterixalus,* the ranid frog *Ptychadena mascareniensis,* and some species of *Mantidactylus*. Different types of agricultural landscapes harbor different assemblages of anuran species. Coffee plantations, for example, often have a relatively high diversity of amphibians and reptiles, whereas rice fields and sugar cane plantations generally have low diversity (Andreone et al. 2003). Many mantellid frogs and nearly all microhylids are forest specialists and hence are susceptible to widespread deforestation and further fragmentation of existing forest habitats in a country that already has lost most of its native forests (Raxworthy and Nussbaum 2000; Vallan 2000, 2002; Andreone and Luiselli 2003; Lehtinen, Ramanamanjato, and Raveloarison 2003). Many of the frogs of Madagascar also have the misfortune of being very colorful and therefore highly desirable in the pet trade. Thousands of individuals of several species of *Mantella,* the unique microhylid tomato frog (*Dyscophus antongili*), and the colorful burrowing frog *Scaphiophryne gottlebei* have been shipped out of the country in recent years. Unfortunately, there is no information on the level of trade in these animals that is ecologically sustainable.

Why Have Amphibian Populations Declined?

When scientists first became concerned about widespread declines of amphibian populations in the late 1980s, the issue attracted much attention from the press and popular science writers (J. Phillips 1994). At the time, the causes of amphibian population declines were poorly understood, and much of the discussion in the popular press created the impression that some mysterious force was eliminating amphibians around the world. Some supermarket tabloids even suggested that aliens from distant planets were depopulating the world of amphibians! Since then, we have learned a great deal about the general causes of amphibian declines, even though the precise causes of declines of particular species often are not fully understood. Some potential causes of population declines have been discussed briefly in the preceeding review of amphibian populations around the world. This section describes the evidence for some of these causes in more detail. It now seems clear that most amphibian declines share the same basic causes as declines of other groups of organisms in the current biodiversity crisis: habitat destruction and degradation, introduction of alien predators and competitors, environmental pollution, the emergence of infectious diseases (perhaps in conjunction with other environmental stressors), and global changes that can have widespread environmental effects (Semlitsch 2003c). Human exploitation of amphibians for food, medicine, scientific research and education, fishing bait, or the pet trade probably has contributed to declines of some amphibian populations, but there is little evidence that this is responsible for widespread population declines (J. Jensen and Camp 2003). Indeed, the impact of direct human exploitation probably has had a much smaller effect on amphibian populations than has exploitation of many other vertebrates, including fishes, marine mammals, large game mammals, primates, birds, large snakes, crocodilians, and turtles.

Habitat Destruction

Throughout the world, complete destruction or removal of critical habitats undoubtedly poses the single greatest threat to amphibian populations (Dodd and Smith 2003; Young et al. 2004). The negative effects of replacing natural habitats with agricultural land, roads, industrial sites, cities, suburbs, and other human uses are obvious and have been discussed in the preceding survey of amphibian populations around the world. Nevertheless, some amphibians exhibit a remarkable capacity to adapt to human-altered habitats, including urban and suburban areas (e.g., Beebee 1979c; Chovanec 1994; Delis, Mushinsky, and McCoy 1996; Hermy and Cornelis 2000; Dudgeon 2003; Rubbo and Kiesecker 2005), although amphibians in such environments are threatened by general habitat degradation and loss of connectivity between patches of suitable habitat (Löfvenhaft, Runborg, and Sjögren-Gulve 2004). Amphibians that do well in human-altered habitats tend to be habitat generalists that favor open areas, whereas those that depend on forested habitats tend to fare poorly (Rubbo and Kiesecker 2005). Some species actually are more abundant in agricultural landscapes than in forested habitats, as long as fish-free ponds are available for reproduction and forested habitat is only moderately fragmented (Kneitz 1998; Knutson et al. 1999; Kolozsvary and Swihart 1999; Quinn, Gallie, and Volsen 2001; Guerry and Hunter 2002; J. M. Lea, Politano, and Luiselli 2003; J. M. Lea, Luiselli, and Politano 2005; Hazell et al. 2004; Johansson et al. 2005). There are limits to amphibian tolerance for agricultural landscapes, however. Intensive, industrial-scale farming that involves destruction of small wetlands and heavy application of pesticides has a much greater impact on amphibian populations than do less intensive forms of agriculture such as livestock grazing (Beebee 1977, 1997; P. Joly et al. 2001; R. Gray and Brown 2005). The negative effects of agriculture can be ameliorated to some extent by adjusting agricultural practices such as plowing schedules and application of pesticides to the phenology of local amphibian species, although this may be economically impractical for some crops (Meyer-Aurich et al. 1998).

Two types of habitats are especially critical for a large proportion of the world's amphibian species: forests and wetlands. Although amphibians also can be found in other types of habitats, including tropical savannas, temperate grasslands, and deserts, these areas generally have lower species diversity than do forest and wetland habitats (nearly all grassland and desert amphibians depend on temporary wetlands for reproduction). More arid habitats sometimes face fewer environmental threats than do forests and wetlands because they are less desirable for human use. Nevertheless, conversion of natural grasslands to agriculture and urban and suburban development can threaten amphibians in some regions. I will focus mostly on forests and wetlands here, because the impact of habitat destruction on amphibian populations is best understood for these habitats. For purposes of discussion, it is useful to treat forest and wetland habitats separately, although in reality, many species depend on both types of habitats for survival (Semlitsch 2003b).

Deforestation and Forest Fragmentation

Many clades of amphibians are largely or entirely dependent on forested habitats that provide moist terrestrial microhabitats for foraging, and in some cases, for reproduction. These include most plethodontid salamanders, by far the most diverse group of salamanders; many ambystomatids and salamandrids; most eleutherodactyline frogs, one of the largest clades of anurans; many hylid and rhacophorid treefrogs; most arthroleptids, centrolenids, dendrobatids, mantellids, heleophrynids, and microhylids; many bufonids, ranids, megophryids, leptodactylids, and myobatrachids; and many caecilians. In tropical rainforests, there often is an abundant and diverse fauna of forest-floor frogs, some of which are entirely terrestrial and dependent on moist leaf litter for reproduction (see chapter 15). Not only do these anurans depend on moist leaf litter for shelter, but they also depend on the diverse arthropods that inhabit the litter (Vitt and Caldwell 2001). This forest-floor anuran fauna is largely absent from temperate-zone forests, where leaf-litter anurans usually are limited to a few species of *Bufo* and *Rana* that breed in water (*Bufo americanus* and *Rana sylvatica* in Eastern North America; *B. bufo* and *R. temporaria* in Europe; various related species in Asia). In North America, plethodontid salamanders largely occupy the leaf-litter niche, where they can reach extraordinary densities of several thousand individuals per hectare (Davic and Welsh 2004).

All of these groups are at risk in places where deforestation is occurring at a rapid rate. This is particularly true in the tropics, where logging of forests often is followed by replacement of forested habitats by urban development, cattle pastures and farms, tree plantations, roads, mining operations, oil drilling, hydroelectric dams, and other uses that result in the loss of critical amphibian habitats (Vitt and Caldwell 2001; T. Lewis 2002; Brook, Sodhi, and Ng 2003; Crump 2003; Hero and Shoo 2003; Yiming and Wilcove 2005; Channing and Howell 2006). Key areas of special concern for amphibian conservation because of widespread deforestation have been mentioned in the previous section: the lowland and montane rainforests of Central America, South America, the Caribbean, Africa, Madagascar, China, Indonesia, Southeast Asia, Sri Lanka, Nepal, and India. In general, tropical forest regions in the Old World have less of their original forest remaining than do tropical forests in the New World, and they often are not as well protected (Hero and Shoo 2003). This comparison is somewhat skewed by the very large size of the Amazon rainforest. Although nearly 90% of the Amazon forest remained intact in 2001, some areas, such as Rondônia, are threatened by very rapid deforestation and could lose most of their primary forest within the next decade (Ferraz et al. 2005). Other regions such as Honduras, El Salvador, Jamaica, and Haiti rank among the highest in the world in amount of forest destroyed or rate of deforestation (Crump 2003; Young et al. 2004). The only practical solution to this problem is to find economic incentives to increase protection of old growth tropical forests and promote the restoration of secondary forests in areas of high amphibian diversity, which in many cases also will be areas of high diversity of other taxa.

Even when tropical forests are not completely destroyed, the remaining patches of forest often form a fragmented landscape with a matrix of agricultural land and other disturbed habitats that can be inhospitable to amphibians (Ferraz et al. 2005). Habitat fragmentation can have a number of detrimental effects, several of which have been mentioned previously. Habitat patches can become isolated from one another, leading to reduced gene flow between local populations and decreased genetic diversity within populations. Small, isolated populations often are susceptible to chance extinction, and lack of connectivity between habitat patches reduces the chances that such populations will be replenished by new immigrants. Small habitat patches may be subject to edge effects, with increased exposure to sunlight resulting in warmer, drier microhabitats with the patches that can be inhospitable to amphibians. Finally, forest streams are key breeding sites for many tropical forest amphibians, and logging can affect the hydrodynamics and silt loads of forest streams in surviving forest patches downstream from logged areas.

In some respects, amphibians may be less susceptible to forest fragmentation than are larger vertebrates such as birds and mammals, because of their small home ranges and sedentary habits (see chapter 6). There has been extensive research on the effects of tropical forest fragmentation on a variety of animals, from butterflies to birds and mammals, but comparatively little work on amphibians. Most studies have focused on the effects of forest fragmentation on the abundance and reproductive success of one or two species, but some studies also have addressed the effect of fragmentation on amphibian species diversity. Not surprisingly, most studies of anuran diversity in tropical forest fragments have shown that forest-interior specialists, including tree-hole breeders, bromeliad breeders, species with direct development of terrestrial eggs, and those that depend on clear forest streams are the most vulnerable to forest disturbance and fragmentation (Gascon 1993; Pearman 1997; Tocher, Gascon, and Zimmerman 1997; Tocher, Gascon, and Meyer 2002; Gascon et al. 1999; Funk and Mills 2003). Similar results were obtained in a study of frogs in a temperate rainforest in Australia (Lemckert 1999). Pond-breeding species tend to be much more plastic in their habitat requirements and often can adapt to disturbed habitats. Indeed, many tropical pond-breeding anurans are more abundant and diverse in moderately disturbed habitats than in primary forest (Pearman 1997), possibly because ponds in open-canopy habitats are more productive than are those in closed-canopy forests and therefore may provide better food resources for tadpoles (Skelly, Friedenburg, and Kiesecker 2002; Skelly et al. 2005).

In a fragmented lowland Amazonian forest landscape in Brazil, less than half of the total complement of anuran species found in primary forest was found in pastures, but nearly 80% was found in disturbed and secondary forest (Tocher Gascon, and Meyer 2002). Some species that are characteristic of open, disturbed habitats, such as the hylid frog *Scinax rubra,* apparently used the matrix of disturbed habitats to disperse into forested habitats where they normally would not be found. Other species exhibited considerable plasticity in choice of oviposition sites and were able to breed in all habitat types. For example, *Phyllomedusa tarsius,* which normally lays its eggs on bushes overhanging water, was capable of breeding in primary forest, disturbed forest, and pasture ponds, and actually was most successful in secondary forest ponds (Neckel-Oliveira 2004).

In Amazonian Ecuador, frog species richness again was greatest in undisturbed forest, especially for *Eleutherodactylus,* but was not significantly different from that of selectively logged forest (Pearman 1997). In a study of tropical montane cloudforest in Veracruz, Mexico, there was a significant reduction in anuran species diversity from undisturbed forest (21 species) to shaded coffee plantations (13 species) to pastures (four species), although some coffee plantations had more species than did some forested sites (Pineda and Halffter 2004; Pineda et al. 2005). As in Amazonia, forest-interior specialists were most likely to be absent from disturbed habitats. In Madagascar, only 54% of rainforest anurans were found in secondary forest, only 46% in *Eucalyptus* plantations, and a meager 12% in rice fields (Vallan 2002). Again, forest-interior specialists (mostly microhylids and mantellids) were the first to disappear, whereas pond-breeding ranids and hyperoliids survived in more open habitats. A similar pattern was seen on several small islands in Indonesia, where amphibian diversity was lower in highly disturbed habitats than in undisturbed or moderately disturbed forest (Gillespie et al. 2005). On a river floodplain in Argentina, 18 anuran species, all aquatic breeders, were found in a protected patch of riparian woodland, whereas species diversity in seven disturbed habitats ranged from one to 14 species (Peltzer, Lajmanovich, and Beltzer 2003). In this case, the degree of disturbance was greater than in the other studies, because most plots outside of the protected forest were in suburban areas with only small remnants of woodlands.

The issue of edge effects is closely related to forest fragmentation, because more fragmented forests have more edges adjacent to pasture or other suboptimal amphibian habitats, and the negative effects of such habitat disturbance may penetrate into the interior of small forest fragments. Studies of edge effects in tropical rainforest frogs have been done almost exclusively in the New World and have focused primarily on species of *Eleutherodactylus,* which tend to be forest specialists. In Amazonian Ecuador, species richness of *Eleutherodactylus* increased with distance to the edge of pastures, even though overall frog species diversity did not, because many hylids did well in disturbed habitats (Pearman 1997). At a higher altitude (3,200–3,600 m) site in Ecuador, two species of *Eleutherodactylus* were virtually absent from disturbed habitats surrounding patches of forest, but in only one species was abundance affected by the size of a forest patch (Marsh and Pearman 1997). Similarly, in a cloud forest (2,400–2,800 m) in Ecuador, there was an abrupt transition between forest and agricultural land in the abundance of *Eleutherodactylus,* with this genus being largely absent from nonforested habitats (Toral, Feinsinger, and Crump 2002). There was little evidence of edge effects penetrating into the forest interior, however. In a fragmented forest in Costa Rica, two species of *Eleutherodactylus* were more abundant in interior forest plots than in plots adjacent to pasture, but three other species were not affected by edges (Schlaepfer and Gavin 2001). There was no effect of either fragment size or distance to the nearest edge on abudance of any species of *Eleutherodactylus.* There was a somewhat surprising seasonal effect, with species that did not appear to avoid forest edges becoming more abundant in the forest interior during the rainy season. Overall, these studies suggest that there is not a consistent edge effect on either the diversity or abundance of forest-floor *Eleutherodactylus,* but some species are better than others at tolerating more open-edge habitats.

In North America, the closest equivalents to *Eleutherodactylus* as forest-interior specialists are plethodontid salamanders. Many of these have direct-developing terrestrial eggs, while other species breed in forest streams. Consequently, salamanders, especially plethodontids, have been widely used as indicator species in studying the effects of clearcutting and other forestry practices in North America (deMaynadier and Hunter 1995; Welsh and Droege 2001; Wyman 2003). In contrast to the tropics, where complete deforestation and conversion of forest to agricultural land are the main threats to amphibian populations, the dynamics of forests in North America are more complex. While clear-cutting of forests is widespread and some forests are destroyed for development, many forests are managed for sustainable yield, with continuous regrowth of harvested stands. In some regions, such as New England, overall forest cover is considerably higher than it was 150 years ago, even though timber harvesting or development continues to reduce forest cover in some areas (A. Miller, Bryant, and Birnie 1998). Forestry practices that can affect amphibian diversity and abundance include the type and extent of tree removal, the maintenance of woody debris on the forest floor after tree clearing, rates of forest regeneration, management of riparian zones along forest streams as habitat for salamanders or stream-breeding frogs, conversion of natural forest to tree plantations, and prescribed burns. In addition, fragmentation of forest stands by clearcuts, roads, agricultural land, or development can reduce amphibian population sizes and restrict movements between populations, with some species being more sensitive to fragmentation and edge effects than others (deMaynadier and Hunter 1998, 2000; Gibbs 1998a, b; DeGraaf and Yamasaki 2002; D. Marsh et al. 2004, 2005; Cushman 2006).

There is clear evidence that clearcutting of mature forests has a negative impact on the abundance of many amphibians, presumably because of the warmer, drier conditions that prevail in cutover stands (deMaynadier and Hunter 1995). There was considerable variation among study sites, however, because of differences in forest moisture regimes, amount of woody debris remaining in cleared sites, variation in the age of mature stands used as control plots, and differences among species of amphibians in their ability to tolerate drier conditions. Overall, data from a variety of studies showed that amphibians were about 3.5 times more abundant in mature forest stands than in clear-cut stands, but plethodontid salamanders were, on avearge, about five times more abundant in mature stands.

Nevertheless, in some studies, salamanders were nearly as abundant in clear-cut areas as in uncut forests, especially if abundant woody debris remained after cutting (Cole et al. 1997; Biek et al. 2002). Although terrestrial plethodontids tend to be the most sensitive to forest clearing, other salamanders that use forested habitats outside of the breeding season can be affected as well (Naughton et al. 2000), while more subterranean species may be less sensitive to clear-cutting (Chazal and Niewiarowski 1998). Even less intensive forms of timber harvest can reduce salamander numbers to some extent, although the negative effects may be less persistent (Mitchell, Wicknick, and Anthony 1996; DeMaynaier and Hunter 1998; Messere and Ducey 1998; R. Brooks 1999; Harpole and Haas 1999; Grialou, West, and Wilkins 2000; B. Ross et al. 2000; Bartman et al. 2001; DeGraaf and

Yamasaki 2002; Duguay and Wood 2002; Hicks and Pearson 2003; S. Knapp et al. 2003; Morneault et al. 2004).

Anurans tend to be less sensitive to forest clearing than are salamanders, probably because of the greater tolerance of anurans to desiccation and their greater mobility, which enables individual animals to move out of inhospitable microhabitats. Hylid treefrogs, which are more resistant to evaporative water loss than any other North American amphibians (Wygoda 1984), actually may benefit from forest clearing. Green treefrogs (*Hyla cinerea*), for example, were considerably more abundant in artificial canopy gaps in southern bottomland hardwood forest than in closed-canopy forest (Horn et al. 2005). About 98% of the frogs captured in the gaps were juveniles, which exhibit considerable cutaneous resistance to water loss once they have left the water (Wygoda and Garman 1993).

Clear-cutting also can alter the demographic characteristics of amphibian populations. For example, Ash et al. (2003) reported that individuals of *Plethodon metcalfi* were more massive in 10-year-old clear-cut forest than in mature forest, and immature individuals were largely absent from the clear-cut area. It was not clear, however, whether this was due to poor reproduction by adults in the younger forest or an inability of smaller animals to survive the drier conditions in that area. Estimates of the age of salamanders in the clear-cut forest based on skeletochronology (see chapter 14) indicated that most adults were younger than the age of the forest, suggesting that they were recent immigrants into the area. Quality of prey also may be different in recently cut and mature forests, with soft-bodied prey such as collembolans, a preferred food item of many plethodontids, being less abundant in the drier microhabitats of recently cut forests (Mitchell, Wicknick, and Anthony 1996), even though overall invertebrate abundance in recently cut forests may be as high or higher than in mature forests (Ash 1997; Harper and Guynn 1999).

There has been some controversy over the fate of salamanders in clear-cut forest stands, with some authors arguing that most individuals in such stands probably perish (Petranka, Eldridge, and Haley 1993; Petranka 1994) and others arguing that some individuals move away from disturbed habitats to more hospitable areas (Ash and Bruce 1994). There is little direct evidence for mortality of amphibians in clear-cut forests, simply because dead and dying individuals are seldom found in the field. There is some evidence for individuals of some plethodontid salamanders moving out of clear-cut areas (Sattler and Reichenbach 1998), but also counter-evidence indicating that the abundance of salamanders in areas adjacent to harvested areas did not increase after cutting (Ash 1997; Bartman et al. 2001). Presumably the ability of salamanders and other amphibians to leave clear-cut areas depends on the size of harvested plots, the nature of adjacent forested habitats, and the vagility of individual species.

The amount of time required for salamander populations to return to predisturbance levels also has been a matter of some debate (deMaynadier and Hunter 1995). In deciduous forests of the eastern United States, estimates of the time required for salamander populations to recover to predisturbance levels in previously cut forests range from less than 30 years in relatively moist habitats to as much as 120 years in drier habitats (Pough et al. 1987; DeGraaf and Yamasaki 1992, 2002; Petranka, Eldridge, and Haley 1993; Petranka et al. 1994; Ash 1997; Ash and Pollock 1999; Harper and Guynn 1999; Herbeck and Larsen 1999; W. Ford et al. 2002). Variation in the estimated time required for salamander populations to recover in harvested forests probably depends on overall forest moisture regime, amount of woody debris, rate of decay of logs, leaf litter depth, and other physical factors that affect rates of water loss in amphibians, as well as sampling methods used to estimate salamander numbers (deMaynadier and Hunter 1995). It is not clear that any species of terrestrial salamander is immediately threatened by current forestry practices, although species with naturally restricted ranges, such as *Plethodon hubrichti,* could be at risk if harvest-rotation schedules are too short or if cleared plots are too large (Kramer et al. 1993; Mitchell, Wicknick, and Anthony 1996).

Some studies of Douglas fir forests in the Pacific Northwest have shown relatively little difference between relatively young forest stands (30–75 years old) and very old (up to 450 years old) forest stands in abundance of amphibians (Aubry, Jones, and Hall 1988; Bury and Corn 1988a; Aubry and Hall 1991; Gilbert and Allwine 1991; Steele, Brodie, and McCracken 2002), but most of these studies examined forests that had not been cut, but were regenerating after fires. Other studies in the same region have shown that at least some salamanders are sensitive to stand age, being more abudandant in mature forests than in younger stands. Some terrestrial plethodontids, such as *Plethodon elongatus* and *P. larselli,* are old-growth forest specialists, making them particularly sensitive to logging (Herrington and Larsen 1985; Welsh 1990; Welsh and Lind 1995), whereas habitat generalists such as *P. vehiculum* and *P. dunni* appear to be more tolerant of managed forest habitats (Cole et al. 1997; Dupuis and Bunnell 1999; Aubry 2000; Grialou, West, and Wilkins 2000; Wilkins and Peterson 2000).

The effect of logging on stream-breeding amphibians is somewhat different from the effect on terrestrial-breeding plethodontids. The best-studied species are stream-breeding amphibians of western North America, including *Dicamptodon, Rhyacotriton, Taricha, Ascaphus,* and *Rana aurora,* with only a few studies having been done on species in eastern forests (Lowe and Bolger 2002). Not only is the terrestrial habitat affected by removal of the forest canopy, but the stream environment can be altered by increased silt loads, increased nutrient input, accumulation of woody debris, and changes in stream temperature and solar radiation (Welsh and Ollivier 1998; Corn, Bury, and Hyde 2003). Because stream-breeding species have aquatic larvae, which sometimes remain in streams for several years, changes in the aquatic habitat may have an even greater impact on populations than do changes in surrounding terrestrial areas inhabited by larger adults (Bury 1983; Corn and Bury 1989; Biek, Mills, and Bury 2002). In addition, adults of many stream-breeding amphibians have a limited ability to move overland out of disturbed habitats into new streams (B. Johnston and Frid 2002; Chan-McLeod 2003), and even movement of larvae within streams may be limited (H. Ferguson 2000). The combined effects of reductions in population size and lack of dispersal to undisturbed streams increases the chances of population fragmentation, loss of genetic diversity, and local population extinctions in stream-breeding species (J. Curtis and Taylor 2003).

The negative effects of logging on stream-breeding amphibians can be partially aleviated by retention of forested buffer strips along streams, provided these areas are sufficiently wide (Dupuis and Steventon 1999; B. Johnston and Frid 2002; Vesely and McComb 2002). Unfortunately, widths of buffer strips currently required by some forestry regulations may not be sufficient to protect riparian amphibian populations, and buffer zones are not always required around headwater streams that lack fish (J. Curtis and Taylor 2003). Susceptibility to disturbance of riparian habitats varies among species. Torrent salamanders (*Rhyacotriton*) and tailed frogs (*Ascaphus*), for example, favor cold, rocky headwater streams with steep gradients and low amounts of silt, sand, or woody debris (Diller and Wallace 1996; Dupuis and Steventon 1999; Wilkins and Peterson 2000; Russell, Mabee, and Cole 2004). Their relatively specialized habitat requirements make them very sensitive to forest clearing, especially in the riparian zone (fig. 16.13). Other riparian amphibians, such as *Dicamptodon, Taricha,* and *Rana aurora,* sometimes decrease in abundance in logged areas, but appear to be somewhat less sensitive than are *Rhyacotriton* and *Ascaphus* (Welsh 1990; Cole et al. 1997; Welsh and Olivier 1998; Dupuis and Steventon 1999; Aubry 2000; MacCracken 2002; Vesely and McComb 2002; Steele, Brodie, and McCracken 2003b; Wahbe and Bunnell 2003; Ashton, Marks, and Welsh 2006). In the eastern United States, stream-dwelling salamanders such as *Gyrinophilus porphyriticus* also are susceptible to logging-related increases in sediment loads (Lowe, Nislow, and Bolger 2004). In areas where both aquatic-breeding and terrestrial-breeding salamanders occur, forest buffer zones around streams need to be large enough to accommodate the terrestrial species that tend to

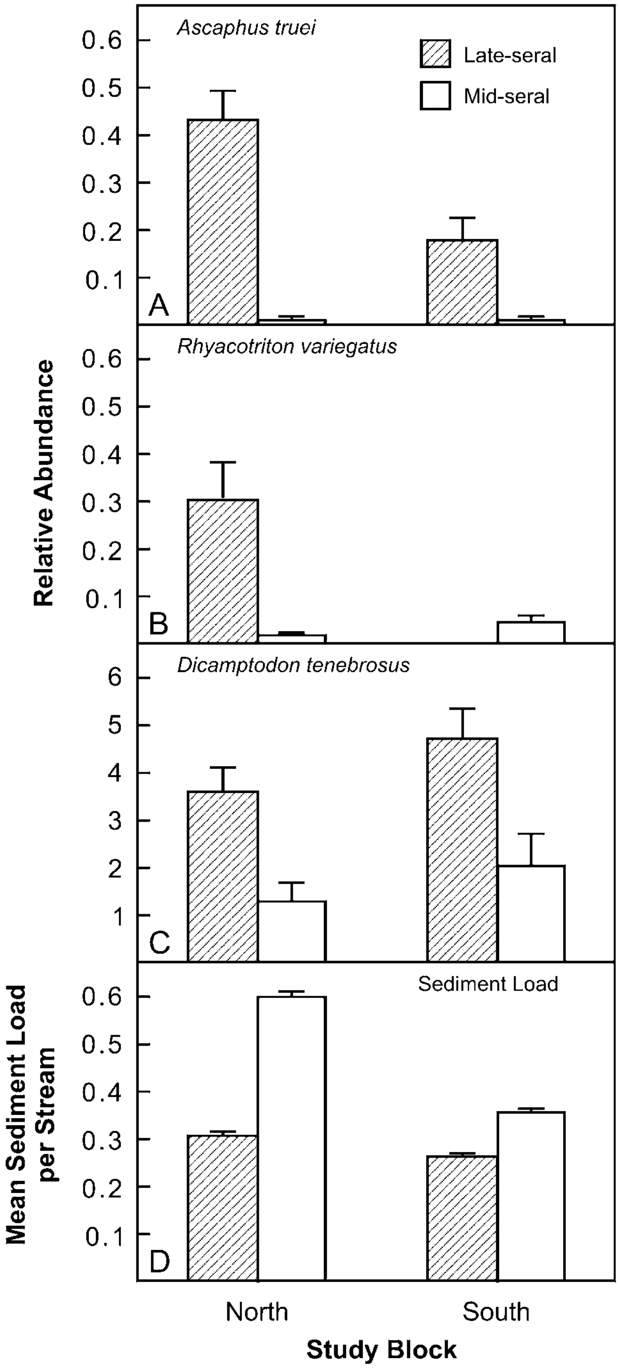

Fig. 16.13. Comparison of relative abundance of three stream-associated amphibians in the forests of the Pacific Northwest in late-seral (unharvested) and midseral (37–60 years post harvest) stands in two different study blocks. Populations of *Ascaphus* (A) and *Rhyacotriton* (B) recovered from timber harvesting more slowly than did populations of *Dicamptodon* (C). Sediment loads (D) were significantly higher in midseral stands than in unharvested stands. After Ashton, Marks, and Welsh (2006).

favor more upland habitats while also minimizing the impact of logging on stream habitats (Petranka and Smith 2005).

In many parts of the world, conversion of natural forests to single-species tree plantations may be as great a threat to amphibian populations as is clear-cutting of forests that eventually are allowed to return to their original state. Plantations of spruce, pine, *Eucalyptus,* and teak generally lack the complex understory and thick leaf litter of natural forests, resulting in warmer, drier conditions on the forest floor. This almost always can be expected to have a negative effect on amphibian populations (Waldick, Freeman, and Wassersug 1999; Vallan 2002; Pawar, Rawat, and Choudhury 2004; Yiming and Wilcove 2005). Management strategies in pine plantations that result in removal of the litter layer are likely to decrease soil moisture and expose amphibians to greater risk of desiccation (Moseley, Castleberry, and Ford 2004). In much of the southeastern United States, the dominant forest type was once longleaf pine (*Pinus palustris*), which often occurred in flatwoods habitats with an understory dominated by wiregrass that was flooded in the winter and spring to form shallow inundated savannas (Dodd 1995). Most of this native vegetation has been replaced by plantations of slash pine or loblolly pine, which form a much denser canopy and do not flood because trees are planted in raised beds. The flatwoods salamander (*Ambystoma cingulatum;* fig. 16.9) is a longleaf pine flatwoods specialist that does poorly in pine plantations (Means, Palis, and Baggett 1996). Consequently, this species has declined in much of its range, although it remains common where suitable habitat is present (Palis 1997; Palis and Means 2005). Other amphibians that share this habitat, particular gopher frogs (*Rana capito* and *R. sevosa*), also have declined in some areas (Richter et al. 2003; Jensen and Richter 2005; Richter and Jensen 2005).

Other forestry practices, such as prescribed burns during the wet season, can be detrimental to amphibians because these practices reduce the litter layer, dry out the understory, and tend to eliminate longleaf pine in favor of loblolly pine, which provides less suitable habitat for amphibians (Schurbon and Fauth 2003). Nevertheless, fires are necessary to maintain longleaf pine savannas, essential habitats for a number of southeastern amphibians. Such habitats are quickly replaced by hardwood forest if fire is completely suppressed, but there has been some debate over the optimum interval between prescribed burns (Means et al. 2004; Robertson and Ostertag 2004; Schurbon and Fauth 2004).

The effect of fire on amphibian populations is complex and depends on the type of forest burned, the time of year when burning occurs, and the particular species of amphibians found in those habitats (Pilliod et al. 2003; Bury 2004). Some studies of prescribed burns in North American hardwood forests found few negative effects on amphibian populations, and in some cases found positive effects (Means and Campbell 1981; Kirkland, Snoddy, and Amster 1996; McLeod and Gates 1998; Ford et al. 1999; Russell, Van Lear, and Guynn 1999; Moseley, Castleberry, and Schweitzer 2003). In the Pacific Northwest, natural wildfires appear to have little effect on terrestrial amphibian populations, but result in reduced numbers of stream-dwelling amphibians. Old-growth forests, which provide habitats for a number of amphibians not found in younger forests, are less susceptible to catastrophic fires than are younger stands (Bury 2004). Because much of this region has been heavily logged, younger fire-prone stands now predominate, resulting in reduced habitat for amphibians, especially old-growth specialists. However, there has been relatively little research on the direct effects of prescribed burning on amphibians in this region. Studies of natural and prescribed burns in various habitats in Australia yielded mixed results, with clear negative effects on some anurans, but not on others (Bamford 1992; Driscoll and Roberts 1997). Fire alone is unlikely to threaten many amphibian species with population declines or extinctions, but small isolated populations could be at risk from catastrophic fires (Driscoll and Roberts 1997). Fires also could threaten amphibians in tropical rainforests in regions such as Indonesia, where a combination of increased logging and global climate change may result in increased frequency of catastrophic fires that destroy critical habitats for a wide variety of species.

Wetland Destruction, Fragmentation, and Management

As mentioned previously, freshwater habitats are under assault throughout the world, and are perhaps the most endangered of all ecosystems. In North America and Europe, which have the strongest wetlands protection programs, many wetlands of importance to amphibians remain highly threatened. In less developed regions, such as South and Central America, wetlands protection is virtually nonexistent or just beginning, and even knowledge of the variety and extent of wetland habitats is rudimentary (Ellison 2004; Junk and Piedade 2004; Loiselle et al. 2004). Threats to stream-breeding amphibians, most of which live in forested habitats, were discussed in the previous section, so I will focus here on amphibians that breed in standing water.

Several characteristics of wetlands that can affect the abundance and diversity of amphibians include wetland size, hydroperiod, the diversity of microhabitats found within a wetland, proximity to other wetland habitats, and proximity to suitable upland habitats. Specific requirements vary among species of amphibians, with some species requiring much longer hydroperiods than others for larvae to reach metamorphosis (Semlitsch 1998, 2000, 2002, 2003b; Paton and Crouch 2002; Semlitsch and Bodie 2003). The array of predators, and particularly the presence or absence of fish, also can affect amphibian diversity and abundance; this is discussed in a separate section that follows.

In most countries where wetland protection has been considered an important conservation issue, including the United States, regulations have focused on protecting relatively large wetlands, such as salt marshes and estuaries, where amphibians do not live, and permanent lakes, ponds, and rivers, which generally have low amphibian diversity. In the United States, Federal protection of small, isolated wetlands and seasonal wetlands is much weaker or nonexistent, although some state and local governments have taken a more active role in protecting such habitats (Semlitsch and Bodie 1998; Russell, Guynn, and Hanlin 2002; Calhoun et al. 2003; Calhoun, Miller, and Klemens 2005; Burne and Griffin 2005b). At the same time, amphibian ecologists have increasingly focused on smaller wetlands with short to intermediate hydroperiods as essential habitats for many pond-breeding amphibians (Dodd 1992; Wellborn, Skelly, and Werner 1996; Griffiths 1997; Babbitt and Tanner 2000; Snodgrass, Komorowski, Bryan, and Burger 2000; Russell, Guynn, and Hanlin 2002; Paton and Crouch 2002; Babbitt, Baber, and Tarr 2003; Babbitt 2005; Burne and Griffin 2005a; Paton 2005; Skidds and Golet 2005). Not only do small isolated wetlands provide fish-free breeding habitats for many amphibians, but they also provide critical stopover points for amphibians moving between larger wetlands (Gibbs 1993; Dodd and Cade 1998; Semlitsch and Bodie 1998) and important foraging sites for amphibians that breed in larger bodies of water (Paton 2005).

Such wetlands go by many names, depending on geographic region, local geology and hydrology, and the nature of the surrounding habitat. Many are simply called seasonal or temporary ponds (Griffiths 1997), but they also include vernal pools (Calhoun et al. 2003; Zedler 2003; Colburn 2004), prairie potholes in the Great Plains (Lannoo et al. 1994; Lannoo 1996), Carolina bays in the southeastern United States (Semlitsch et al. 1996; Sharitz 2003), desert pools and playa wetlands in the arid southwestern United States (A. Anderson, Haukos, and Anderson 1999a, b; M. Gray, Smith, and Brenes 2004), shallow pans in Australia and southern Africa (M. Tyler 1998; Minter et al. 2004), blackwater vlies in South African fynbos habitats (Minter et al. 2004), and shallow seasonal rock pools (D. C. Smith 1983; Spieler 2000; Spieler and Linsenmair 1997). Amphibians also make use of many other types of small depressions that fill temporarily with water, including pools in tropical rainforests (Gascon 1991; Marsh et al. 1999, 2000; Marsh 2000) and animal-generated pools such as bison, hog, peccary, and rhino wallows (Bragg and Smith 1942, 1943; Gascon 1991; Inger and Steubing 1997; Gerlanc and Kaufman 2003) and animal tracks (Rand 1983).

All of these wetlands share certain characteristics, including being filled by precipitation, relatively small size, a lack of permanent connections with other wetlands, a tendency to dry out on a regular basis, and the absence of large predators such as fish that require more permanent water. In addition, their ephemeral nature makes legal protection of such habitats especially difficult. Seasonal pools and even more permanent ponds that form on river floodplains also can be important habitats for amphibians, although such pools are more likely to be invaded by fish than are more isolated wetlands in upland wooded habitats (Healey, Thompson, and Robertson 1997; Burbrink, Phillips, and Heske 1998; Tockner, Schiemer, and Ward 1998; Godreau et al. 1999). Because of river channelization, dams, flood control projects, shoreline development, pollution, and other alterations, floodplain habitats are threatened throughout the world. In Australia, intensive grazing by cattle around floodplain wetlands resulted in degraded habitats and reduced anuran species richness and abundance (Jansen and Healey 2003).

In addition to the size, hydroperiod, and biological communities of temporary wetlands themselves, two critical aspects of such habitats for amphibian conservation are the nature of the habitat surrounding temporary ponds and the degree to which individual ponds are connected by suitable habitat that provides corridors for movement of amphibians between ponds. Because vernal pools and other temporary ponds are, by definition, dry for much of the year, all amphibians that use such ponds must spend considerable time in terrestrial habitats surrounding these ponds, and even amphibians that breed in more permanent aquatic habitats often rely on the surrounding terrestrial habitat outside of the breeding season (e.g., Pope, Fahrig, and Merriam 2000; Pilliod, Peterson, and Ritson 2002). Consequently, amphibian populations are susceptible to degradation of the surrounding terrestrial habitat unless steps are taken to ensure protection of adequate buffer zones around ponds (Dodd and Cade 1998; Semlitsch 1998, 2000, 2002, 2003b; J. Gibbons 2003b; Semlitsch and Bodie 2003). Furthermore, temporary wetlands are by their very nature unpredictable in occurrence. Some vernal pools, for example, may not fill in years due to low winter snowfall or spring rainfall. This makes nearby wetlands essential for amphibians that are displaced from their usual breeding sites, so connectivity between wetlands is critical for amphibian populations (Trenham et al. 2003).

A number of studies have examined the effects of the surrounding habitat on the abundance and diversity of amphibians in breeding ponds, particularly in North America and Europe (Laan and Verboom 1990; Vos and Stumpel 1996; Findlay and Houlahan 1997; J. Mitchell et al. 1997; Hecnar and M'Closkey 1998; Knutson et al. 1999; Kolozsvary and Swihart 1999; Lehtinen, Galatowitsch, and Tester 1999; Pope, Fahrig, and Merriam 2000; Findlay, Lenton, and Zheng 2001; Houlahan and Findlay 2003). Most of these studies have shown that the type of terrestrial habitat surrounding a pond, especially the amount of forest cover, affects species abundance and the composition of wetland amphibian communities. Nevertheless, species differ in their sensitivity to habitat disturbance and alteration. For example, a study of largely agricultural landscapes in Ohio showed that the presence of wood frogs (*Rana sylvatica*), spotted salamanders (*Ambystoma maculatum*), Jefferson's salamander (*A. jeffersonianum*), and smallmouth salamanders (*A. texanum*) was strongly influenced by the amount of forested habitat near breeding sites, whereas tiger salamanders (*A. tigrinum*) were more tolerant of agricultural habitats (Porej, Micacchion, and Hetherington 2004). Several species of amphibians that used temporary playa wetlands in Texas as breeding sites actually were more abundant at ponds surrounded by cultivated agricultural land than at those surrounded by natural grasslands (M. Gray, Smith, and Brenes 2004). Suitable terrestrial habitat is essential for adult amphibians during the non-breeding season (e.g., Pope, Fahrig, and Merriam 2004). In addition, juvenile amphibians emerging from breeding ponds often are reluctant to move across open areas, such as powerline right-of-ways and agricultural fields, that lack the moist microhabitats found in forests (deMaynadier and Hunter 1999; Rothermel and Semlitsch 2002; Vasconcelos and Calhoun 2004). Consequently, dispersal of juveniles between potential breeding sites may be limited by the surrounding habitat. For example, playa wetlands in Texas surrounded by agricultural land could function as population sinks, despite high population abundance, if the ability of metamorphs to move across cultivated land is limited (M. Gray, Smith, and Brenes 2004).

In addition to the presence of suitable terrestrial habitat around breeding ponds, the proximity of ponds to other wetlands and the availability of dispersal corridors between potential breeding sites can be critical for the maintence of healthy amphibian populations. Habitat fragmentation can result either from destruction of wetlands themselves, leading to a reduction in wetland density, or from destruction or alteration of intervening terrestrial habitat that serves to connect wetlands (D. Marsh and Trenham 2001; Trenham et al. 2003). Consequently, it is important to characterize wetland habitats for amphibians on a landscape level, rather than focusing on individual wetlands in isolation. There are many examples of regions in which large numbers of small wetlands persist, but connectivity among wetlands has markedly decreased in recent decades due to increased urban and suburban development, road construction, and other types of habitat alteration (Boothby 1997; Gibbs 2000; Löfvenhaft, Runborg, and Sjögren-Gulve 2004).

Roads can be particularly important in isolating suitable amphibian habitats, because some amphibians are reluctant to move across paved roads, and because of the high mortality of individuals attempting to cross them (Gibbs and Shriver 2005). Consequently, several studies have found negative associations between amphibian abundance or diversity and road density (Findlay and Houlahan 1997; Lehtinen, Galatowitsch, and Tester 1999; Findlay, Lenton, and Zheng 2001; Houlahan and Findlay 2003; Porej, Micacchion, and Hetherington 2004). The effect of roads differs for different species of amphibians, depending on their tendency to move long distances and the speed with which individuals can cross roads (Gibbs 1998c; deMaynadier and Hunter 2000; L. Carr and Fahrig 2001). Certain wetland amphibians, such as the North American red-spotted newt (*Notophthalmus viridescens*), appear to be particularly sensitive to habitat fragmentation because they have difficulty crossing roads and are highly sensitive to loss of forest cover (Gibbs 1998b; deMaynadier and Hunter 2000; Guerry and Hunter 2002; Porej, Micacchion, and Hetherington 2004). In contrast, some inhabitants of open habitats, such as the European natterjack toad (*Bufo calamita*) actually prefer to move through open sandy areas or along roads rather than through forested habitats, although using roads as dispersal corridors still could result in high mortality from cars (Stevens et al. 2004).

Although the focus of this discussion has been on small, temporary wetlands, some amphibians breed in more permanent wetlands and remain at those sites thoughout much of the year. They are susceptible to various sorts of habitat alteration in or near breeding sites. For example, North American green frogs (*Rana clamitans*) are found mostly along the margins of permanent ponds and lakes and are susceptible to the negative effects of shoreline development of lakeside cottages and homes (Woodford and Meyer 2003). These frogs may not be directly affected by the presence of houses per se, but by habitat alteration associated with development, such as removal of submerged woody debris and emergent shoreline vegetation that are considered undesirable because they tend to interfere with boating and swimming. In northern parts of their range, green frogs often are found around peat bog ponds, which apparently are used mainly as nonbreeding habitat, and populations can be negatively affected by peat mining operations that tend to dry out the bogs (Mazerolle and Cormier 2003). Both the behavior and overall abundance of other amphibians can be affected as well (Mazerolle 2001, 2003). Another potential threat to amphibians is mechanical removal of accumulated sediments in recreational ponds and lakes, which often is done to improve conditions for swimming, boating, and fishing. Such drastic habitat alteration not only can cause direct mortality of amphibians that are dredged up with the sediments, but it also can destroy submerged and emergent plants that provide crucial habitat for amphibians (Aresco and Gunzburger 2004). Large salamanders such as *Siren* and *Amphiuma* that use accumlated sediments for estivation in dry weather may be particularly at risk. Streamside habitats also can be degraded by even relatively benign human use, resulting in reductions of habitats for stream-breeding amphibians (Rodríguez-Prieto and Fernández-Juricic 2005).

There is no doubt that wetlands created by human activities, either intentionally or unintentionally, can be important habitats for some amphibians. In agricultural areas, for examples, farm ponds can be essential habitats for amphibians in an otherwise inhospitable landscape (Kneitz 1998; Quinn, Gallie, and Volsen 2001; Knutson et al. 2004). In some cases such ponds may not support all of the species that normally would occur in the region (Hazell et al. 2004), but this is not always true (M. Gray, Smith, and Brenes 2004). There have been extensive efforts in some areas, particularly Europe, to create new habitats for pond-breeding amphibians by building artificial ponds. These often have been colonized by both anurans and urodeles, although the success of these efforts is heavily influenced by the proximity of source populations and the nature of the surrounding habitat (Thielcke et al. 1985; Laan and Verboom 1990; Stumpel and Tester 1993; Chovanec 1994; Hödl, Jehle, and Gollmann 1997; Stumpel and van der Voet 1998; Baker and Halliday 1999; Directorate of Culture and Cultural and Natural Heritage, Council of Europe 2003).

In the United States, there have been numerous attempts to restore degraded wetlands or to build new wetlands to mitigate the loss of natural habitats due to road construction or other projects. Most studies of amphibians in these artificial wetlands have followed populations for less than 10 years after construction of the ponds, so the long-term suitability of constructed wetlands for amphibians is not yet clear. Most studies have shown that amphibians colonize newly constructed wetlands within a year or two of construction and often successfully reproduce (Lehtinen and Galatowitsch 2001; Pechmann et al. 2001; Petranka, Murray, and Kennedy 2003; Vasconcelos and Calhoun 2004). Nevertheless, it is virtually impossible to replicate a natural wetland precisely, because underlying soil permeability and the nature of the surrounding habitat may differ. It can be particularly difficult to replicate the hydroperiod of temporary ponds, because the formation of temporary ponds often is a consequence of local variation in underlying geology and soil conditions. The result is that some species of amphibians that occur in natural wetlands may not use constructed wetlands (Pearl et al. 2005). Nevertheless, some local amphibian populations probably are better off with replacement wetlands than with no wetlands at all. Some anthropogenic wetlands, however, may appear suitable as breeding sites, but actually function as population sinks if amphibians use them as oviposition sites but hydroperiods are too short for larvae to reach metamorphosis in most years (DiMauro and Hunter 2002).

Introduced and Invasive Species

Aside from habitat destruction, the most clear-cut threat to many amphibian populations is the introduction of exotic predators or competitors into ecosystems where such animals were previously absent (Kats and Ferrer 2003; Kiesecker 2003). A variety of introduced animals have been implicated in declines of amphibian populations in various parts of the world, with the most important being fishes, amphibians, snakes, and crayfish. Introduced mammals, such as the American mink (*Mustela vison*) in Europe and the Russian Far East, also prey on local amphibians (Kuzmin and Mazlova 2003; see also chapter 14). In most cases, these predators target the most common species of amphibians. There is little direct evidence that introduced mammals have had a widespread effect on amphibian populations, but some island populations may be at risk (Ahola et al. 2006). Introduced populations of human commensals such as rats may have contributed to the decline of amphibians such as populations of *Leiopelma* in New Zealand (Towns and Daugherty 1994). Invasive species of birds, such as crows and cattle egrets, often prey on amphibians, but again, there is little evidence that these predators have significantly impacted amphibian populations. Most predatory mammals and birds that feed on amphibians are generalist predators that tend to switch to more abundant prey if amphibians become scarce, or feed on amphibians only as secondary prey items.

Introduced Fish and Amphibian Populations

For many amphibians, the aquatic stages of the life history, especially eggs and larvae, are most vulnerable to predators, so it is not surprising that aquatic predators such as fish have had a large impact on amphibian populations. The importance of predatory fishes in limiting the distribution of aquatic-breeding amphibians was discussed in some detail in chapter 14. The larvae of many amphibians, especially those that breed in temporary ponds or in high-altitude lakes that normally are devoid of fish, lack behavioral or chemical defenses against fishes. Consequently, the introduction of predatory fishes into formerly fish-free habitats often has a major impact on local amphibian populations.

The largest literature on the effects of introduced fishes on amphibian populations deals with introductions of trout into streams and lakes. Because of their popularity with recreational anglers, various species of trout have been introduced into streams, rivers, and lakes throughout the world, even in protected national parks and wilderness areas. North American rainbow trout (*Oncorhynchus mykiss*) and brook trout (*Salvelinus fontinalis*) and Eurasian brown trout (*Salmo* *trutta*) have been the most widely introduced species. Introduced populations of these fish are now well established in many montane habitats in North America, Europe, South America, Australia, and New Zealand (this country, however, lacks native aquatic-breeding amphibians).

Most of these introductions have been initiated by local or national government agencies at the behest of sport fishermen, and generally have been undertaken without prior ecological study of the impact of fish introductions on native species (R. Knapp, Corn, and Schindler 2001). Such introductions have a long history, with nonnative trout having been introduced into Yosemite National Park in California as early as the 1870s (R. Knapp 2005). The impact on amphibian populations probably began soon thereafter (Grinnell and Storer 1924), but was limited by the difficulty of transporting fish into remote wilderness areas. With the advent of fish stocking from airplanes, even the most remote fish-free mountain lakes could be supplied with fish for the entertainment of sportsmen, and the impact on amphibian populations appears to have accelerated in the late twentieth century. Although fish stocking was halted in national parks in the western United States in the 1970s and 1980s, stocking continues in many other lakes in national forests, state forests, and wilderness areas. The result is that an estimated 60% of all montane lakes and 95% of all large lakes in the western United States, nearly all of which originally lacked fish, are now inhabited by introduced salmonids (R. Knapp, Corn, and Schindler 2001). In most western states, stocking of fish continues in 20–75% of all high-altitude lakes (Dunham, Pilliod, and Young 2004).

The impact of these introductions on amphibian populations has been clear and dramatic, as indicated by four lines of evidence: (1) surveys of amphibians in fishless and fish-inhabited lakes, (2) observations of amphibian population declines following the introduction of trout into previously fish-free habitats, (3) experimental studies of predation on amphibians by introduced trout, and (4) recolonization of lakes by amphibians after removal or extinction of introduced trout. Surveys of formerly fish-free lakes in many western states, including California, Oregon, Washington, Idaho, Utah, and Colorado have demonstrated a strong negative correlation between the presence of introduced trout and the presence or abundance of several species of amphibians, including *Ambystoma macrodactylum, A. gracile, Pseudacris regilla, P. maculata, Rana luteiventris, R. cascadae,* and *R. muscosa* (Bradford 1989; Bradford et al. 1998; T. Tyler, Liss, Ganio et al. 1998; T. Tyler, Liss, Hoffman et al. 1998; R. Knapp and Matthews 2000; R. Knapp, Matthews, and Sarnelle 2001; Matthews et al. 2001; Pilliod and Peterson 2001; Bull and Marx 2002; R. Knapp et al. 2003; Dunham, Pilliod, and Young 2004; R. Knapp 2005; Welch and MacMahon 2005). Some species that are distasteful to fish as larvae or adults, such as *Bufo boreas, B. canorus, Taricha torosa,* and *T. granulosa,* do not appear to be as strongly affected by the presence of fish (Corn, Jennings and Muths 1997; Bull and Marx 2002; R. Knapp 2005; Pearl et al. 2005). *Ambystoma gracile,* which often breeds in relatively deep lakes, appears to be more tolerant of fish than are other species of *Ambystoma,* although salamander abundance and patterns of activity can be altered by the presence of trout (Corn, Jennings and Muths 1997; T. Tyler, Liss, Ganio et al. 1998; R. Hoffman, Larson, and Brokes 2004; Pearl et al. 2005).

Studies in other parts of North America and on other continents have shown a similar negative correlation between the presence and abundance of amphibians and the presence of introduced trout or other introduced fish (Brönmark and Edenhamn 1994; Aronsson and Stenson 1995; Braña, Frechilla, and Orizaola 1996; Hecnar and M'Closkey 1997b; Reshetnikov and Manteifel 1997; Funk and Dunlap 1999; Gillespie 2001; Rodríguez 2001; Nyström et al. 2002; Pascual et al. 2002; Böll 2003; Martínez-Solano, Barbadillo, and Lapena 2003; Martínez-Solano, Bosch, and García-París 2003; Reshetnikov 2003; Crochet et al. 2004; Bosch et al. 2006). Introduced trout are present in some streams in South and Central America where toads of the genus *Atelopus* have declined or disappeared, but in some cases, these species coexisted for decades before toad populations declined, suggesting the fish were not a direct cause of the declines (La Marca et al. 2005). In Europe, the impact on both metmorphosing and paedomorphic populations of newts (*Triturus*), many of which occur in isolated populations in formerly fish-free lakes, has been particularly severe (Aronsson and Stenson 1995; Reshetnikov and Manteifel 1997; Denoël, Džukić, and Kalezić 2005). In addition to the effects of fish introductions on previously fish-free lakes, conversion of temporary wetlands to more permanent farm ponds also can encourage stocking of ponds with fish, with negative consequences for amphibians that normally breed in temporary water (Monello and Wright 1999; M. Adams 2000; M. Adams, Pearl, and Bury 2003; Pearl et al. 2005)

For many of these surveys, there are few quantitative data on the occurrence or abundance of amphibians before the introduction of fish, although in some cases, the disappearance of a local amphibian population could be tied to a known fish introduction. The ability of trout and other fishes to prey on amphibians, particularly larvae, is well documented (T. Tyler, Liss, Ganio et al. 1998; T. Tyler, Liss, Hoffman et al. 1998; M. Adams 2000; Kats and Ferrer 2003; see also chapter 14). The virtual exclusion of many amphibian species from lakes inhabited by fish is strong evidence that recent declines in some of these amphibian populations are due to the introduction of fish. The presence of fish also can inhibit recolonization of fish-free lakes by amphibians by making aquatic habitats located between amphibian populations uninhabitable for amphibians (Bradford, Tabatabai, and Graber 1993). Furthermore, the effect of fishes can extend beyond amphibians to impact entire ecosystems of high-altitude lakes. Introduced fishes often alter the composition and abundance of aquatic invertebrates, from small zooplankton to larger invertebrates such as aquatic insects, and this in turn can affect the composition and abundance of algal communities (Bradford et al. 1998; Kats and Ferrer 2003; Dunham, Pilliod, and Young 2004). The effects of introduced fishes can extend up the food chain as well, reducing or eliminating populations of predators such as garter snakes (*Thamnophis elegans* and *T. couchi*) that are heavily dependent on amphibians for food (Matthews, Knapp, and Pope 2002; R. Knapp 2005).

The strongest evidence for introduced trout causing declines or disappearances of amphibian populations comes from studies of recolonization of lakes from which trout have disappeared, either through natural extinction or deliberate removal. In some lakes, introduced trout are not able to establish self-maintaining populations without artificial stocking, and trout populations have subsequently gone extinct. In one study in Montana, Funk and Dunlap (1999) found that long-toed salamanders (*Ambystoma macrodactylum*) recolonized five of six lakes in which trout had gone extinct. The precise timing of recolonization is not known, but it occurred within 20 years, and in some cases, probably within 15 years after fish stocking ceased. In Mount Rainier National Park, introduced brook trout (*Salvelinus fontinalis*) were experimentally removed from one lake, and within a few years, there was a substantial increase in the number of eggs, larvae, and paedomorphic adults of *Ambystoma gracile* seen in the lake (R. Hoffman, Larson, and Samora 2004). Although this experiment lacked replication, the pattern of increasing abudance constrasted with the pattern of random fluctuation seen in one control lake that never contained fish.

A more comprehensive study, with better replication and controls, was conducted by Vredenburg (2004) in Kings Canyon National Park in the Sierra Nevada of California. Introduced trout were removed from five lakes between 1996 and 2003. The abundance of mountain yellow-legged frogs (*Rana muscosa*), a declining species, was monitored in these lakes and in eight fish-control lakes and eight fishless-control lakes. Fish-control lakes were largely devoid of frogs, but there was a rapid increase in numbers of frogs in the fish-removal lakes (fig. 16.14). The key to the rapid recolonization of lakes after the removal of fish was the close proximity of robust frog populations in the remaining fish-free lakes. These results suggest that halting fish stocking, along with removal of the remaining fish, is a viable management strategy to increase populations of amphibians that have declined due to fish introductions. Full recovery of the aquatic ecosystem to conditions that existed before the introduction of fishes, particularly the invertebrate community, may require 20 years or more (Drake and Naiman 2000; Donald et al. 2001; R. Knapp, Matthews, and Sarnelle 2001).

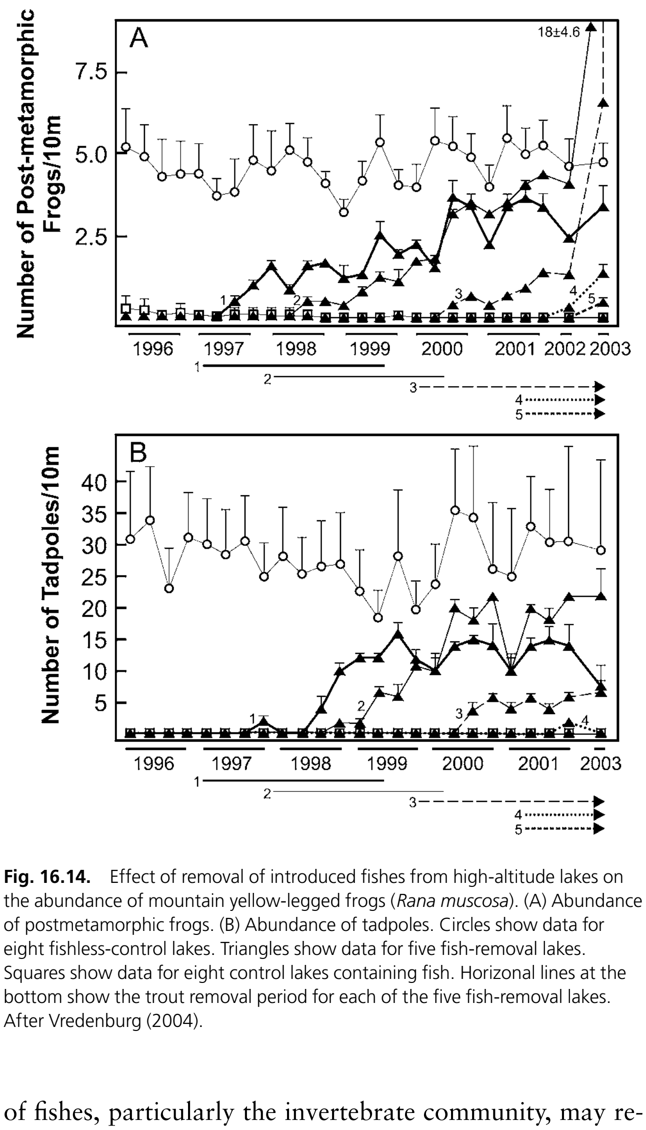

Fig. 16.14. Effect of removal of introduced fishes from high-altitude lakes on the abundance of mountain yellow-legged frogs (*Rana muscosa*). (A) Abundance of postmetamorphic frogs. (B) Abundance of tadpoles. Circles show data for eight fishless-control lakes. Triangles show data for five fish-removal lakes. Squares show data for eight control lakes containing fish. Horizonal lines at the bottom show the trout removal period for each of the five fish-removal lakes. After Vredenburg (2004).

Although the effects of introduced salmonids have received the most attention from amphibian ecologists, a variety of other fish species have been introduced into nonnative habitats around the world, and some of these also negatively impact amphibian populations. Probably the best documented is the effect of introduced mosquitofish (*Gambusia*) on both pond and stream-breeding amphibians. These highly adaptable fish readily invade temporary wetlands within their natural range, especially in low-lying areas that are frequently flooded by overflow from more permanent water. In central Florida, the native mosquitofish, *Gambusia holbrooki,* was a more voracious predator on anuran tadpoles than was a much larger introduced walking catfish, *Clarias batrachus,* but had about the same impact as did other native fishes (*Fundulus chrysotus* and *Jordanella floridae;* Baber and Babbitt 2003). Hylid and microhylid tadpoles were particularly susceptible to predation by these native fishes, whereas bufonid tadpoles were less vulnerable.

The tendency for mosquitofish to prey on amphibian larvae can have a devastating effect on amphibian populations in habitats where mosquitofish are not native and amphibians presumably have few defenses against them. For example, mosquitofish have been widely introduced into streams in the western United States for mosquito control and have been implicated in declines of native amphibians, including *Pseudacris regilla, Rana aurora,* and *Taricha torosa* (Gamradt and Kats 1996; Goodsell and Kats 1999; Lawler et al. 1999). Introduced mosquitofish also have been implicated in the decline of the Australian golden bell frog (*Litoria aurea*), although here the evidence is somewhat mixed. These fish readily feed on *Litoria* eggs and tadpoles (L. Morgan and Buttemer 1996; Pyke and White 2000). One survey found that *L. aurea* was largely absent from permanent ponds where mosquitofish were abundant, and used mostly ephemeral habitats for breeding (Pyke and White 1996). Another study found that the presence of mosquitofish did not influence the use of aquatic habitats by treefrogs, and tadpoles were found coexisting with the fish (Hamer, Lane, and Mahony 2002a). Nevertheless, *Litoria* tadpoles appear to lack effective antipredator responses to mosquitofish, so reproductive success may be lower in permanent ponds, which once were the preferred habitats of this frog (Hamer, Lane, and Mahony 2002b). Another Australian frog, *Limnodynastes tasmaniensis,* exhibits a greater tendency to avoid bodies of water inhabited by mosquitofish. This species, and another myobatrachid frog, *Crinia signifera,* both exhibited behavioral avoidance of mosquitofish in experimental tanks, even though neither species evolved in contact with these fish. It is not clear if this represents a general tendency to avoid fish predators, although *Crinia* breeds in ephemeral pools not normally inhabited by fish, whereas *Limnodynastes* breeds in more permanent pools (Lane and Mahony 2002).

In addition to the direct effect of introduced fishes as predators on amphibians, the presence of these species can indirectly facilitate the establishment of other nonnative organisms. One concern is that introduced fishes, especially those from fish hatcheries, can be a source for emerging diseases that attack amphibians (Kiesecker, Miller, and Blaustein 2001; Jancovich et al. 2005; see the following further discussion). Introduced fishes also can improve the chances that other invasive vertebrates become established. For example, in the heavily agricultural Willamette Valley of Oregon, introduced bullfrogs (*Rana catesbeiana*) are widespread. Invasion of ponds by bullfrogs is facilitated by the presence of introduced bluegill sunfish (*Lepomis machrochirus;* M. Adams, Pearl, and Bury 2003). The bluegills are major predators on dragonfly naiads, which in turn are more important predators on bullfrog tadpoles than are the fish themselves (see also chapter 15). Consequently, survival of dragonfly naiads was lower and survival of bullfrog tadpoles was higher in ponds with sunfish than in ponds without fish. M. Adams, Pearl, and Bury (2003) suggested that removing introduced bluegills from ponds may be a more practical way to control densities of introduced bullfrogs than removing the frogs themselves.

Amphibian Invaders

With the growing concern about declining amphibian populations, it is easy to overlook the potential for some amphibians to become established and even invade new habitats once they are introduced into a new region. One of the most common invasive species is the American bullfrog (*Rana catesbeiana*), which has been widely introduced in western North America, South America, Europe, and Asia. There is evidence that introduced bullfrogs in western North America have had a negative impact on native amphibians (fig. 16.15), especially ranids, through both competition and predation (Kiesecker and Blaustein 1997b, 1998; Kupferberg 1997a; Kiesecker, Blaustein, and Miller 2001; Pearl et al. 2004), although it can be difficult to separate the effects of bullfrogs from other changes in habitat structure and the synergistic effects of other introduced predators, such as fishes (Jennings and Hayes 1985; M. Adams 1999; M. Adams, Pearl, and Bury 2003; Doubledee, Muller, and Nisbet 2003). Experimental studies of predation and competition between introduced bullfrogs and native frogs were discussed in chapter 15 and need not be described in detail here.

As mentioned in the discussion of amphibian declines in

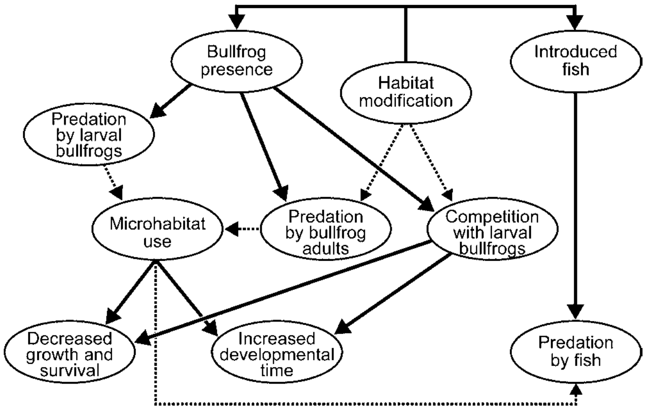

Fig. 16.15. Hypothesized interactions between the effects of habitat modification, the presence of introduced bullfrogs (*Rana catesbeiana*), and the presence of introduced predatory fishes on red-legged frogs (*Rana aurora*) in the western United States. Tadpoles and adults of bullfrogs can negatively impact red-legged frogs through both predation and competition, and changes in habitat use induced by bullfrogs can make red-legged frog tadpoles more susceptible to predation by fishes. Solid arrows indicate direct effects; dashed arrows indicate indirect effects. After Kiesecker (2003).

Europe, surprisingly little ecological work has been done on introduced populations of bullfrogs in Europe or other regions of the world. An internet search reveals scores of websites that routinely describe bullfrogs as voracious predators that will eat almost anything. Nevertheless, most studies of the diets of introduced bullfrogs have shown that they eat mostly invertebrates (e.g., Hirai 2004), so the impact on native amphibians is largely unknown. One threat posed by the introduction and international trade in bullfrogs is their potential as reservoirs for disease organisms such as the chytrid fungus (*Batrachochytrium dendrobatidis*), which is thought to be responsible for some amphibian declines. This fungus has been identified in introduced and farmed populations of bullfrogs in South America, although the bullfrogs themselves seem not to be affected by the disease (Mazzoni et al. 2003; Hanselmann et al. 2004). It is not yet known, however, whether bullfrogs actually are responsible for transmission of the disease to native amphibians (Daszak et al. 2004; see the following further discussion of this disease).

The only other species of amphibian that has been as widely introduced as the American bullfrog is the marine or cane toad (*Bufo marinus*). This species has many traits characteristic of an invasive species (Lever 2001). It can reproduce in a wide variety of aquatic sites, from polluted ditches and ponds to pristine rivers. Females produce thousands of eggs, and both egg and tadpole development is very rapid, with metamorphs emerging at a very small size relative to adult size. The toads are highly mobile, with both juveniles and adults being able to move over long distances (Schwarzkopf and Alford 2002). They tend to favor disturbed habitats and often are associated with human habitation. Finally, the eggs, tadpoles, and adults all are highly toxic and distasteful to many predators.

Originally native to South and Central America, this large toad has been introduced accidentally or intentionally, mostly to control insect pests, to Hawaii and many other Pacific islands, Australia, New Guinea, several of the smaller islands of Japan, the Philippines, Diego Garcia in the Indian Ocean, most islands in the Caribbean, Bermuda, and Florida (Lever 2001). Some of these regions, particularly oceanic islands, lack native species of amphibians, although the introduced toads may negatively impact other groups, such as native insects (Matsumoto, Matsumoto, and Miyashita 1984). Other regions, such as the Philippines, where the toad has been widely established for decades (Alcala 1957), have a rich native anuran fauna, but the impact of the toads on native species is largely unknown. Even within South America, *Bufo marinus* may be expanding its range. In Ecuador, for example, the toads now occur at higher altitudes than previously reported (Bustamante, Ron, and Coloma 2005). Although this altitudinal shift has been attributed to increased temperatures at high altitudes, it also could be related to the tendency of this species to spread with human settlement and alteration of natural habitats.

Most ecological studies on the effects of cane toad introductions have been done in Australia, where the species has been considered a major invasive threat to native wildlife. Much of the concern over the cane toad in Australia has focused on its impact on native wildlife species, including mammals, birds, and reptiles, that are poisoned after attacking the highly toxic toads (Covacevich and Archer, 1975; Burnett 1997; Lever 2001; B. Phillips, Brown, and Shine 2003; Aldhous 2004; Webb, Shine, and Christian 2005). The long-term impact of the toads on native predators is unclear (Catling et al. 1999). It is possible that some of these predators eventually will develop learned or evolved behavioral avoidance of adult toads, just as some native fish rapidly learn to avoid their toxic tadpoles (Crossland 2001). There also is evidence of toad-induced selection on morphology in some snakes, with body size and gape size decreasing in a way that makes it more difficult for them to eat large toads (B. Phillips and Shine 2004). Toads also are potential predators on smaller vertebrates, although most studies have shown that insects and other invertebrates comprise most of the diet (Lever 2001). A particularly bizarre impact of cane toads is their ability to prey on the eggs and nestlings of ground-nesting birds, such as the rainbow bee-eater (*Merops ornatus;* Boland 2004).

Despite widespread concern in Australia about the impact of rapidly expanding cane toad populations, there have been surprisingly few detailed ecological studies of the interactions between cane toads and native anurans. Anecdotal observations indicate that cane toads sometimes consume native frogs (M. Tyler 1976), but whether they do so in sufficient numbers to impact frog populations is unknown. Crossland (1998a) found that *Bufo marinus* tadpoles were not significant predators on the eggs or larvae of native frogs, but their own eggs are sufficiently toxic to be a threat to native tadpoles that consume them (Crossland 1998b; Crossland and Alford 1998; Crossland and Azevedo-Ramos 1999; Williamson 1999). The presence of *B. marinus* tadpoles can reduce growth rates and survival of native tapoles, particularly of the genus *Limnodynastes,* in competition experiments (Crossland 1998, 2000; Williamson 1999), but most of the native species do not breed in permanent water, which often is used by cane toads. A study using tadpoles of introduced cane toads in Florida found little impact of this species on growth and development of two native species of tadpoles, *Bufo terrestris* and *Hyla cinerea* (K. G. Smith 2005).

Several other species of amphibians have been introduced into or have invaded new habitats in various parts of the world, but in most cases, the impact on local amphibian populations is poorly understood. The major concerns are competition with or predation on native amphibians and possible genetic consquences of hybridization between introduced species and closely related native species. Populations of African clawed frogs (*Xenopus laevis*) have become established in several parts of the world as a result of releases from laboratory stocks or pets. In California, these frogs are very successful, especially in artificial bodies of water. Although they are voracious predators of invertebrates, predation on amphibians appears to mostly involve cannibalism of conspecifics (McCoid and Fritts 1980, 1993). This species also has become established in Chile, again mostly in artificial ponds (Lobos and Jaksic 2005). As in California, the only amphibians found in the stomachs of *Xenopus* were conspecific tadpoles, so the impact on native amphibians appears to be minimal. Whether these frogs compete with native species has yet to be determined. Introduced populations also are known from Wales, where the only amphibian prey items were conspecific eggs and tadpoles (Measey 1998).

In South Africa, the replacement of natural bodies of water with artificial ponds has facilitated the invasion of *Xenopus laevis* into habitats formerly inhabited by *X. gilli.* The latter species is now endangered because of habitat destruction, predation by *X. laevis,* and hybridization with *X. laevis* in the few remaining habitats that now support *X. gilli* (Picker, Harrison, and Wallace 1996; De Villiers 2004). Hybridization between native species and closely related invasive species also is a concern in Europe, where *Rana ridibunda* has spread into new habitats (Arano et al. 1995; Pagano et al. 2003; Vorburger and Reyer 2003), and in California, where the endangered California tiger salamander (*Ambystoma californiense*) hybridizes with introduced *A. tigrinum* (Riley et al. 2003).

Florida is particularly susceptible to invasive species because of its subtropical climate, and a number of nonnative amphibians have become established there (Meshaka, Butterfield, and Hauge 2004; Meshaka 2005). The best-studied is the Cuban treefrog (*Osteopilus septentrionalis*), which is widespread in the state and favors human-altered habitats (Meshaka 2001). This species is larger than any of the native hylids and generally eats a wider range of prey, including large insects not generally consumed by other species. Although there is considerable overlap in diet between the Cuban treefrog and other hylids, the extent to which competition negatively affects the native species is unknown. Cuban treefrogs also prey on smaller frogs (Meshaka 2001; Wyatt and Forys 2004), but again, the ecological impact of such predation on native frog populations is unknown.

Florida also has been invaded by two species of *Eleutherodactylus* from Caribbean islands. *Eleutherodactylus planirostris* has been widespread in the state for decades, and localized populations of *Eleutherodactylus coqui* from Puerto Rico also have become established near urban areas (Meshaka, Butterfield, and Hauge 2004; Meshaka 2005). These direct-developing frogs have a very different life history from all other Florida anurans and appear to occupy a different niche, so their ecological impact may be minimal. The same two species have become established in Hawaii, presumbly introduced in imported ornamental plants. Since Hawaii lacks native species of amphibians, the main impact appears to be on humans annoyed by their loud calls, although there is a potential for these frogs to negatively impact endemic species of insects, because their populations are expanding rapidly (Kraus and Campbell 2002). Several species of *Eleutherodactylus* also have moved around among various Caribbean islands and from the Caribbean to Central and South America. Invasive species, such as *Eleutherodactylus johnstonei* and *E. planirostris,* appear to be more tolerant of open habitats and dry conditions than are native *Eleutherodactylus* on the same islands. Even if these invasive species do not directly compete with native *Eleutherodactylus,* they eventually may dominate island ecosystems increasingly characterized by heavy deforestation and expanding human occupation of the landscape (Pough, Stewart, and Thomas 1977; M. Stewart 1979; M. Stewart and Martin 1980; Kaiser and Henderson 1994; Kaiser 1997).

Other Introduced Organisms

A variety of other animals and plants have been introduced all over the world, and many of these species have become highly invasive. For the most part, the impact of these organisms on amphibian populations is poorly studied, although some clearly are potential predators on native amphibians. Introduced crayfish prey on native amphibians, both in North America and Europe, and may exclude amphibians from some habitats (Gamradt and Kats 1996; Axelsson et al. 1997; Gherardi, Renai, and Corti 2001; Beja and Alcazar 2003; Kats and Ferrer 2003). Invasive crayfish also can alter habitat quality by removing aquatic vegetation used for cover by amphibians (Carey et al. 2003). On the Spanish island of Mallorca, the endemic midwife toad (*Alytes muletensis*) is largely excluded from areas inhabited by introduced frogs (*Rana perezi*) and snakes (*Natrix maura*). The distribution of these two species on the island is similar, being limited to lower elevations, and the introduced frogs probabably are the principal prey of the snakes. The midwife toads are now confined to pools in steep, higher-elevation gorges (R. Moore, Griffiths, and Román 2004). The snakes have been present for more than 2,000 years. Both adults and tadpoles of the midwife toads show some behavioral avoidance of chemical cues from snakes, and tadpoles also exhibit morphological changes in areas where snakes are present (Griffiths et al. 1998; Schley and Griffiths 1998; R. Moore et al. 2004). This suggests that the toads have some capacity to adapt to and coexist with the introduced predators. Other introduced species of snakes have the potential to affect amphibian populations, although their impact on amphibian populations has not been studied. For example, large Burmese pythons have become established in the Florida Everglades, but their impact on the native fauna is largely uknown (Lovgren 2004).

Even organisms that are not predators of amphibians have the potential to affect amphibian populations when introduced into nonnative habitats. For example, some invasive aquatic plants, such as water hyacinth (*Eichhornia crassipes*), form dense mats on lakes and ponds that can block light for photosynthesis and reduce the oxygen content of the water. Although some air-breathing amphibians, such as sirens, can tolerate and even thrive in such conditions (Ultsch 1973b), most other vertebrates are excluded from such habitats. Other invasive aquatic plants can alter the hydroperiods, nutrient cycling, and food web dynamics of ponds used by amphibians for reproduction (D. Gordon 1998; Zedler and Kercher 2004). Invasive aquatic snails have the potential to affect larval amphibians, not only as competitors for periphyton (Brönmark, Rundle, and Erlandsson 1991; Cattaneo and Mousseau 1995; P. Harris 1995), but also as reservoirs for trematode parasites that can infect amphibians (Rader, Belk, and Keleher 2003; Johnson and Lunde 2005). Invasive European earthworms, which are gradually spreading in forests of the northeastern United States, could affect amphibians such as plethodontid salamanders by accelerating the removal of leaf litter, thereby depriving salamanders of critical cover and moisture and changing the abundance and distribution of soil invertebrates on which they feed (Bohlen et al. 2004). Even the introduced gypsy moth, which defoliates deciduous trees, and the wooly adelgid, which kills hemlocks, could reduce salamander populations by altering canopy cover and moisture conditions in forests (Carey et al. 2003). None of these interactions has been studied in much detail, and the effect of exotic species on amphibian populations deserves further investigation.

Emerging Diseases of Amphibians

Although most amphibians have strong natural immunity to all sorts of infectious diseases (Rollins-Smith 2001; Rollins-Smith et al. 2005), there has been great concern in recent years about the emergence of diseases that can decimate amphibian populations, even in well-protected habitats. Indeed, many of the amphibian population declines observed in seemingly pristine areas of montane rainforest in various parts of the world have been attributed to the effects of disease. These effects may act in conjuction with other environmental stressors that weaken the immune defenses of amphibians, such as climate change, human habitat alteration, and environmental pollution (Carey 2000; Carey, Bradford, et al. 2003; Carey, Pessier, and Peace 2003; J. P. Collins et al. 2003; Kiesecker et al. 2004; Rollins et al. 2005). In many cases, emerging infectious diseases are an extension of the problem of introduced organisms, because (1) the pathogens themselves may be newly introduced to an area, (2) other introduced species may serve as reservoirs or vectors for disease organisms, or (3) synergistic effects of disease organisms and other introduced species may precipitate declines of amphibian populations. This problem certainly is not limited to amphibians—emerging diseases are considered major threats to crop plants, wild plants, coral reefs, aquatic and terrestrial wildlife, and even humans (Carey 2000; Daszak, Cunningham, and Hyatt 2000; Cleaveland et al. 2002; Harvell et al. 2002; P. K. Anderson et al. 2004; Sutherland, Porter, and Torres 2004). In some cases, such as the grotesque facial tumors afflicting Tasmanian devils (Bostanci 2005), emerging diseases have wiped out entire populations very rapidly, just as has been observed in some amphibian populations. The effects of disease on key organisms such as corals and forest trees have the potential to alter entire ecosystems by contributing to the decline of other species that depend on them for food or habitat structure (Canterbury and Blockstein 1997; D. Bellwood et al. 2004; G. Jones et al. 2004).

Chytridiomycosis and Amphibian Declines

Most of the recent literature on the role of disease in amphibian population declines has focused on chytridiomycosis, a fungal disease that attacks keratinized tissue, especially the skin of adult amphibians, but also the keratinized mouthparts of tadpoles. The first indication that amphibians might be dying from an unknown disease was the rapid decline of many species of stream-breeding frogs in the rainforests of Queensland, Australia. On the basis of the timing of declines in different species, Laurance, McDonald, and Speare (1996) argued that the most likely agent of decline was an exotic pathogen, and they suggested a virus was the most likely candidate. This suggestion met with initial skepticism from other Australian ecologists, who argued that there was little or no evidence for the presence of an infectious agent in declining amphibian populations (Alford and Richards 1997; Hero and Gillespie 1997). At about the same time, Lips (1999) was observing massive die-offs of frogs in the mountains of western Panama, even finding dead and dying frogs on the forest floor, certainly a most unusual occurrence. Necropsies of the dead frogs showed that all of them were infected with an unknown fungal disease, and there were signs of fungal infection on the mouthparts of living tadpoles as well. Comparative research revealed that the same fungus was associated with the mortality of frogs in Australia and Central America (Berger et al. 1998). The fungus was subsequently described as a new species, *Batrachochytrium dendrobatidis* (fig. 16.16), a member of a common group of fungi found in soil and water that represents the earliest diverging clade of fungi (Longcore, Pessier, and Nichols 1999; Carey et al. 2003).

There has now been a large body of research on the chytrid fungus and its role in amphibian declines. Amphibians (mostly anurans) infected with *Batrachochytrium* have been reported from every continent except Asia, in both captive and wild populations (Carey et al. 2003; Ouellet et al. 2005; see also a continuously updated website at: http://www.jcu.edu.au/school/phtm/PHTM/frogs/chyglob.htm). In addition to the mass mortality or declines attributed to chytrid fungus infections in Australia and Panama, other population declines associated with chytrid infections have been reported from Costa Rica (Lips, Green, and Papendick 2003), Ecuador (Ron and Merino 2000), Venezuela (Bonaccorso et al. 2003), western North America (D. E. Green and Kagarise Sherman 2001; Bradley et al. 2002; D. E. Green, Converse, and Schrader 2002; Muths, Corn, Pessier, and Green 2003), Europe (Bosch, Martínez-Solano, and García-París 2001), and New Zealand (Waldman et al. 2001). Almost all of these reports come from mid- to high-elevation sites, mostly in stream-breeding frogs. In Costa Rica and Panama, population declines have progressed in a southeasterly direction, having started in the highlands of Costa Rica in the late 1980s, reaching western Panama in the 1990s, and continuing to the present (fig. 16.17). The most recent decline attributable to chytridiomycosis occurred at El Copé, Panama, and was extraordinarily fast, with a decline of more than 50% in density of individuals and number of species within a few months after the first appearance of the fungus in the area (Lips et al. 2006). Most affected were frogs associated with streams, with terrestrial species showing little evidence of decline. Mass die-offs attributable to chytrid infections have not been reported from lowland populations of amphibians in either temperate or tropical regions. This is consistent with laboratory studies showing that the fungus grows best in cool, wet conditions (Longcore, Pessier, and Nichols 1999; Woodhams, Alford, and Marantelli 2003; Berger et al. 2004), and field studies showing that mortality of chytrid-infected Australian frogs was higher in the winter than in other seasons (Berger et al. 2004; Woodhams and Alford 2005). Nevertheless, there are some reports of chytridiomy-

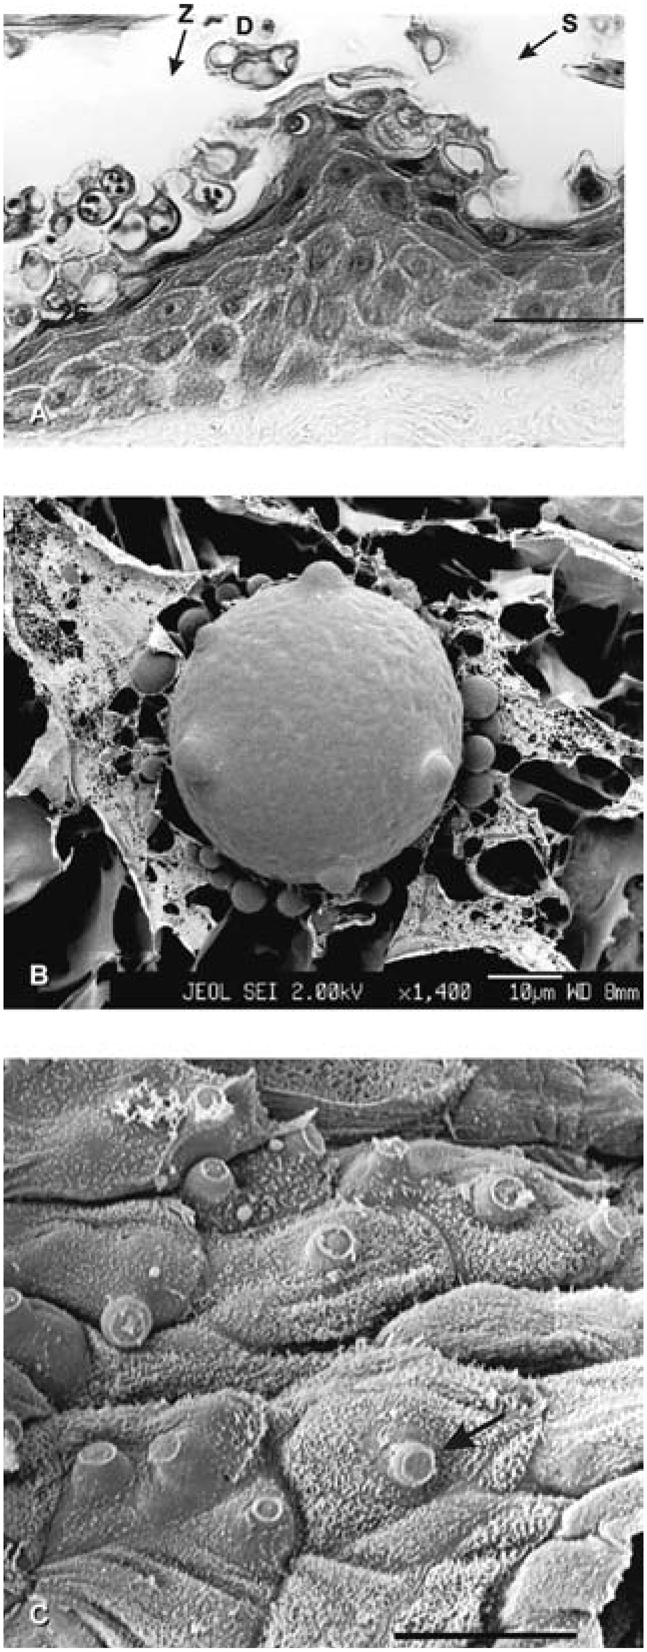

Fig. 16.16. The chytrid fungus *Batrachochytrium dendrobatidis* has emerged as a major threat to amphibian populations in several parts of the world, especially in tropical montane regions. The fungus attacks keratinized cells in the skin, as well as the mouthparts of tadpoles. (A) Cross-section of the skin of a frog infected with *B. dendrobatidis.* Z = zoosporagium containing zoospores. D = discharge tube of the zoosporangium. S = septum in a sporangium. (B) Scanning electron microscope photograph of a large sporangium in culture, showing discharge tubes that release zoospores. (C) Scanning electron microscope photograph of the surface of frog skin infected with *B. dendrobatidis.* Arrow points to discharge tube protruding through the skin. Photos by Lee Berger.

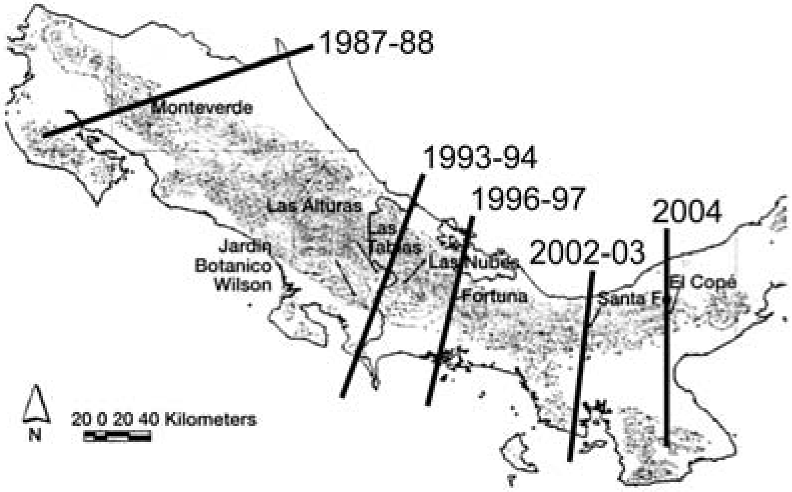

Fig. 16.17. Declines of amphibian populations associated with chytridiomycosis have rapidly spread from western Costa Rica, where declines occurred in the late 1980s, to the highlands of western Panama, where declines began in the 1990s and are continuing today. Many species of stream-breeding frogs and some species not associated with streams have been affected. Lines and dates show when declines occurred. After Lips et al. (2006).

cosis from warmer, lower elevation sites as well (Herrera, Steciow, and Natale 2005; Ouellet et al. 2005).

Although chytrid infection clearly has been shown to be the cause of mortality of adult anurans both in the laboratory and in the field (Carey et al. 2003; Berger et al. 2004), the actual mechanism responsible for mortality is not clear. The fungus could interfere with essential functions of the skin, or it could release a toxin that is fatal to many frogs. Infections of tadpoles generally are not fatal, although there is some variation among species in susceptiblity to the fungus (Blaustein et al. 2005). Fungal infections in tadpoles can result in deformed mouthparts that interfere with feeding and can affect rates of growth and development and alter interactions with competitors and predators living in the same pond (Fellers, Green, and Longcore 2001; Parris 2004; Parris and Beaudoin 2004; Parris and Cornelius 2004; Parris, Reese, and Storfer 2006). Nevertheless, the fungus can be transmitted from larvae to adults (Rachowicz and Vrendenburg 2004), so infected tadpoles represent a potential reservoir for the disease, particularly in species with long larval periods.

While many aspects of the basic biology of *Batrachchytrium* are now well understood, many others remain a mystery (McCallum 2005). The three most important unanswered questions are: (1) Where did the fungus originate? (2) Why has it emerged recently as a deadly disease in amphibians? (3) Why are some amphibians highly susceptible to the disease, whereas others can be infected but show few pathological symptoms? Recent genetic analyses of strains from amphibians on different continents indicate that all strains are genetically similar, suggesting a relatively recent common origin of the fungus in widely separated parts of the world (Morehouse et al. 2003). This has led many authors to suggest that the fungus is not native to areas where mass mortality of amphibians has occurred, including Australia and the Western Hemisphere, but was recently spread from another source (Carey et al. 2003). On the other hand, the low level of genetic diversity in tested strains of chytrid fungus is not, in itself, evidence of recent origin, because we lack comparative data on closely related fungi that would provide an expected level of genetic variation (Rachowicz et al. 2005).

If chytridiomycosis is a newly evolved disease, then we must account for its appearance in widely separated parts of the world, and its sudden appearance in areas where it had not previously been present (Lips et al. 2006). One hypothesis is that the fungus has spread around the world through international trade or accidental importation of infected amphibians. Once infected animals are released into the wild, they may encounter species with little or no immunity to the disease. This idea has been supported by reports of nonlethal infections of the fungus in nonnative bullfrogs (*Rana catesbeiana*) in South America, which could serve as reservoirs for the disease (Mazzoni et al. 2003; Hanselmann et al. 2004; Rachowicz et al. 2005).

Weldon et al. (2004) went further in proposing that the fungus most likely originated in Africa and spread to the rest of the world through widespread importation of African clawed frogs (*Xenopus laevis*), which can carry the disease, but are largely resistant to its effects. The evidence for an African origin of the disease is largely circumstantial (McCallum 2005; Rachowicz et al. 2005). Weldon et al. (2004) found infected *Xenopus* specimens in African museum collections dating back to 1938, much earlier than any other reported infection. This frog has been widely transported around the world since the 1930s, initially for pregnancy testing and later as a laboratory animal. Feral populations have become established in a number of locations, including California, Chile, and Wales, and in some cases, have subsequently expanded their ranges. Nevertheless, several lines of evidence argue against this hypothesis. First, the areas in which feral populations of *Xenopus* have become established do not correspond geographically to the hotspots of mortality attributed to chytridiomycosis. Second, feral populations of *Xenopus* almost invariably thrive in warm, manmade bodies of water at low elevations, such as farm ponds (McCoid and Fritts 1980, 1993; Lobos and Jaksic 2005). They are not found in cool, mid- to high-elevation lakes and streams or in montane rainforests, where most instances of the disease have been reported. Although the fungus can survive in water, at least for limited periods of time (Johnson and Speare 2003), we do not yet have a plausible mechanism to explain the dispersal of the fungus from infected to uninfected populations at higher elevations, especially in tropical forest reserves seldom visited by humans.

Until we have more definitive evidence about the origin of this fungus, it will be difficult to determine why the disease has emerged relatively recently as a threat to amphibians. One possibility already mentioned is that the fungus has been transported to areas in which the local amphibians lack defenses against the disease, thereby causing a fast-moving epidemic. Another favorite hypothesis is that other kinds of environmental stressors, such as global climate change, pollution, or habitat alteration have resulted in increased stress for amphibians, leading to impared immune function (Carey, Cohen, and Rollins-Smith 1999; Carey 2000, 2005; Carey and Alexander 2003; Carey et al. 2003; Rachowicz et al. 2005).

Another possibility is that global climate change has altered growing conditions for the fungus itself, making it more of a threat to amphibians. Pounds et al. (2006) reported a strong correlation between episodes of climate warming in Neotropical montane regions and the years in which various species of *Atelopus* disappeared. This stream-breeding genus has been severely impacted by population declines, and chytridiomycosis has been implicated as a cause of these declines. Although the fungus does best at relatively cool temperatures, the effect of a warming climate has been to increase the amount of cloud cover in montane forests. This not only could reduce the frogs' exposure to direct sunlight, but it also decreases maximum daytime temperatures while increasing minimum nighttime temperatures. The result is a narrowing of the daily range of temperatures experienced by the frogs, and by the fungus, with more temperatures falling within the optimum range for fungal growth. Although the data presented by Pounds et al. (2006) show a strong correlation between variation in temperature and declines of *Atelopus* (fig. 16.18), we do not yet have experimental evidence to establish a cause-and-effect relationship between climate change and amphibian declines.

The importance of direct exposure to sunlight as a defense against chytridiomycosis has yet to be explored. Like many organisms, the fungus probably is susceptible to excessive doses of UV-B radiation present in unflitered sunlight, and basking by diurnal amphibians could be one mechanism to combat fungal growth in the skin. Many diurnal anurans that occur at high altitudes, including several species of *Atelopus,* have unusually dark dorsal coloration, and many are nearly all black (Lötters 1996). One likely function of dark coloration is to protect the skin from harmful exposure to UV-B radiation. Many frogs, including some high-altitude species, are known to bask in full sunlight (see chapter 3). It has been suggested that basking could reduce chytrid infections by elevating body temperature (Woodhams, Alford, and Marantelli 2003; Rachowicz et al. 2005). However, neither basking nor dark coloration has a dramatic effect on core body temperature in amphibians, especially small species. Any increase in skin temperature due to increased absorption of sunlight is likely to increase evaporative cooling, thereby lowering core body temperature (see Tracy 1979, and discussion in chapter 3). Nevertheless, it is possible that basking does increase skin temperature, even if core body temperature is relatively unchanged, and dark coloration could enhance this effect. Even a small increase in skin temperature, coupled with direct exposure of the fungus to UV-B radiation, could be important in defending against fungal infections, because the skin is the main target of infection.

A final aspect of chytridiomycosis that remains poorly understood is inherent variation in susceptibility to the disease among different species of amphibians. Reports of mass die-offs of amphibians due to chytrid infection have received wide attention, but there are at least as many reports of amphibians infected with chytrid fungus that do not die from the infection (Carey et al. 2003; Daszak et al. 2005; McCallum 2005; Ouellet et al. 2005; Rachowicz et al. 2005; Woodhams and Alford 2005; Lips et al. 2006). Even in areas where many species of amphibians experienced precipitous declines or disappeared altogether, as in Australia, in Central and South America, and in western North America, other species in the same habitats were unaffected. In Panama, a number of arboreal and terrestrial frogs, includ-

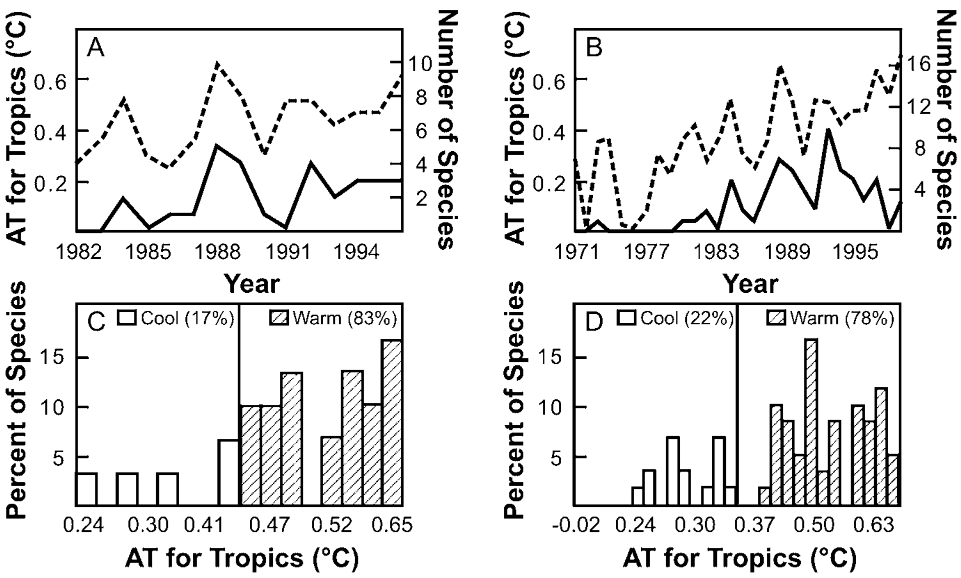

Fig. 16.18. Changes in climate appear to be related to the declines of populations of the genus *Atelopus.* (A, B) Relationship of the number of species of *Atelopus* seen for the last time each year (solid lines) to the deviation in air temperature for the tropics (dashed lines. Data in A are for species known to be in decline (*N* = 51); data in B are for those species, plus 49 others suspected of being in decline. Peaks in disappearances of species correspond to unusually warm weather. (C, D) Percentage of species observed for the last time in relative cool and relatively warm years. Data as in A and B. Species of *Atelopus* were much more likely to be seen for the last time following an unusually warm year. After Pounds et al. (2006).

ing *Agalychnis callidryas, Bufo marinus, Hyla microcephala, Leptodactylus pentadacylus, Smilisca phaeota,* and a species of *Rana* appear to be thriving in areas already decimated by the disease, despite the continuing presence of the fungus in the habitat and in the frogs (Lips et al. 2006). In Queensland, one species that suffered drastic declines in the 1980s, *Taudactylus eungellenis,* persists in a number of remant populations. These are infected at low levels with *Batrachochytrium,* but there was little evidence of reduced survival among infected individuals relative to infected animals. A treefrog in the genus *Litoria* in the same area that did not suffer population declines also had low levels of chytrid infection, but with few signs of negative effects on the population (Retallick, McCallum, and Speare 2004). In species such as *Xenopus laevis* and some populations of *Rana catesbeiana,* chytrid infections appear to be endemic, but the frogs show few symptoms of disease, and nonlethal chytrid infections have been reported in many other species of frogs as well (Carey et al. 2003; Davidson et al. 2003; Hopkins and Channing 2003; Daszak et al. 2004; Ouellet et al. 2005). Finally, among salamanders, chytrid infections have been reported in the genus *Ambystoma,* but the disease rarely appears to be fatal (Carey et al. 2003; Davidson et al. 2003; Padgett-Flohr and Longcore 2005).

All of this evidence suggests wide variation among amphibian species in their ability to fight off chytrid infections. What accounts for this variation? The first line of defense against fungal or microbial infections in amphibians is not a cellular immune response, but antimicrobial peptides produced in the skin. Amphibians produce a wide range of peptides that have been intensively studied by biochemists and pharmacologists interested primarily in their potential use as antibiotics in humans (Simmaco et al. 1998; Rinaldi 2002; Nascimento et al. 2003; Sima 2003; Conlon, Kolodziejek, and Nowotny 2004). The importance of these compounds as defenses against disease in wild populations of amphibians is just beginning to be explored (Rollins-Smith et al. 2005).

Recent research has shown that the polypeptide precursors of antimicrobial peptides are remarkably conservative evolutionarily, not only among amphibians, but also among vertebrates in general. These precursors have given rise to thousands of different peptides, all of which may have slightly different antimicrobial properties. Most species of frogs probably have unique combinations of several dozen antimicrobial peptides. The evolutionary strategy in this type of defense is to throw a wide variety of compounds at potential disease organisms, reducing the chances that microbes will evolve immunity to any one compound (Nicolas, Vanhoye, and Amiche 2003; Vanhoye et al. 2003). Not only does the great variety of peptides produced by a given species of frog enable them to defend against a variety of microbes, but the peptides act synergistically, so a combination of peptides has up to 100 times greater antimicrobial activity than does any single peptide (Nicolas, Vanhoye, and

Amiche 2003). This is an ancient evoutionary strategy, with a variety of antimicrobial peptides being present even in the most primitive living anuran, *Ascaphus* (Conlon, Sonnevend et al. 2004).

Most of the antimicrobial peptides that have been tested for activity against chytrid infections have been from ranid frogs, and most have shown strong activity against the fungus (Rollins-Smith, Carey et al. 2002; Rollins-Smith, Reinert et al. 2002; Rollins-Smith et al. 2003, 2005). Recently, additional work with peptides from hylids, leptodactylids, myobatrachids, and pipids turned up other peptides that inhibit growth of the fungus (Rollins-Smith and Conlon 2005; Woodhams et al. 2006). In some cases, such as *Rana tarahumarae,* the frogs produce peptides active against chytrid infections, but infections have been found in both dead and healthy individuals, and the species as a whole has suffered major population declines (Rollins-Smith, Reinert et al. 2002). This has led to the suggestion that other environmental stressors have somehow weakened the defenses of the frogs against the fungus, but evidence that population declines in this species actually were caused by chytridiomycosis is circumstantial (Rorabaugh and Hale 2005).

While much is known about the biochemistry of antimicrobial peptides in amphibians, little is known about the ecology of immune defense or the effect of habitat on the production of such compounds. One alternative to the environmental stressor hypothesis to explain variation among amphibians in susceptibility to chytrid infections is that different species have different innate immunity to the fungus for ecological reasons. In tropical Australia, frog species that have not suffered major declines appear to have skin peptides with greater effectiveness against chytridiomycosis than do species that have suffered declines (fig. 16.19; Woodhams et al. 2006). It seems likely that antimicrobial peptides have undergone rapid evolutionary diversification in response to selection for disease resistance (Duda, Vanhoye, and Nicholas 2002; W. Lee et al. 2005). The presence of a diverse array of bacteria and fungi in the natural environment of amphibians is expected to select for an ever-increasing array of compounds to combat these infectious agents. Furthermore, there is evidence that production of antimicrobial peptides is induced by exposure to soil microbes (Mangoni et al. 2001) or to environments conducive to the growth of fungi and bacteria (Matutte et al. 2000). This suggests that amphibians probably exhibit both plastic phenotypic responses to local assemblages of microbes and long-term evolutionary adaptation to microbes present in the environment.

If this is a general pattern in amphibians, then one would expect to see the evolution of a more powerful and diverse array of antimicrobial skin secretions in amphibians that are regularly exposed to microbe-filled environments. These would include burrowing amphibians in constant contact with moist soil, most terrestrial salamanders, leaf-litter frogs in tropical forests, and both salamanders and frogs that breed in warm, eutrophic ponds that are veritable microbial stews. In contrast, amphibians that normally breed in cool, low-productivity environments such as mountain streams or high-altitude lakes would not necessarily be expected to evolve such an array of defenses. If these relatively "clean" habitats are invaded by a newly arrived organism such as a chytrid fungus, the local amphibians may lack the ability to fight off infection, and the result could be an epidemic of disease and rapid declines of local populations, such as those seen at mid- and high-elevation sites in the Western Hemisphere, Australia, and Europe. At the same time, amphib-

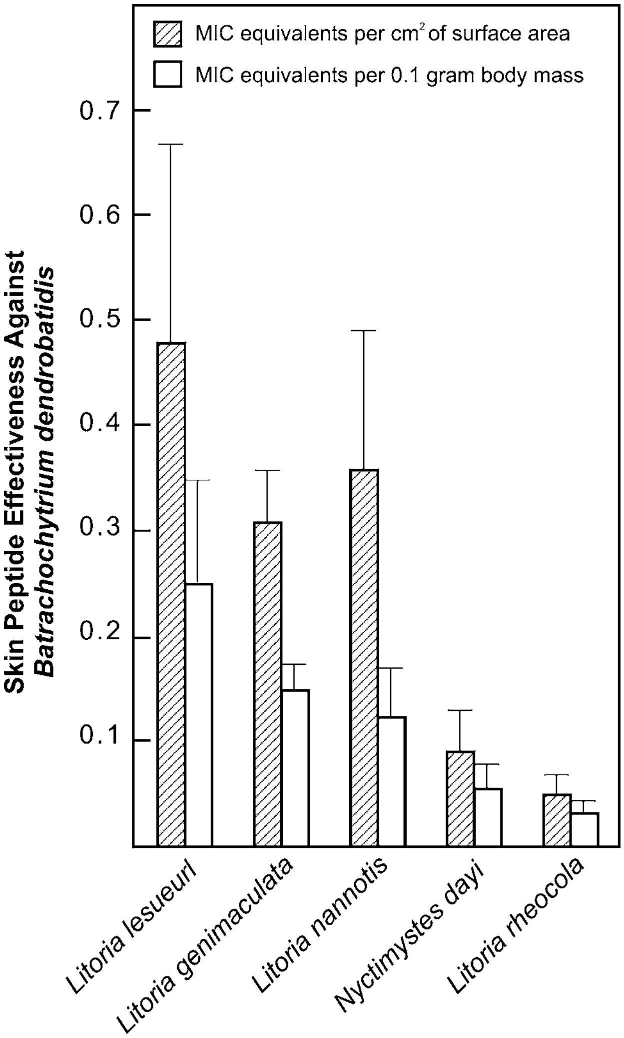

Fig. 16.19. Relative effectiveness of skin peptides against the chytrid fungus *Batrachochytrium dendrobatidis* in five species of Australian stream-breeding hylid frogs. Data show Minimal Inhibitory Concentrations (MIC) of mixed skin peptides, expressed in relation to both skin surface area and body mass. The two species on the left (*Litoria lesueri* and *L. genimaculata*) have not experienced population declines, whereas the other three species have declined. The two species on the right have particularly ineffective defenses against the fungus. After Woodhams et al. (2006).

ians in the same area that do not breed in streams, such as ground-dwelling *Eleutherodactylus* in South and Central America, might possess greater resistance to infection simply by virture of having a wider array of antimicrobial compounds in the skin. Because the peptides have not necessarily evolved as defenses against specific infectious agents, some terrestrial or pond-breeding amphibians might, by chance, also be susceptible to the disease. Similarly, some stream-breeding frogs might, by chance, be more resistant to the fungus than are others. What is needed to fully understand amphibian defenses against chytrid infection is a comprehensive survey of antimicrobial defenses that combines a rigorous phylogenetic perspective with a realistic ecological context.

The discovery and identification of the organism responsible for chitridiomycosis in amphibians generated a lot of excitement among biologists looking for causes of amphibian declines, and in the popular press. While there is strong evidence associating the presence of chytrid infections in both time and space with certain dramatic amphibian population declines, this disease does not necessarily represent the smoking gun that explains all or even most population declines (McCallum 2005). Nevertheless, it is critical to understand more about this emerging disease and the factors that mediate amphibian susceptibility to it, because there is considerable potential for the disease to spread to areas where it has not yet been encountered (Ron 2005; Lips et al. 2006).

It is important to keep in mind that (1) many amphibian populations have declined in areas where chytrid infection has not been found; (2) not all amphibians infected with the chytrid fungus die or even become sick, (3) there appears to be considerable natural variation in susceptibility to the fungus among amphibian species, and (4) even in species in which chytrid infections have been reported, the disease may not be the principal cause of population declines. A good example is *Rana muscosa* in the western United States. Chytrid infections have been reported from both ranid frogs and bufonid toads in the western United States (D. E. Green and Kagarise Sherman 2001; Bradley et al. 2002; D. E. Green, Converse, and Schrader 2002; Muths, Corn, Pessier, and Green 2003), and *R. muscosa* can be infected with the disease (Rachowicz and Vredenburg 2004), which could be a major threat to now-diminished populations. Nevertheless, it seems clear that the primary cause of population declines in this species up to now has been the introduction of nonnative fish into breeding sites (Vredenburg 2004), and in some areas, pollution from airborne pesticide residues (Davidson, Shaffer, and Jennings 2001, 2002; Davidson 2004; see the following discussion).

Ranaviruses

Although chytridiomycosis has received the most attention from biologists searching for causes of amphibian population declines, it is not the only disease that can cause mass mortality in amphibians. A survey of reports of dead or dying amphibians in the United States over a six-year period showed that by far the most common cause of mass mortality was infection by ranaviruses (D. E. Green, Converse, and Schrader 2002) in members of the iridovirus family (Chinchar 2002). Molecular genetic techniques have identified a number of different strains of ranaviruses, some of which infect anurans and others that infect mostly urodeles. Different species of salamanders can be susceptible to different strains of virus (Docherty et al. 2003). In contrast to chytridiomycosis, ranaviruses have caused mortality mostly in widely distributed species such as tiger salamanders (*Ambystoma tigrinum;* Collins et al. 2004) and various common ranid frogs, but not in declining species. Nevertheless, viral epidemics are a potential threat to species with restricted ranges, such as the endangered Sonora tiger salamander (*Ambystoma tigrinum stebbensi;* Jancovich et al. 1997) or the California tiger salamander (*A. californiense*).

Viral infections are especially common at high densities, which favor transmission of the disease among individuals. Usually mortality is highest in larvae approaching metamorphosis or in metamorphosed young. The result is that a ranavirus epidemic, sometimes accompanied by a secondary bacterial epidemic, can quickly eliminate a local population, although these often eventually recover. Spread of the virus between populations is less likely because mortality of infected young animals is so high, although there is the potential for sublethally infected metamorphs to harbor the disease and subsequently carry it back to their home ponds or to other nearby ponds (Brunner et al. 2004). There also is the potential for human-assisted transport of infectious agents, or movement of infectious animals though commerce in salamander larvae used for bait (Collins et al. 2003).

Another potential mode of transmission of ranaviruses throughout the world is the widespread commerce in large ranid frogs, including *Rana catesbeiana* and *R. grylio,* for food and for aquaculture. Viral epidemics have been reported in frog farms in China and Thailand, where both North American ranids and Asian ranids (*Hoplobatrachus chinensis*) are raised for food (Chinchar 2002; Weng et al. 2002; Collins et al. 2003). Viral epidemics also may be responsible for die-offs of the most common anuran in Britain, *Rana temporaria* (Cunningham et al. 1996), with imported goldfish in garden ponds being a possible reservoir for the disease (Hyatt et al. 2000; Collins et al. 2003). Because ranaviruses can infect a variety of fish species (Chinchar 2002), stocking of lakes, ponds, and streams with infected game fish provides another potential mode of transfer to amphibian populations (Jancovich et al. 2005). Ranaviruses probably have been endemic in amphibian populations for a long time and cannot be definitively linked to any cases of amphibian population declines, but increased human-assisted transmission of the viruses has the potential to threaten amphibian populations in the future, particularly those that already have restricted ranges or have suffered population declines for other reasons. Isolated populations that have reduced genetic heterozygosity because of natural genetic bottlenecks or habitat fragmentation also may be at risk from newly arriving pathogens such as ranaviruses (Pearman and Garner 2005).

Other Amphibian Diseases

Amphibians are subject to a variety of other viral, bacterial, and fungal diseases, most of which are endemic in populations and may cause occasional die-offs, but are not thought to be responsible for widespread population declines. One of the most frequently cited diseases is "red-leg," caused by a bacterium, *Aeromonas hydrophila,* but recent research indicates that this is not a major cause of amphibian mass mortality. In many cases, mortality attributed to *Aeromonas* infections may have been misdiagnosed ranavirus infections, or bacterial infections may have been secondary to a viral infection (D. E. Green, Converse, and Schrader 2002) or chytrid infection (Muths and Nanjappa 2005). Some amphibians show little or no sign of disease even when experimentally injected with *Aeromonas* under conditions designed to suppress immune function (Carey, Maniero, and Stinn 1996; Maniero and Carey 1997).

A variety of fungi are found in the digestive tracts of amphibians, although not all of these are pathogenic (R. Nelson et al. 2002). Both eggs and larvae sometimes are attacked by fungal diseases (Czeczuga, Myszyńska, and Krzemińska 1998; Berger et al. 2001), but only *Saprolegnia* fungi have been cited as a major cause of population-wide mortality (Blaustein et al. 1994). Fungal infections of the eggs of *Bufo boreas* (see fig. 15.25 in chapter 15) have been cited as one possible cause of the decline of this species in western North America, but chytridiomycosis also has been found in some populations of this species (Muths and Nanjappa 2005). Susceptibility to fungal infection appears to be related to a number of factors, including water depth, temperature, incident UV-B radiation, a tendency to clump eggs in communal masses, and innate differences in susceptibility of different species to the fungus (Kiesecker and Blaustein 1995, 1997a; Kiesecker, Blaustein, and Miller 2001; J. Robinson, Griffiths, and Jeffries 2003). There is no indication that this fungus is a cause of widespread amphibian population declines.

Parasites and Amphibian Deformities

At about the same time that public attention first turned to the problem of declining amphibian populations, there also were increasing reports of amphibians turning up with serious deformities, including both missing and extra limbs. There has been a tendency, especially in the popular literature (Souder 2000), to conflate these two issues, but there is little evidence that physical deformities are a widespread cause of amphibian population declines (Carey et al. 2003; P. Johnson and Lunde 2005). Instead, these deformities, usually malformed limbs in metamorphosing frogs, tend to be a local phenomenon that can cause high mortality in particularly ponds (Hoppe 2005), but does not necessarily threaten populations at larger spatial scales. Mortality can be a direct effect of parasite infection, or limb deformites can impact frog locomotion, which in turn affect their foraging behavior or their vulnerability to predators, including wading birds that are the definitive hosts for the trematodes. Although not a direct cause of amphibian population declines, the phenomenon of malformed frogs is of concern to amphibian conservation biologists, because an increased incidence of limb malformations could impact species that already are threatened for other reasons (P. Johnson and Lunde 2005).

When malformed frogs started to appear in large numbers, especially in the midwestern United States, a host of possible causes were proposed, including chemical pollution, increased ultraviolet radiation, and predation (Ouellet 2000; Sessions 2003). Most recent work has focused on the role of trematode parasites in causing limb malformations, although this is not necessarily the only cause of deformities (Bridges et al. 2004). In particular, the trematode *Ribeiroia ondatrae* has been shown to cause limb malformations in a number of anuran species (P. Johnson et al. 1999, 2002, 2003, 2004; P. Johnson, Lunde, Haight et al. 2001; P. Johnson, Lunde, Ritchie et al. 2001; Schotthoefer et al. 2003; Sessions 2003; P. Johnson and Lunde 2005; Sutherland 2005). Although these parasites are a natural part of the ecosystems in which frogs live, there are connections between human-induced habitat changes and the frequency of parasite infection. Limb malformations caused by *Ribeiroia* tend to be most common in eutrophic farm ponds, where increased nutrient input tends to favor snails in the genus *Planorbella,* the first intermediate host of the trematode (Lannoo et al. 2003; P. Johnson and Chase 2004; P. Johnson and Lunde 2005). In addition, widespread, but mostly accidental, transport and introduction of nonnative snails into new habitats has the potential to increase the incidence of trematode infection if the invasive snail species are suitable intermediate hosts. The parasites also can be spread to new habitats by birds that serve as definitive hosts, such as the great blue heron (*Ardea herodias*), which does well in human-altered habitats and is expanding its range in North America (P. Johnson and Lunde 2005).

Chemical Pollution

Chemical pollution, especially of freshwater habitats, has long been recognized as a potential threat to amphibian populations (Sparling, Linder, and Bishop 2000; Burkhart et al. 2003; Bridges and Semlitsch 2005b). The difficulty in addressing this issue is the enormous number and variety of chemical substances released into the environment by human activities. Heavy metals (Lefcourt et al. 1998), industrial waste products such as PCBs (Fontenot et al. 2000; de Solla et al. 2002), coal ash (Raimondo, Rowe, and Congdon 1998; Rowe et al. 1998; Hopkins, Congdon, and Ray 2000), road salt (Turtle 2000; Kaushal et al. 2005), oil (Mahaney 1994; Lefcourt et al. 1997; Pollet and Bendall-Young 2000), wastewater effluent from factories and sewage treatment plants (Yesilada, Ozmen, and Yesilada 1999; Laposata and Dunson 2000), chemicals leaching from landfills (Bruner et al. 2002), pesticides (see the followng), and fertilizers (see the following) are just some of the many chemical pollutants that have potential negative effects on amphibian populations. It is not possible to individually test the effects of each chemical pollutant on amphibians, and multiple chemical stressors, or chemicals acting in concert with other stressors, often act synergistically to have a greater impact than a single chemical alone (Burkhart et al. 2003). Standard laboratory toxicity assays often provide incomplete or misleading information on the ecological effects of chemical pollutants, because interactions with other environmental factors can either increase or decrease the toxic effects of chemicals on amphibians (Boone and Bridges 2003b, c; Bridges and Semlitsch 2005a, b).

In many cases, amphibians will simply disappear from highly polluted habitats as they avoid using such habitats for breeding or die from exposure to toxic chemicals. In other cases, adults may continue to migrate to polluted habitats to breed, but recruitment of metamorphosing young is so low that these sites constitute population sinks that fail to contribute to the growth of the regional population (Rowe and Hopkins 2003). Low recruitment may result from direct mortality of large numbers of eggs, larvae, or metamorphs, or from sublethal effects of pollutants that increase physiological costs and decrease performance of larvae and metamorphs. There also may be direct effects on adults visiting these sites during the breeding season that further reduce reproductive performance or survival. On a landscape scale, widely dispersed sources of pollution can have a major impact on amphibian populations, whereas the impact of more localized sources probabably is minimal.

Chemical pollution is a symptom of a general degradation of ecosystems by human actitivies. Although high concentrations of chemical pollutants often have localized sources, the problem of chemical pollution is a global one, with many kinds of chemical residues having been found in remote, seemingly pristine areas (Collins and Storfer 2003). Many ecosystems are remarkably resilient and eventually can recover from acute insults, such as dioxin spills, with a variety of animals, including amphibians, eventually recolonizing the area (Garagna et al. 2001). Chronic pollution presents a more difficult problem, both for human health and for ecosystem health. Possible solutions for reducing the effects of pollution on amphibian populations are almost as varied as the number and sources of pollutants themselves, and all come at some economic cost. In some cases, reduced use or elimination of certain chemicals from the environment may be the only solution. In other cases, the effects of pollution may be ameliorated by reducing the number of pollution sources, restricting the dispersal of pollutants, adjusting the timing of chemical use to reduce impacts on amphibians, or preventing amphibians from using polluted sites for breeding. Rather than catalog all possible effects of chemical pollutants on amphibians, I will focus on a few well-studied cases of chemicals that have direct toxic effects on amphibians, those that have sublethal effects on physiology and performance, and those that have indirect effects through interaction with other environmental stressors, both physical and biological (see Sparling, Linder, and Bishop 2000, for a comprehensive review of amphibian ecotoxicology, and Linder, Krest, and Sparling 2003, for a review of multiple stressor effects).

Pesticides and Amphibian Declines

The toxic effects of pesticides have long been considered a potential cause of amphibian population declines (Boone and Bridges 2003b). Many studies have shown a negative correlation between the amount of agicultural land use and the diversity and abundance of amphibians (see discussion earlier in this chapter), but showing that agricultural pesticides are responsible for these declines has been surprisingly difficult, for a number of reasons. First, agricultural land use itself may produce a habitat structure that is unsuitable for amphibians, independent of chemical applications. Second, there is considerable variation among species of amphibians in sensitivity to pesticides (Bridges and Semlitsch 2000, 2005a), and genetic variation for pesticide resistance among individuals indicates the potential for amphibians to evolve increased resistance to these chemicals (Bridges and Semlitsch 2001; Boone and Bridges 2003b). Third, different pesticides have different effects on amphibians in both aquatic larvae and in terrestrial individuals, and multiple pesticides acting together may have a greater effect than a single pesticide (Relyea 2004a; Bridges and Semlitsch 2005b). Finally, concentrations of pesticides that are lethal to amphibians often are much higher than typical concentrations found in natural habitats or in the tissues of animals from the wild (Fagotti et al. 2005). Standard toxicological tests sometimes show relatively low sensitivity to some pesticides (e.g., Pauli, Coulson, and Berrill 1999; Battaglin and Fairchild 2002), whereas tests of other pesticides have shown strong lethal effects on amphibians (Berrill et al. 1994, 1998). Nevertheless, many pesticides can have sublethal negative effects on amphibians that ultimately affect individual fitness (Boone and Bridges 2003b).

Some of the best evidence for the effect of pesticides on amphibian populations comes not from populations located in agricultural areas, which often are unsuitable for amphibians, but from parks and other seemingly pristine areas that are near agricultural land heavily impacted by pesticides. There is strong circumstantial evidence, for example, that wind-blown pesticides originating in the heavily agricultural Central Valley of California have contributed to the decline of several species of amphibians in the southern Sierra Nevada, especially on the western slopes of the mountains. Severe population declines have been found in several protected areas, including Yosemite National Park (Fellers and Drost 1993; Drost and Fellers 1996). Pesticides are readily transported to higher elevations from the Central Valley by prevailing westerly winds (fig. 16.20 A, B), and pesticide residues have been found in amphibians at considerable distances from major sources of pesticides (Sparling, Fellers, and McConnell 2001; Sparling and Cowman 2003). Furthermore, the geographic pattern of population declines in several species of ranid frogs is strongly correlated with the amount of upwind agricultural land (fig. 16.20 C, D; Davidson, Shaffer, and Jennings 2002) and the amount of pesticides applied to that land (Davidson 2004).

Perhaps the most severely impacted has been the California red-legged frog (*Rana draytonii;* see Shaffer et al. 2004, for recent changes in the taxonomic status of this frog). Originally one of the most common amphibians in California, *R. draytonii* was found in the Central Valley and the Sierra Nevada, as well as many locations along the coast east of the Central Valley, from northern California to Baja California in Mexico. The species is now extinct in the Central Valley and nearly extinct in the Sierra Nevada and southern California, but still occurs in the coastal mountains (Shaffer et al. 2004; Fellers 2005). As with several other ranid frogs, the pattern of decline and extinction in this species is most consistent with the hypothesis that wind-blown pesticides have wiped out populations downwind from the Central Valley (Davidson, Shaffer, and Jennings 2001, 2002; Davidson 2004). Consequently, the prospects for recovery of this endangered species seem slim without major changes in agricultural practices in California.

Atrazine and Endocrine Disruption

Although one can expect that pesticides designed to kill a variety of plants and animals will have lethal effects on at least some amphibians, sublethal effects of these chemicals also can have dramatic effects on the physiology, behavior, morphology, and ecology of amphibians. One of the best-studied examples is the effect of atrazine on sexual development in anurans. Atrazine is the most widely used herbicide in the world, and is a major contaminant of both surface and groundwater supplies. Atrazine has a variety of negative physiological effects on amphibians, including inhibiting growth and development of larvae, producing morphological deformities, and influencing the behavior and physiology of metamorphosed individuals (Diana et al. 2000; Allran and Karasov 2001; Rohr and Palmer 2005). More disturbing is the fact that at very low, but ecologically realistic doses, atrazine affects gonadal development by producing intersex individuals with both male and female gonadal tissue. In addition, males of some species exhibit reduced larynx size and show other signs of feminization (Reeder et al. 1998; T. Hayes, Collins et al. 2002; T. Hayes, Haston et al. 2002, 2003; Carr et al. 2003).

Although these studies have generated a lot of controversy, primarily from the manufacturers of atrazine, there is no doubt that this widely used chemical can have serious negative effects on amphibian development, even at very low concentrations (T. Hayes 2004). The precise exposure of amphibians to atrazine in the environment depends on a number of factors, including the timing of chemical use and the concentrations used, geology of soils in agricultural fields, the rate of runoff from fields, and the nature of the ponds used for reproduction. These in turn will interact with a variety of biological factors to determine the effects on individuals and populations (fig. 16.21). A direct link between the developmental effects of atrazine and declines of particular populations of amphibians has yet to be established. There is circumstantial evidence that atrazine, or other endocrine disruptors, such as PCBs, could have contributed to the decline of cricket frogs (*Acris crepitans*) in the upper Midwest (Reeder et al. 1998, 2005). Atrazine is only one of several thousand agricultural chemicals that are regularly used in the United States and elsewhere. The effects of most of these chemicals on amphibians are unknown, but the documented effects of atrazine are symptomatic of a broader range of problems caused by many different endocrine-disrupting chemicals in the environment that affect not only amphibians, but many other vertebrates as well (T. Hayes 2000, 2005; Kloas 2002; Mosconi et al. 2002).

Other Sublethal Effects of Pesticides

Although some pesticides are not directly lethal to amphibians at ecologically realistic doses, these chemicals can have many other effects on amphibians in addition to altering sexual development. Some studies have found that exposure to carbaryl, a widely used insecticide, actually increases rates of growth and size at metamorphosis in some tadpoles, while reducing survival to metamorphosis in others. This occurs when carbaryl kills most zooplankton in ponds, thereby

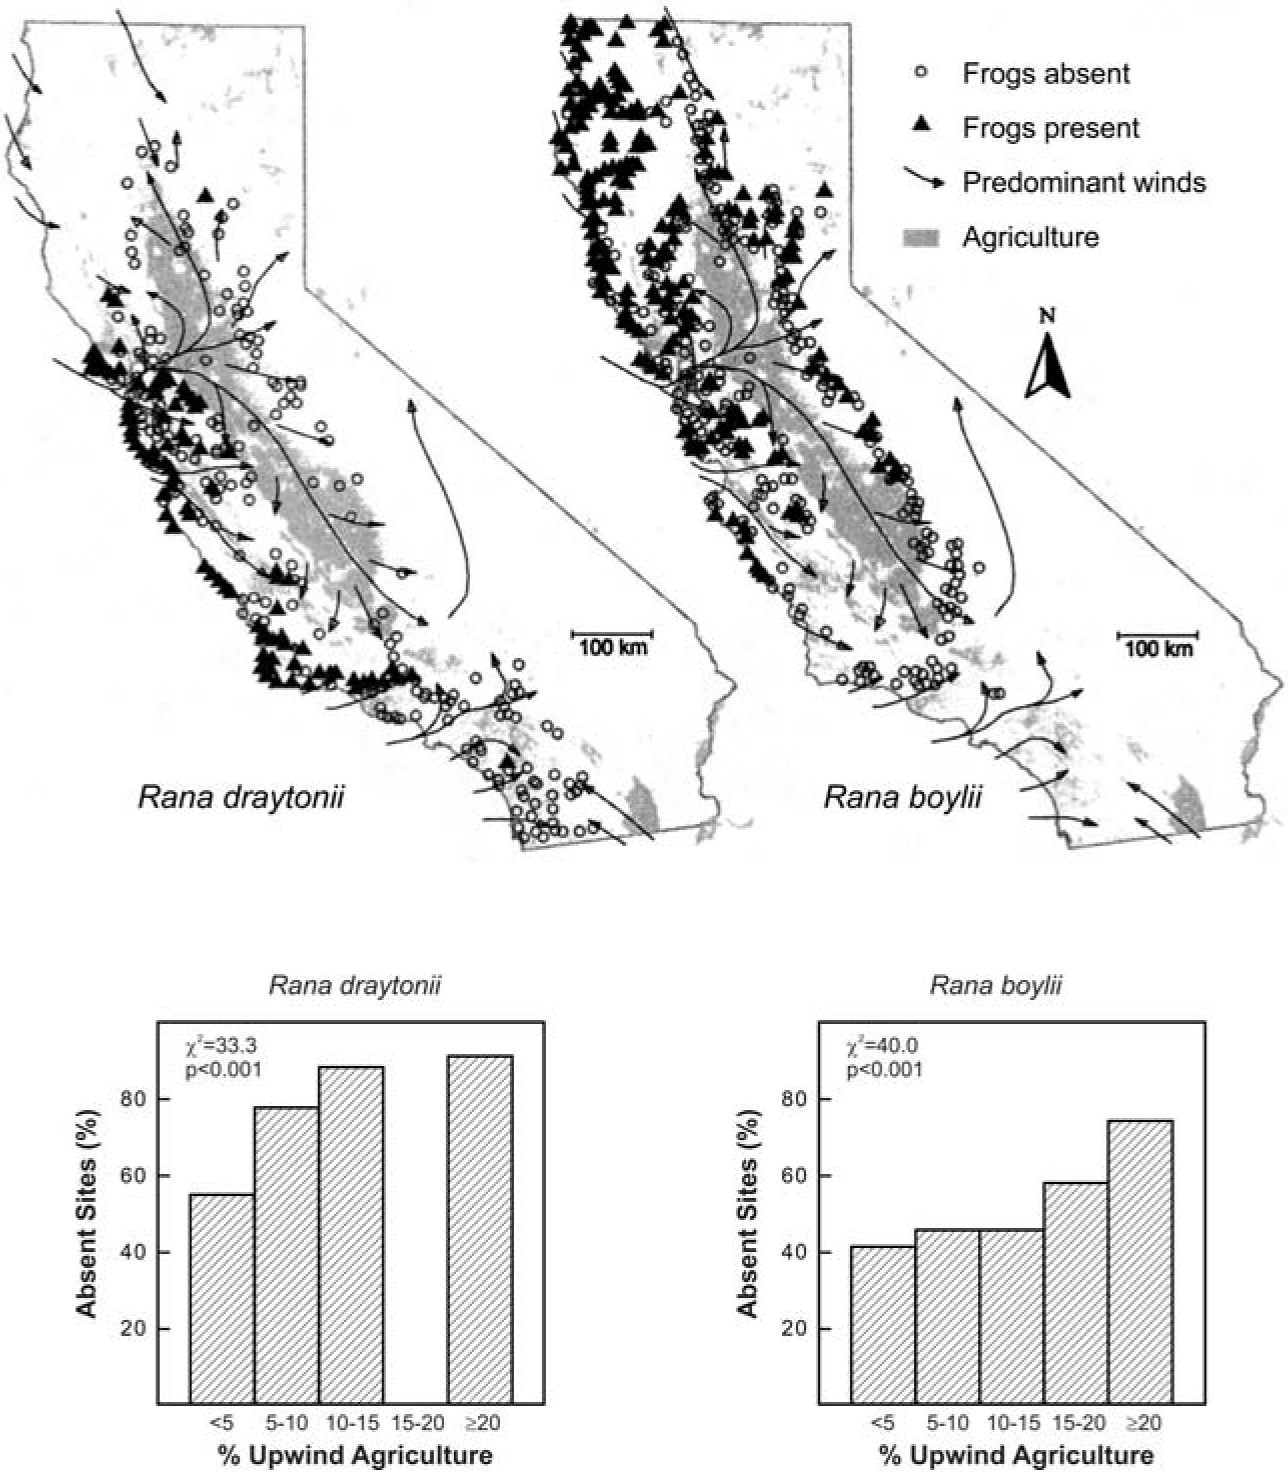

Fig. 16.20. Relationship of wind direction and proximity to the heavily agricultural Central Valley of California to the declines of two species of frogs in California. Map on left shows the distribution of historic sites where the California red-legged frog (*Rana draytonii*) is now absent (open circles) and still present (closed triangles). Map on the right shows the distribution of sites for the foothill yellow-legged frog (*Rana boylii*). Graphs show the percentage of sites lacking *R. draytonii* (left) or *R. boylii* (right) in relation to percentage of upwind agriculture. After Davidson et al. (2002).

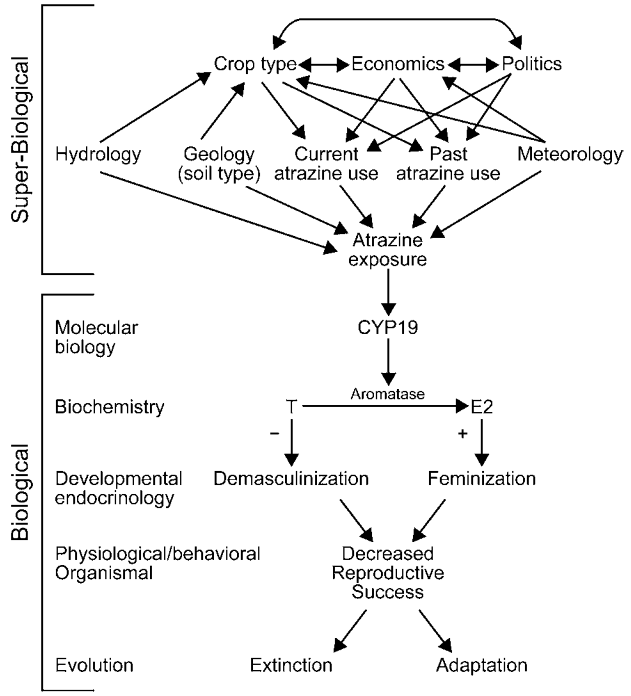

Fig. 16.21. Interactions between ecological factors, application of atrazine to agricultural fields, and biological factors that can affect the developmental endocrinology and reproductive success of male amphibians, with potential effects on amphibian populations. After T. Hayes (2005).

increasing the standing crop of algae and providing more food for anuran tadpoles. The effects were most pronounced at higher densities, because tadpoles are most likely to be food-limited at high density (Boone and Semlitsch 2001; Boone et al. 2001; Boone et al. 2004). Although laboratory studies have shown that exposure to UV-B raditation can increase the toxicity of carbaryl to amphibians (Zaga et al. 1998), tadpoles in artificial ponds exposed to both UV-B radiation and carbaryl actually showed increased growth. Again, carbaryl increased the standing crop of algae in ponds, not only providing more food for the tadpoles, but also probably shielding tadpoles from UV-B radiation because of decreased water clarity (Bridges and Boone 2003). Multiple exposure to carbaryl can actually stimulate metamorphosis in green frog (*Rana clamitans*) tadpoles (Boone and Bridges 2003a).

Unfortunately for amphibians, pesticides such as carbaryl are seldom used alone, but often are applied in combination with other agricultural chemicals that can act synergistically to increase mortality of amphibians. For example, Boone and James (2003) examined the effects of exposure to carbaryl (an insecticide), atrazine (a herbicide), and changing water levels on two species of anuran tadpoles and two species of salamander larvae. Carbaryl killed most salamanders in all treatments, and increased mortality of toad (*Bufo americanus*) tadpoles as well. Tadpoles of *Rana sphenocephala* exposed to carbaryl alone increased in size because of an increase in food, but exposure to atrazine decreased body size and development rate because this chemical reduced algal biomass. On the other hand, larvae of spotted salamanders (*Ambystoma maculatum*) did better when exposed to both atrazine and carbaryl than to carbaryl alone. These effects interacted in complex ways with pond hydroperiod and larval density, and also are affected by genetic differences within and among species in sensitivity to the chemicals (Bridges and Semlitsch 2000). Other studies have shown that exposure to multiple pesticides has a greater effect on tadpole mortality than does exposure to single pestcides (Relyea 2004a, 2005b). Synergistic effects of chemicals sometimes can have unexpected results. For example, both carbaryl and ammonium nitrate fertilizer tend to increase algal biomass in ponds, but tadpoles exposed to both of these chemicals together did not show the positive effects on growth and development seen in tadpoles exposed to only one chemical. This suggests that metabolic costs associated with multiple chemical exposure reduce the ability of tadpoles to exploit enhanced food resources (Boone et al. 2005).

Carbaryl also can alter interactions between predators and tadpoles. In one set of experiments, even relatively low doses of carbaryl killed crayfish, which were predators on bullfrog (*Rana catesbeiana*) tadpoles, and higher doses killed predatory sunfish. Consequently, bullfrog tadpoles were released from predation at low carbaryl concentrations, thereby increasing survivorship. As in the other experiments, carbaryl also increased algal biomass, so tadpoles actually were larger with low doses of carbaryl. At higher carbaryl concentrations, however, mortality of tadpoles increased (Boone and Semlitsch 2003). Low doses of carbaryl can inhibit antipredator behavior, such as seeking cover, but also reduce tadpole activity, which makes them less vulnerable to predators (Bridges 1999). Conversely, exposure to predators can affect the toxicity of pesticides to amphibians, presumably because predators increase levels of stress. For example, tadpoles of gray treefrogs (*Hyla versicolor*) suffered higher mortality from exposure to carbaryl in the presence of caged predatory *Ambystoma maculatum* larvae than in the absence of predator cues (Relyea and Mills 2001). Similar increases in mortality from pesticide exposure in the presence of predator cues have been found in several other species (Relyea 2003b, 2004b, 2005c).

Another major concern among amphibian conservation biologists is that pesticides and other chemical pollutants can act as general environmental stressors that may impare immune function in amphibians, thereby making them more susceptible to infection by viruses, bacteria, fungi, or parasites. This indirect effect of chemical exposure has been suggested as one possible reason for the emergence of new diseases that contribute to amphibian population declines (Carey and Bryant 1995). Indeed, a number of studies have shown that exposure to single chemicals, such as malathion or atrazine, or to combinations of chemicals, does diminish immune function in a variety of amphibians (S. K. Taylor, Williams, and Mills 1999; Christin et al. 2003, 2004). Whether this has actually contributed to amphibian population declines has yet to be determined.

Nitrogen Pollution

The discharge of excess nitrogen into aquatic ecosystems represents one of the major environmental issues of our time, but often receives less attention than the effects of more obviously toxic chemical pollutants. The main sources of excess nitrogen are the heavy application of nitrogenous fertilizers on agricultural lands, managed forests, and lawns (these fertilizers also contain large amounts of phosphorus); runoff from livestock feedlots and slaughterhouses; and the discharge of treated sewage effluent into waterways. Sewage effluent discharged into rivers probably has a minimal impact on amphibians, most of which do not breed in rivers. Nevertheless, wastewater effluent sometimes is used to irrigate agricultural fields, a practice that could contaminate temporary ponds used by amphibians (Laposata and Dunson 2000). Excess nitrogen also can be deposited in both terrestrial and aquatic habitats in the form of airborne residues from the burning of fossil fuels and other human activities (Rouse, Bishop, and Struger 1999). Deposition of atmospheric nitrogen can have negative consequences for ecosystems far from the original source, including relatively remote areas that are considered hotspots of biodiversity (Phoenix et al. 2006).

At low concentrations, nitrogenous fertilizers can enhance tadpole growth and development, particularly at high tadpole densities, by increasing food availability (De Wijer et al. 2003; Boone et al. 2005). Excess nitrogen has a number of negative effects as well, including depeletion of oxygen in eutrophic ponds, inhibition of feeding in tadpoles, and induction of various physical and behavioral abnormalities (Hecnar 1995; Xu and Oldham 1997; Rouse, Bishop, and Struger 1999). At high concentrations, excess nitrogen in the form of nitrates or ammonia can be directly toxic to amphibians (Hecnar 1995; Oldham et al. 1997; P. Watt and Jarvis 1997; Marco, Quilchano, and Blaustein 1999; Marco et al. 2001; Hamer et al. 2004). As with pesticides, sensitivity to nitrogen pollution varies among species of amphibians, and the effects of nitrogen are mediated by interactions with other environmental factors, such as UV-B radiation (Hatch and Blaustein 2003). Diversity and abundance of amphibians often is reduced in agricultural areas where heavy application of fertilizer occurs (Berger 1989; C. Bishop et al. 1999; Oldham 1999; de Solla, Pettit, Bishop, Cheng, and Elliot 2002), and the decline of at least one species of Australian frog, *Litoria aurea,* has been attributed at least in part to heavy use of agricultural fertilizers (Hamer et al. 2004). Nevertheless, the global impact of nitrogen pollution on amphibian population declines has yet to be thoroughly investigated.

Acid Rain

In addition to direct toxic effects of chemical pollutants, both aquatic and terrestrial habitats can be affected by the increasing acidity of precipitation, which itself is largely a byproduct of air pollution, mostly from coal-burning power plants. Habitat acidity is measured in two ways. First, pH is a measure of instantaneous acidity, with pH values <5.0 being considered acidic. This can vary seasonally with snowmelt or rainfall. Second, habitats differ in acid-neutralizing capacity (ANC), a measure of how well habitats are buffered against changes in acidity. Low pH and low ANC can have a variety of negative effects on amphibians, including inhibiting development and hatching of embryos, retarding growth of larvae, and disrupting the osmoregulation and ion balance of both larvae and terrestrial adults (see chapter 2). These negative effects have been extensively documented in laboratory studies (Beattie and Tyler-Jones 1992; Bradford, Swanson, and Gordon 1992; Dunson, Wyman, and Corbett 1992; Frisbie and Wyman 1992; Rowe and Freda 2000). Acidic habitats also can contain high levels of dissolved metals, such as aluminum, which also negatively impact amphibians (Rowe and Freda 2000).

There is significant variation both within and among species of amphibians in acid tolerance, with those from naturally acidic habitats generally being the most acid tolerant (Pierce 1985; Karns 1992; Pierce and Wooton 1992; Sadinski and Dunson 1992; Räsänen, Laurila, and Merilä 2003a, b). These differences are largely due to maternal effects, but whether they are entirely genetic is not clear. Natural variation in acid tolerance affects the choice of habitats by different species. Acid-tolerant species such as carpenter frogs (*Rana virgatipes*), wood frogs (*Rana sylvatica*), pine-barrens treefrogs (*Hyla andersonii*), and spotted salamanders (*Ambystoma maculatum*), can breed in more acidic water and show less behavioral avoidance of acidic conditions than do less tolerant species such as leopard frogs (*Rana pipiens*) and Jefferson salamanders (*Ambystoma jeffersonianum*). In areas where pond acidity varies on a relatively small spatial scale, amphibians generally avoid the most acidic habitats. In Minnesota peatlands, for example, most amphibian species breed successfully in fens with a pH > 5.0, but not in acidic bogs (pH < 4.5; Karns 1992).

When concern over declining amphibian populations began to grow in the 1980s, acid rain was one of many possible culprits considered by biologists seeking causes for the declines. Of particular concern were montane habitats, where the impact of acid rain can be the most severe, and where negative effects of acidity on fish and invertebrate populations had been well documented. A number of studies in the western United States have documented periodic fluctuations in the acidity of aquatic habitats, largely due to snowmelt. There is little evidence, however, that most aquatic habitats are sufficiently acidic to have caused the decline of amphibian populations (Bradford, Swanson, and Gordon 1992; Corn and Vertucci 1992; Wissinger and Whiteman, 1992; Vertucci and Corn 1996; Muths, Campbell, and Corn 2003). Shenandoah National Park, Virginia, has been heavily impacted by air pollution and increasing stream acidity resulting from forest defoliation by gypsy moth caterpillars. Nevertheless, variation in stream pH and ANC appears to have little effect on the distribution and abundance of plethodontid salamanders (Campbell Grant, Jung, and Rice 2005). All of these studies indicate that acid precipitation is not a significant cause of amphibian population declines, although it could be a threat to some amphibian populations on a local scale (Rowe and Freda 2000).

Global Changes and Amphibian Population Declines

Most of the potential causes of amphibian declines discussed so far have both local origins and local effects, although in some cases, such as the spread of pesticide residues, effects can be more widespread. Other types of environmental changes take place on a global scale and therefore are much more difficult to combat. Two types of global change that often are conflated in public discourse on the environment are thinning of the ozone layer that protects the earth from ultraviolet radiation, and global warming. The former is caused by the release of certain ozone-destroying industrial chemicals into the atmosphere. The problem is most acute at high latitudes, because so-called "ozone holes" that develop mostly in the summer are centered over the poles. Nevertheless, measurable changes in ultraviolet radiation, and in particular, harmful UV-B radiation, have been detected in equatorial regions as well (Middleton et al. 2001). Global warming is associated with the buildup of greenhouse gases, such as methane and carbon dioxide, in the atmosphere, primarily from the burning of fossil fuels. These gases increase the amount of solar radiation that is retained at the earth's surface, thereby increasing global temperatures. Either of these environmental changes has the potential to affect amphibian populations, although the current impact of both factors remains poorly understood.

Ultraviolet Radiation

Ultraviolet radiation, and UV-B radiation (wavelengths of 280–320 nm) in particular, is a natural part of the environment of most terrestrial plants and animals and aquatic organisms that live in shallow water exposed to intense sunlight. UV-B radiation in high doses damages DNA and can have a variety of effects on amphibians at all life-history stages, including killing embryos, disrupting embryonic growth and development, producing morphological abnormalities in larvae, making larvae more susceptible to chemical pollutants or disease, and causing cell and retinal damage and altering behavior in terrestrial juveniles and adults (Blaustein et al. 1994, 1997, 1998, 2000; 2003; Kiesecker and Blaustein 1995; L. Long, Saylor, and Soulé 1995; Licht and Grant 1997; Fite et al. 1998; Cummins, Gleenslade, and McLeod 1999; Ankley et al. 2000; Lesser et al. 2001; Formicki, Zamachowski, and Stawarz 2003; Hatch and Blaustein 2003; Pahkala, Laurila, Björn, and Merilä 2003; Pahkala, Merilä, Ots, and Laurila (2003); Blaustein, Romansic, and Scheessele 2005).

Because of these negative effects of UV-B radiation, amphibians have experienced strong selection for various mechanisms to protect themselves from its harmful effects. Larval and adult amphibians generally are well protected against UV-B radiation by melanin in the skin, and amphibians that are most likely to be exposed to high levels of UV-B radiation are the best protected. For example, the black coloration of many tadpoles that habitually live in very shallow, sunny water, often has been interpreted either as a thermoregulatory adaptation (chapter 3) or aposematic coloration (chapter 14), but is just as likely to be an adaptation to avoid harmful UV-B radiation. Similarly, the prevalence of very dark or black coloration in adults of various amphibians at high altitudes generally has been considered an adaptation to enhance thermoregulatory basking (chapter 3), but is more likely an adaptation to avoid the high levels of UV-B radiation present at high altitudes.
