

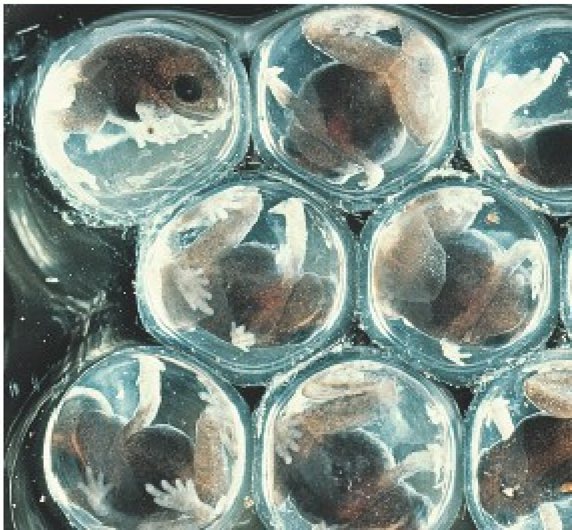
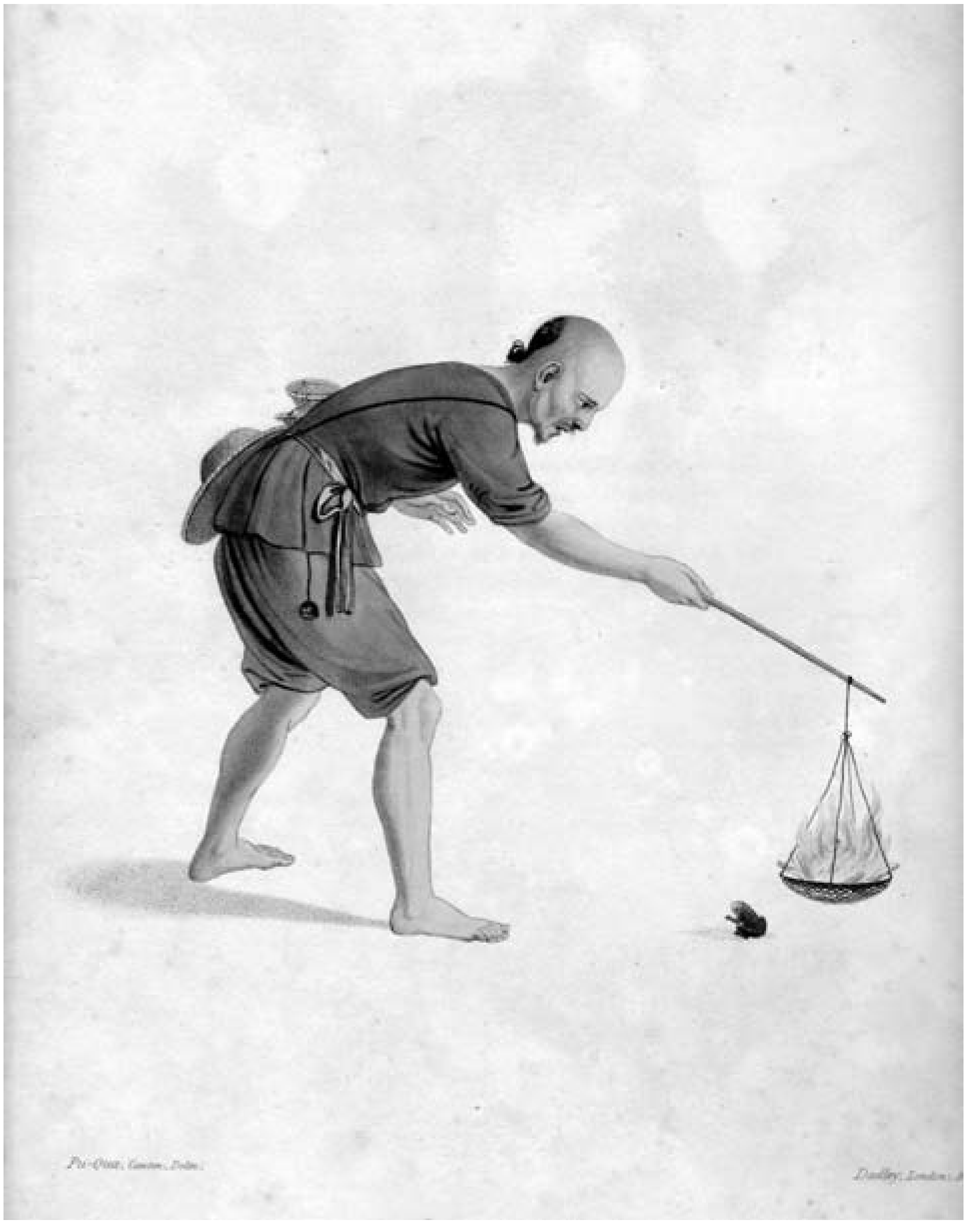
The Ecology and Behavior of Amphibians

Kentwood D. Wells



The Ecology & Behavior of Amphibians



A FROG-CATCHER

The lower sort of people in China are not delicate in their eating; they do not scruple to feed heartily upon animals which die a natural death, as is noticed by several voyagers. The poor eat frogs and rats, dried hams of which latter are exposed to sale in the streets; and the middling sort think a young dog no bad food . . . . They have a method of taking frogs in China, during the night, by means of fire, which is carried in a wire net, as reproduced in this plate.
—George Henry Mason, *The Costume of China* (London: W. Miller, 1800).

Traditional frog catchers in China probably had detailed knowledge of the natural history of the animals they sought as food. Here the image of the frog-catcher represents the many biologists who have ventured into the field, often at night, to study the ecology and behavior of amphibians. This print is dated May 4, 1799, from a drawing by a Chinese artist, Pu-Qua, of Canton. From the author's collection.

Contents

Preface

The train from Balboa Station moved slowly at first, making its way past the warehouses, military bases, and red-tiled roofs of Canal Zone houses, past the locks of Miraflores and Pedro Miguel, and alongside the Gaillard Cut. There it picked up speed, traveling parallel to the Panama Canal and eventually reaching stretches of tropical rainforest, dotted with small farms and banana fields. As I gazed out the window at the ponds and lakes that lay alongside the tracks, I thought about all the frogs that must be out there, feeding, calling, defending territories, laying eggs, avoiding snakes, and otherwise going about their lives. I couldn't see them, of course, nor could I hear them at night over the din and clatter of the train, but I knew they were there. On some nights, arriving on the 11:00 o'clock train at Frijoles Station on the way to Barro Colorado Island, I could hear the last few squeaks and clicks of the small treefrogs along the shore, or the last plaintive whines of túngara frogs finishing up a night of calling.

I had come to Panama in 1976 as a postdoctoral fellow of the Smithsonian Tropical Research Institute. Fresh out of graduate school, I had little experience in the tropics, but I knew of the great diversity of frogs to be found there, sometimes with more species breeding at a single pond than can be found in the entire northeastern United States. I am not sure when I first thought of writing a book on the ecology and behavior of amphibians, but certainly ideas began to germinate as I took those long train rides along the Panama Canal and my many boat rides across Gatun Lake to the jungle island of Barro Colorado.

I actually began writing this book in the early 1980s, so to say it has had a long gestation period would be a gross understatement. Indeed, at times the project seemed to take on a life of its own, like one of those never-ending scholarly endeavors usually associated with the humanities, such as editing the correspondence of Charles Darwin or writing the definitive multivolume biography of Herman Melville. Much has changed in the intervening years, both in my life and in the study of amphibian ecology and behavior. I began the book as a young assistant professor and now find myself one of the most senior members of my department. I got married, raised two young daughters, bought and remodeled a house, taught classes, supervised graduate students, conducted field research, and served on more departmental and university committees than I can remember.

At every opportunity, I continued working on the book, sometimes for months at a time, sometimes in fits and starts as time allowed. I spent many fulfilling hours in libraries, not only at the University of Connecticut, but also at the Smithsonian Tropical Research Institute during summer trips for field research. Over the years, much of the technology associated with book writing has changed. The initial version of the first chapter I wrote was composed on a portable electric typewriter, and from there I graduated to an IBM Selectric, a mainframe computer terminal, and a succession of desktop computers. Frequent trips to the library to fill notebooks with handwritten notes have largely been replaced by access to electronic journals and the printing of thousands of pages of recent journal articles. Figures drawn by hand with a lettering set have given way to computerized graphics, while the tedious developing of black and white photographs in the darkroom has been replaced by digitally scanned images.

What also has changed over the years is the amount of information available on the ecology and behavior of amphibians, which has increased at an exponential rate, as has the number of researchers studying amphibians. When I began this book, the most recent scholarly treatment of amphibian biology was G. K. Noble's *Biology of the Amphibia,* published in 1931 and reprinted by Dover Publications in the 1950s. Since then, we have seen the publication of Duellman and Trueb's *Biology of Amphibians* (1986); the multivolume Australian series *Amphibian Biology,* edited by Harold Heatwole (and others), which began in 1994; and volumes dealing with the environmental physiology of amphibians (Feder and Burggren 1992), amphibian hearing and acoustic communication (Fritzsch et al. 1988; Ryan 2001; Gerhardt and Huber 2002; Narins and Feng 2006), reproductive biology (Jamieson 2003; Sever 2003a), tadpole biology (McDiarmid and Altig 1999a), salamander ecology (Hairston 1987; Bruce, Jaeger, and Houck 2000), amphibian distribution (Duellman 1999c), and amphibian conservation (Beebee 1996; Semlitsch 2003a; Lannoo 2005). There also have been many other books and monographs dealing with specialized aspects of amphibian biology, or geographic treatments such as Petranka's *Salamanders of the United States and Canada* (1998) and Savage's *The Amphibians and Reptiles of Costa Rica* (2002). Meanwhile, the explosion of journal literature dealing with amphibian ecology and behavior over the last 25 years often left me feeling like Lewis Carroll's Red Queen, always running faster and faster just to keep up. At some point, the search for that last key paper must come to an end. For this book, that point essentially was reached in the fall of 2005, although a few papers from 2006 did find their way into the references. The impossibility of being completely up-to-date is illustrated by the appearance of a 370-page monograph on the phylogeny and classification of amphibians (Frost et al. 2006) just as I was making final preparations to send this book to the publisher (see chapter 1).

Of course, the amphibians themselves have changed as well. Several species have gone extinct since I began writing this book, and many more are in decline or threatened by assaults on their environment. Consequently, many researchers have shifted their focus from investigating the basic biology of amphibians to research programs aimed at understanding the decline of many amphibian populations and identifying ways to prevent it. Yet a clear understanding of the basic physiology, ecology, and behavior of amphibians remains central to any successful conservation effort, and my hope is that this book will contribute to this body of knowledge.

Although I wrote this book myself, it would not have been possible without the encouragement and assistance of many family members, friends, and colleagues. In acknowledging these people, it seems appropriate to start at the beginning. I owe a tremendous debt to my parents, W. Willeroy Wells and Leora Wood Wells, who unfortunately did not live to see this book completed. My father, having been a Rhodes scholar with a keen interest in history, instilled in me a love of research on all sorts of subjects. My mother, a voracious reader, a writer, and an accomplished editor, conveyed to me her love of books and her sense that writing is the essence of communicating both facts and ideas. My parents never questioned my desire to become a naturalist, or to fill our basement with tanks and cages full of frogs, salamanders, and snakes, to major in zoology in college, or to pursue a PhD in the obscure field of frog behavior. They provided love and financial support, without which this book would not have been possible. I am saddened that they did not get to see the final product.

Next to my parents, perhaps the greatest influence on my development from boy naturalist to college professor has been my teachers, starting with my high school biology teacher, Richard Ailstock, who often accompanied my friends and me on expeditions to various swamps, presented me with my first copies of *Copeia,* and invited me back to his classroom for years after I was a student to show slides of frogs to the next generation of students. At Duke University, I got my first taste of real field research in an ecology class taught by Dan Livingstone, and encouraged by him and the late Joe Bailey, I continued my class project and eventually published two papers from the work. My development as a biologist continued in a PhD program at Cornell University, a wonderful center for research in ecology and behavior. I benefited especially from the guidance, encouragement, and criticism of my major professor, F. Harvey Pough, who taught me the importance of integrating studies of physiology, ecology, and behavior to understand the biology of organisms. Steve Emlen, an inspirational teacher and pioneer in the study of vertebrate social behavior, encouraged me in every aspect of my research with frogs by his sheer enthusiasm for all things behavioral. Kraig Adler gave me access to his incredible library as I was writing my first review of frog mating systems, which was the key to getting my career as a scientist underway. Interactions with other faculty members, graduate students, and postdocs at Cornell enriched my experience and shaped my development as a biologist. There are too many of these people to mention individually, but especially influential were Jack Bradbury, Will Provine, Carl Gerhardt, Peter Narins, John Heiser, Tom Wiewandt, Bill Mautz, Gene Helfman, Gary McCracken, and the late Jasper Loftus-Hills. My formal education was completed with the postdoctoral fellowship that took me to Panama, where I benefited from interactions with many graduate students, postdocs, and staff members at the Smithsonian Tropical Research Institute. Especially important was the influence of my postdoctoral advisor, Stan Rand, field naturalist and tropical herpetologist extraordinaire, who unfortunately also did not live to see this book completed.

During the long gestation of this book, many friends and colleagues have provided me with information, unpublished manuscripts, Master's theses, PhD dissertations, and comments on various drafts of chapters, in some cases so long ago that the final version may not be recognizable. I hope I have not forgotten to acknowledge anyone: Kraig Adler, Stevan J. Arnold, David Bickford, Andrew Blaustein, Ron Brandon, Janalee P. Caldwell, Adão Cardoso, Tun-Yu Dave Chen, Martha Crump, Sharon Emerson, Martin Feder, Robert Gatten, H. Carl Gerhardt, Harry Greene, Tim Halliday, Mark Hayes, Lynne Houck, Richard D. Howard, Victor H. Hutchison, Robert Jaeger, Michael Jennions, Murray J. Littlejohn, Horst Lüddecke, Ralph Mac Nally, Peter Morin, Peter Narins, Carlos Navas, Kiisa Nishikawa, Jim O'Reilly, Neville Passmore, John Phillips, Ken Prestwich, Michael J. Ryan, Andreas Schlüter, Joshua J. Schwartz, Ray Semlitsch, Roger Seymour, Cynthia Kagarise Sherman, Vaughan Shoemaker, Martin P. Simon, David Skelly, Margaret M. Stewart, Stephen G. Tilley, Catherine A. Toft, Daniel S. Townsend, C. Richard Tracy, Joe Travis, Paul Verrell, David Wake, Marvalee Wake, Bruce Waldman, Richard Wassersug, Earl Werner, Henry Wilbur, and Larry Woolbright. Two of my graduate students, Patrick C. Owen and Noah Gordon, did yeoman service one summer in checking all of the references in the text and reference list for the first 15 chapters, finding many errors and omissions.

Walter Hödl and Wayne Van Devender contributed many photographs to the book, and their skill as photographers has enhanced it immensely. Others who also contributed photographs or other illustrative materials include Allen Allison, Milos Andera, Carl D. Anthony, Stevan J. Arnold, David Bickford, David Bradford, Edmund D. Brodie, Jr., Edmund D. Brodie III, Janalee P. Caldwell, Alan Channing, Reginald B. Cocroft, Harold Cogger, Jon Costanzo, Martha Crump, Stephen Deban, Robert Drewes, Sharon Emerson, H. Carl Gerhardt, Mac F. Given, Ulmar Grafe, Margaret Gunzburger, Celio F. B. Haddad, James Hanken, Susan Z. Herrick, Lynne Houck, Richard D. Howard, Kristiina Hurme, Victor H. Hutchison, Carlos Jared, Rafael Joglar, Karl Heinz Jungfer, Y.-C. Kam, Stefan Kaminsky, Joseph M. Kiesecker, Krushnamegh Kunte, Julian C. Lee, William P. Leonard, Marcio Martins, Kerry Matz, Charles W. Myers, Kiisa Nishikawa, David Pfennig, Michael Plummer, Rick Relyea, Stephen J. Ressel, Carl W. Rettenmeyer, Stephen Richter, Mark Oliver Rödel, Rudolfo Ruibal, Ivan Sazima, Nancy Staub, Margaret M. Stewart, Daniel S. Townsend, James Vonesh, Karen Warkentin, and Richard J. Wassersug. Very special thanks go to Mary Jane Spring and Virge Kask, biological illustrators at the University of Connecticut, who showed great skill and unending patience in preparing the graphs and line drawings. Virge Kask scanned many slides and combined these with digital images provided by many different people to create the photographic figures.

My many colleagues in the Department of Ecology and Evolutionary Biology at the University of Connecticut have enhanced my work environment immeasurably. I am particularly grateful to Theodore L. Taigen for our years of collaboration on the calling energetics of frogs. Thanks also to the Vertebrate Lunch Group (Kurt Schwenk, Eric Schultz, Margaret Rubega, Elizabeth Jockusch, Chris Elphick, Bruce Goldman, and many students) for many semesters of stimulating discussion. My department heads, especially William Crepet and Gregory J. Anderson, showed enormous patience and encouraged my work on this book, even though it detracted from fieldwork and from my getting lucrative grants. Working on this book and on amphibians in the field would not have been nearly as much fun without my interactions with the many University of Connecticut students who have shared my enthusiasm for amphibians, especially Joshua J. Schwartz, Ellen M. Dawley, Mac F. Given, Catherine R. Bevier, Stephen J. Ressel, Patrick C. Owen, Roberto Ibañez, L. Kealoha Freidenburg, Jennifer A. O'Brien, Susan Z. Herrick, Kristiina Hurme, Philip Robakiewicz, Carlos Navas, Tobias Landberg, Noah Gordon, Laura Runkle, Katherine Bard, Beverly Greer, Joseph Markow, Dawn McKay, Sal Zimmitti, Sharyn Rusch, and Stacey Lance.

The editors and staff of the University of Chicago Press have shown infinite patience and provided much encouragement as the years of book writing rolled on, often with no end in sight. I am especially grateful to the late Susan Abrams, my original editor, who did so much to get this project off the ground, and to Christie Henry, my current ever-helpful editor. The University of Chicago Press provided financial support for the preparation of figures, as did the University of Connecticut Research Foundation, the Department of Ecology and Evolutionary Biology, and the Biological Illustration Office. The Interlibrary Loan Department of the Homer Babbidge Library at the University of Connecticut was endlessly helpful and surely is one of the most efficient operations in the entire university.

Finally, very special thanks go to my wife, Marta Lucía Martínez Wells, and my two daughters, Camila (who thinks frogs are kind of slimy) and Gabriela (who will grab any amphibian she sees), for enhancing my life in every possible way. This book is dedicated to them.

Storrs, Connecticut
April 2006

Chapter 1 Phylogeny, Classification, and Morphological Evolution

These foul and loathsome animals . . . are abhorrent because of their cold body, pale color, cartilaginous skeleton, filthy skin, fierce aspect, calculating eye, offensive smell, harsh voice, squalid habitation, and terrible venom; and so their Creator has not exerted His powers to make many of them.
—Carl von Linne (Linnaeus), *Systema Naturae* (1758)

Linneaus, the Swedish naturalist who founded the modern system for classifying animals and plants, took a rather dim view of amphibians (he actually did not distinguish between amphibians and reptiles). He was not unique in holding such negative opinions of these animals. Amphibians often seem to evoke fear and loathing from people who are repelled by their cold, clammy skin and noxious skin secretions. They frequently have been invested with magical powers. European fire salamanders (*Salamandra salamandra*), for example, were long thought to have a miraculous ability to survive in fire, no doubt because they sometimes were seen crawling from logs that had been tossed on the kitchen hearth. Toads have come in for special opprobrium, being considered hideous, frightening, and even dangerous animals that possessed a variety of magical powers and an ability to live for extraordinarily long periods of time, perhaps even for centuries. Toads, newts, and salamanders were frequent ingredients in witches' brews and other magical potions that might be used to poison an enemy or cast a spell on a particularly irritating neighbor. Toads appear frequently in European art and literature as symbols of evil and agents of the Devil (De Graaff 1991). In other cultures, however, frogs and toads were widely considered to be symbols of fertility and life. This was particularly true in places where frogs seemed to appear almost by magic at the start of the rainy season, as in Ancient Egypt and the Maya culture of Central America (see chapter 2).

In more recent times, attitudes toward amphibians have shifted, and frogs in particular rank with pandas, lions, and dinosaurs as among the most popular animals in our culture (J. Gibbons 2003a). By the mid-nineteenth century, frogs and toads were popular subjects for children's stories, as they are today. All manner of toys, knickknacks, and decorative objects for the home have been produced with a frog or toad motif, and many people, including some biologists who study amphibians, are avid collectors of amphibian paraphernalia (Donaldson 1980; Ribuoli and Robbiani 1990). There also is a thriving worldwide pet trade in frogs and other amphibians. Yet the average person seldom sees any kind of amphibian in the wild and knows almost nothing about their natural history. People who can expound at length on the social behavior of lions or the latest discoveries in dinosaur paleontology often do not know anything about the feeding habits or reproductive biology of the toads living in their backyard gardens. Most probably could not identify a salamander if they encountered one in the woods.

Even among biologists, there is considerable ignorance about the vast diversity of amphibian species and their great variety of lifestyles. All too often, biologists are familiar with only the few species of amphibians that are widely used for laboratory studies in physiology, genetics, developmental biology, and molecular biology. This can lead to uncritical use of such animals as model organisms, based on the assumption that animals chosen mainly for their suitability as laboratory animals are representative of amphibians as a whole (Cannatella and de Sa 1993; Shaffer 1993). Yet amphibians are an enormously diverse group. With more than 6,000 species currently known, and more being described every year, they represent a greater proportion of living vertebrates than do the mammals, which often are considered the dominant group of terrestrial vertebrates (Glaw and Köhler 1998; Hanken 1999b; for a current count of species, see Amphibia Web at http://elib.cs.berkeley.edu/aw/index.html). Furthermore, living amphibians have a very long evolutionary history, with many of the modern families having been well established for at least 50 to 100 million years (Savage 1973; Duellman and Trueb 1986; Heatwole and Carroll 2000). This means that different types of amphibians are potentially as different from one another biologically as a horse is from an opossum, a bat, or an anteater.

Amphibians occupy nearly every available habitat on earth except for the open oceans, distant oceanic islands, and the frozen reaches of the Arctic and Antarctic. Some amphibians live entirely in water, others entirely on the land. Some live in freshwater swamps, fens, bogs, ponds, lakes, rivers, and streams, environments where water is nearly always available. Others live in deserts, where water is present only for very brief periods each year. Frogs and caecilians are most diverse in tropical rainforests, which provide an ideal combination of warm temperatures and abundant rainfall. Yet a few frogs live above the Arctic Circle in both North America and Europe. Salamanders are most common in the relatively cool, moist forests of eastern North America and the mountains of Central America, but others have penetrated into lowland tropical rainforests, deserts, and even the tundra of Siberia.

This book is about the diversity of amphibian life and the ecological and behavioral adaptations that have made amphibians a successful, if somewhat inconspicuous, component of terrestrial and aquatic ecosystems. The remainder of this chapter provides an evolutionary context for understanding the ecology and behavior of amphibians. The first section reviews general characteristics of amphibians and then briefly discusses the origins of amphibians and their evolutionary history. The rest of the chapter provides a discussion of phylogenetic relationships of the major clades of amphibians and brief synopses of the classification, geographical distribution, and natural history of all amphibian families, followed by more detailed discussions of major features of morphological evolution that are important for understanding their ecology and behavior.

For the most part, the classification used here follows that of Frost (2004). A monograph that proposes a radically revised phylogeny and classification of all amphibians (Frost et al. 2006) appeared just as I was preparing the final manuscript of this book. It seemed neither possible nor desirable to incorporate these changes into the book, especially because this would result in the use of many genus and family names that differ from those cited in the literature being discussed. Such a major change in phylogeny and classification will require time for other scientists to analyze the implications of the proposed changes before the new scheme is widely adopted, and using the new names here would simply cause unnecessary confusion. One implication of the revised phylogeny of amphibians proposed in Frost et al. (2006) is that many previous phylogentic analyses of ecological or behavioral traits discussed in this book, such as the evolution of feeding modes, reproductive modes, life histories, courtship behavior, or parental care, may need to be reexamined. While I have not adopted the taxonomic changes recommended in Frost et al., I have made note of cases in which their taxonomy would be significantly different from the classification used in this book.

The other chapters of the book are roughly divided into three major themes. Chapters 2 to 6 deal mainly with the interactions of amphibians with the physical environment and therefore focus on physiological ecology. Chapters 7 to 13 are concerned with biological interactions among members of the same species, covering such topics as reproduction, parental care, communication, sexual selection and mate choice, aggressive behavior, and the biology of amphibian larvae. Chapters 14 to 16 discuss interspecific interactions, including interactions of amphibians with their predators, the organization of amphibian communities, and prospects for future survival and conservation.

General Characteristics of Living Amphibians

The three major groups of amphibians are very different from one another morphologically (fig. 1.1). Frogs and toads (order Anura) are specialized for jumping, with greatly enlarged hind legs, shortened bodies, no tail, and large heads and eyes. Salamanders and newts (order Urodela) are much more elongate, with front and back legs of approximately equal size and a long tail (this clade is called Caudata by some systematists, derived from the Latin rather than the Greek word for “tail”). Caecilians (order Gymnophiona) are specialized for life underground. They have elongated, snakelike bodies that lack legs, and they have greatly reduced eyes. Despite these differences, all amphibians share certain physiological characteristics that together set them apart from other terrestrial vertebrates. One such feature is their scaleless, highly permeable skin, which allows for rapid passage of both water and respiratory gases. This feature prevents them from living in salt water or being active in very dry environments (chapter 2). However, it allows them to make use of the skin for respiration to a much

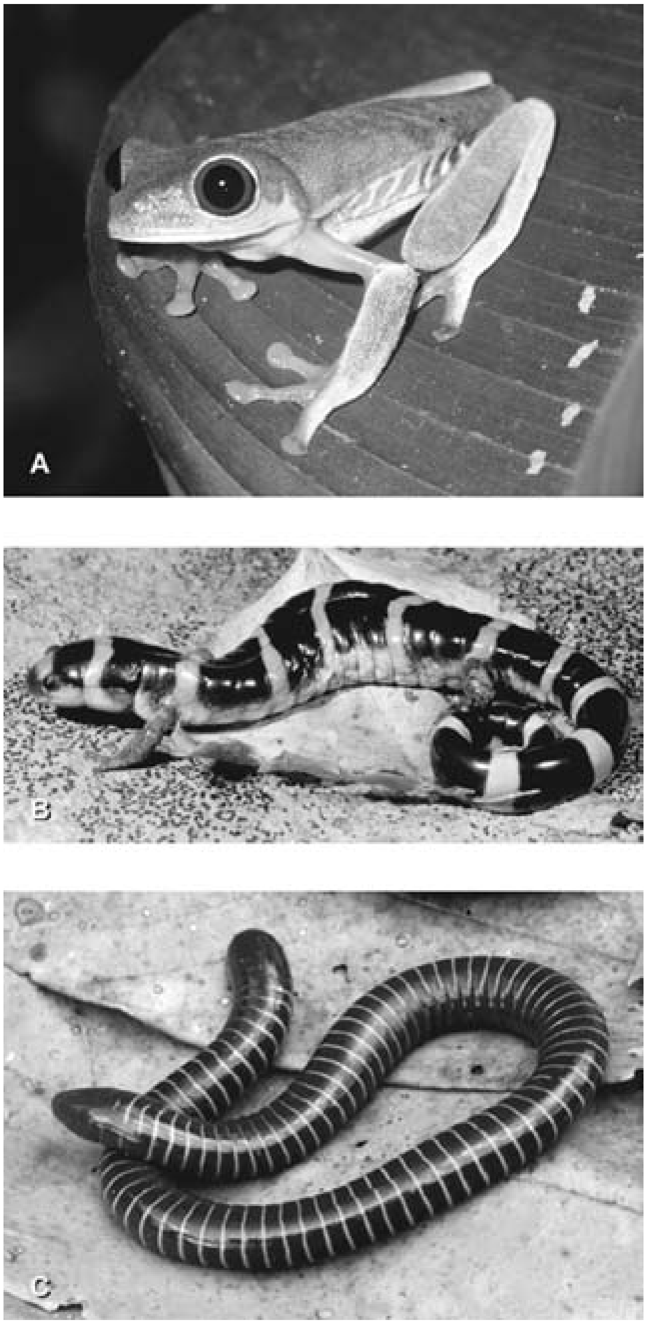

Fig. 1.1. Representatives of the three major clades of living amphibians. (A) *Agalychnis callidryas* (Anura, Hylidae). (B) *Ambystoma annulatum* (Urodela, Ambystomatidae). (C) *Siphonops annulatus* (Gymnophiona, Caeciliidae). Photos by Kentwood D. Wells (A), Wayne Van Devender (B), and Janalee P. Caldwell (C).

greater degree than any other vertebrate group (chapter 4). It also has a major effect on their ability to maintain a constant body temperature. Amphibians are ectothermic, a physiological trait inherited from their aquatic ancestors. They are incapable of generating their own body heat (chapter 3) and consequently have much lower metabolic rates than endothermic birds and mammals (chapter 5).

Most amphibians are somewhat dependent on water for reproduction, even when adults are terrestrial, although several of the most successful clades have evolved completely terrestrial reproduction. The egg is never protected by a hard shell, like that of reptiles and birds, and therefore loses and gains water across the egg membrane very rapidly. Even when amphibians breed on land, they must place their eggs in wet microhabitats (chapter 10). Amphibians that lay aquatic eggs, and some that place their eggs out of water, have aquatic larvae that lead lives very different from those of adult amphibians, particularly in frogs (chapter 12). These eventually undergo metamorphosis, a major reshaping of larval morphology into an adult form that is usually adapted for life on land (chapter 13). While the change to a completely terrestrial adult is a new innovation in amphibians, many fishes have larval stages that are very different from the adults.

The Origin and Evolution of Amphibians

The three living groups of amphibians are descended from a diverse group of tetrapods that first appeared in the Devonian Period, about 400 million years ago (for reviews, see Heatwole and Carroll 2000, and R. Carroll 2001). At this time, the ancient continents were uniting into a single large landmass, Pangaea, much of which was situated in tropical or subtropical latitudes. The climate is assumed to have been relatively warm and equable for terrestrial life. Land communities were characterized by assemblages of relatively primitive plants and arthropods (Benton 1997). We can only speculate about the selective pressures that led a group of fishes to emerge onto land, thus beginning the vast radiation of vertebrates into terrestrial habitats (for general reviews, see Little 1990; Benton 1997; Pough et al. 2004). Some authors have argued that the unexploited food resources in the emerging terrestrial communities and the absence of large predators would have favored the evolution of a more terrestrial lifestyle. Others have suggested that the earliest amphibians evolved from air-breathing fishes in warm, swampy environments where oxygen content of the water was low, favoring the emergence onto land, where oxygen is virtually unlimited. Another theory is that the aquatic habitats of tetrapod ancestors were subject to periodic drought, favoring the ability to leave drying pools to seek out other aquatic habitats.

Devonian Tetrapods

The precise group of fishes that gave rise to the first tetrapods has been a matter of some debate. All authors agree that the most likely ancestors were sarcopterygian (lobe-finned) fishes, because of the similarities in the structure of the lobed fins and tetrapod limbs. The only living representatives are the lungfishes (order Dipnoi) and the coelacanths (*Latimeria,* order Actinistia), peculiar lobe-finned fishes from the Indian Ocean. There has been considerable disagreement over which of these is the closest living relative of modern amphibians, and both morphological and molecular data have been interpreted differently by various authors (Rosen et al. 1981; Forey 1986, 1988, 1991; Panchen and Smithson 1987; Robineau 1987; A. Meyer and Wilson 1990; Forey, Gardiner, and Patterson 1991; Gorr, Kleinschmidt, and Fricke 1991; Gorr and Kleinschmidt 1993; Zardoya and Meyer 997; Zardoya et al. 1998). Indeed, some workers have maintained that the coelacanth and lungfishes are more closely related to each other than either is to tetrapods (Forey 1988). Regardless of which theory proves to be true, it is clear that neither of these living groups very closely resembles the actual ancestor of tetrapods.

Until relatively recently, the traditional view of most paleontologists has been that the earliest tetrapods evolved from a group of lobe-finned fishes called the osteolepiforms, which had a limb-structure and other skeletal features similar to that of a putative tetrapod ancestor (Schultze 1991; Benton 1997). This was disputed by Rosen et al. (1981), who argued that most of the characters uniting these fishes with tetrapods were ancestral rather than derived; they favored a close relationship of tetrapods to lungfishes. More recent cladistic analyses of fossil morphology have focused on a group of lobe-finned fishes called panderichthyids (fig. 1.2). These resemble osteolepiforms, and sometimes are considered part of that group, but are considered by other paleontologists to be a separate lineage closely related to osteolepiforms (Vorobyeva and Schultze 1991).

The panderichthyids had a number of tetrapod-like features of the skull, axial skeleton, and general body morphology, although the braincase lacked certain key tetrapod features (Ahlberg, Clack, and Lukševičs 1996). These fishes had relatively long snouts, eyes placed on the top rather than on the sides of the head, flattened bodies, and reduced median fins. They probably were predators in shallow water that were capable of limited locomotion on land, similar to that seen in some living fishes such as mud-skippers and walking catfish (Ahlberg and Milner 1994). The pectoral fins of these fishes were more derived and more tetrapod-like than were the pelvic fins, suggesting that tetrapod limb characters did not all evolve at the same rate (Boisvert 2005). Recent phylogenetic analyses place the panderichthyids as the sister group to the tetrapods, with the combined clade formed by these two groups comprising part of a larger clade Tetrapodomorpha, which includes the Osteolepiformes (fig. 1.3). The latter is paraphyletic with respect to tetrapods (Ahlberg and Johanson 1998). This analysis

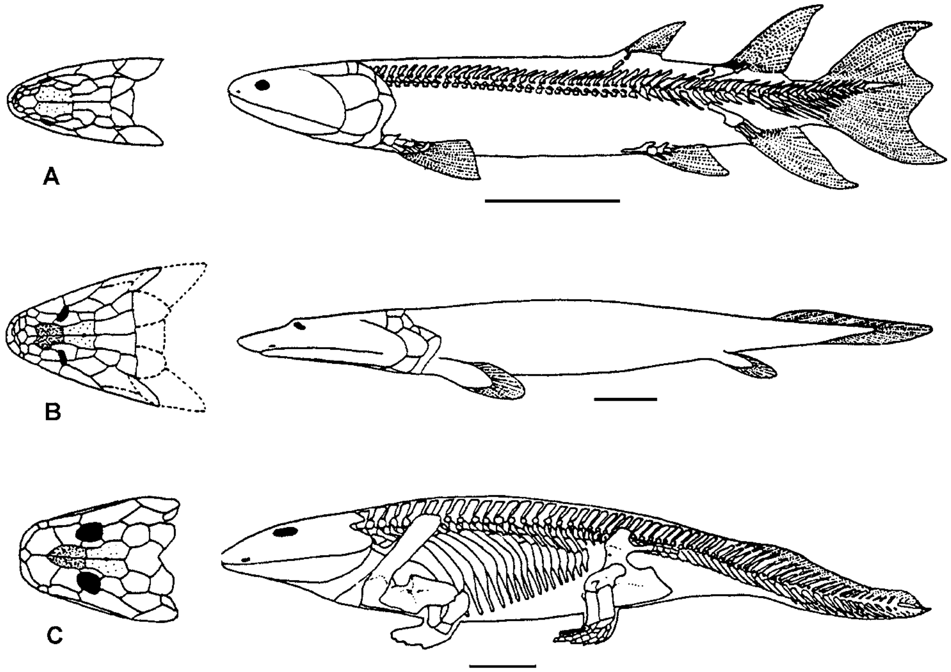

Fig. 1.2. A comparison of skull morphology and body form in osteolepiform fishes, panderichthyid fishes, and early tetrapods. (A) Skull and lateral view of the osteolepiform fish *Eusthenopteron.* Scale bar is 100 mm. (B) Skull and lateral view of the panderichthyid fish *Paderichthys rhombolepis.* Scale bar is 10 mm. (C) Skull and lateral view of the Devonian tetrapod *Ichthyostega.* Scale bar is 100 mm. After Ahlberg and Milner (1994).

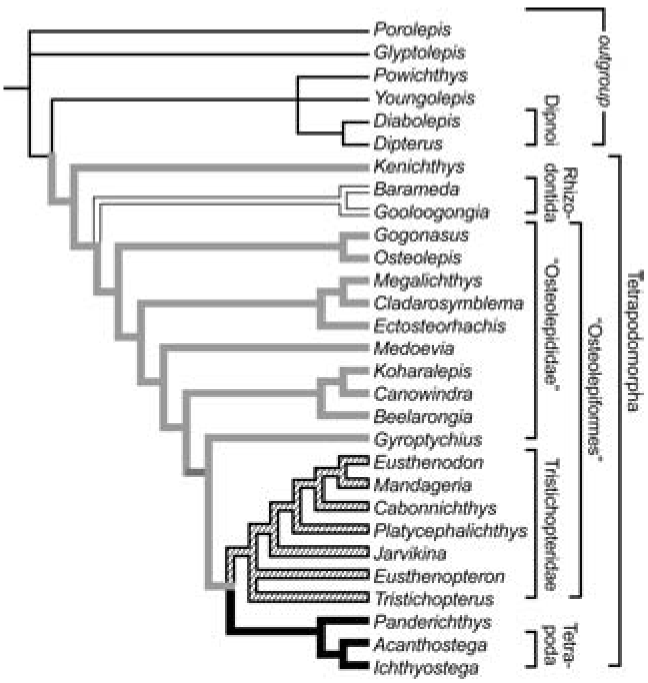

Fig. 1.3. Phylogeny of the tetrapodamorph stem group. Thin black lines represent outgroups. Gray bars indicate members of the paraphyletic family Osteolepididae. Open bars indicate the Rhizodontida. Hatched bars indicate the Tristichopteridae, a family of osteolepiform fishes. Black bars indicate the early tetrapods and their closest relatives. After Ahlberg and Johanson (1998).

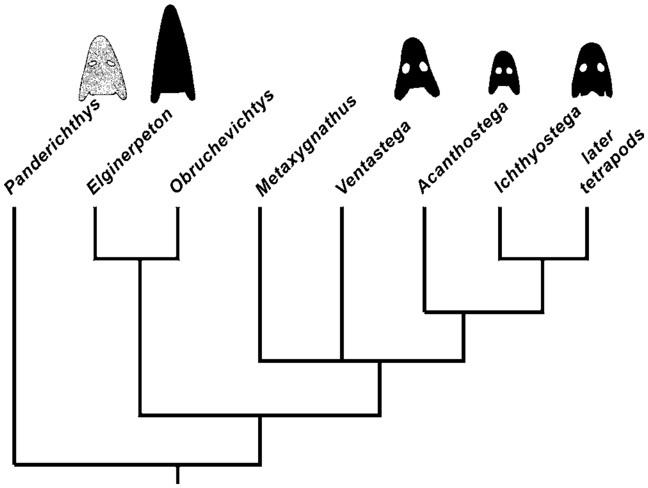

Fig. 1.4. Phylogeny of Devonian tetrapods, with diagrammatic representations of skull structure of major clades. *Ichthyostega* is considered the sister group to the later tetrapods. After Ahlberg (1995).

also suggests that the evolution of certain tetrapod-like morphological features of the skull and reduction or loss of median fins occurred independently in several clades. These apparently represent separate evolutionary experiments leading to large aquatic predators, only one of which survives as the modern tetrapod lineage.

The recent discovery of a new tetrapodomorph fossil from Ellesmere Island in Canada provides an intermediate link between *Panderichthys* and the later Devonian tetrapods. This animal, *Tiktaalik roseae,* had crocodile-like body morphology similar to that of Panderichthys, but had front limbs that were more tetrapod-like than those of panderichthyids (Daeschler et al. 2006). Although this animal had fishlike pectoral fins, the forelimb skeleton had bones apparently homologous to the wrist and finger bones of later tetrapods. These bones gave the animal the ability to adopt a variety of postures, including standing on the substrate while supported by the limbs, as in tetrapods (Shubin, Daeschler, and Jenkins 2006). This intermediate fossil confirms earlier analyses indicating that various tetrapod-like features of the limbs first evolved in aquatic animals with otherwise fishlike morphology (Ahlberg and Clack 2006).

One difficulty in trying to unravel the relationships of various groups of vertebrates is the poor fossil record of Devonian tetrapods (Clack 2000). As of 2001, only eight Devonian tetrapods were known. Two genera, *Elginerpeton* and *Obruchevichthys,* are known mainly from fossil jaws, which were very long and equipped with numerous fishlike teeth. These are thought to be closely related and currently are considered the sister group to all other tetrapods (fig. 1.4). However, these have a relatively derived head and jaw morphology compared to panderichthyids and probably represent an early, specialized lineage. The other Devonian tetrapods, *Ichthyostega, Acanthostega, Ventastega, Metaxygnathus, Hynerpeton,* and *Tulerpeton,* had relatively broad snouts and dorsally placed eyes and were more similar to the panderichthyids (fig. 1.4). Although collectively referred to as "stem tetrapods," this group probably represents several independent lines of evolution, suggesting a considerable diversification of tetrapods by the late Devonian (Ahlberg and Milner 1994; Ahlberg 1995; Jarvik 1996; Clack 2000; R. Carroll 2001; Ruta, Coates, and Quicke 2003). One interesting morphological feature of these fossils is the presence of up to eight toes on the feet, suggesting that a five-toed condition is derived, not ancestral for tetrapods. Other features of the limbs, along with the panderichthyid-like body morphology of these animals, suggest that walking limbs may have evolved in water, rather than for terrestrial locomotion. One possibility is that these limbs facilitated movement through shallow, weed-choked swamps and ponds (Coates and Clack 1990, 1995; Ahlberg and Milner 1994; Clack 2000, 2004; Shubin, Daeschler, and Coates 2004).

Tetrapods from the Carboniferous to the Triassic

The fossil record for tetrapods is virtually nonexistent over the next 30 million years (R. Carroll 1987; Clack and Car-

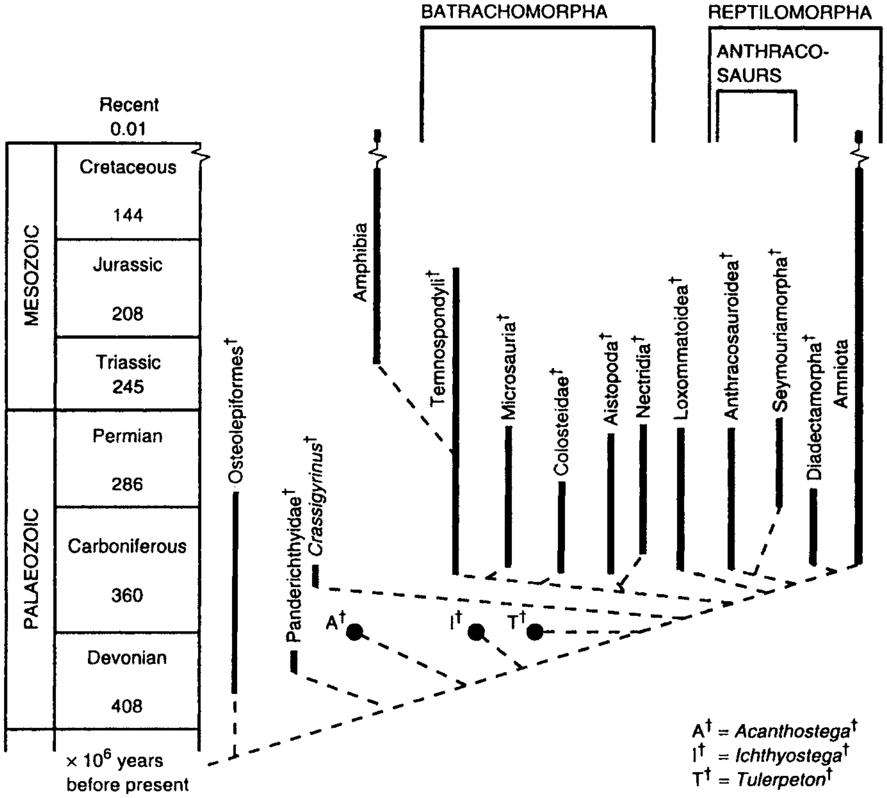

Fig. 1.5. Phylogenetic relationships of sarcopterygian fishes and tetrapods, showing the approximate dates of appearance of each clade in the fossil record. Many tetrapod clades were present by the mid-Carboniferous Period, but their relationships to one another are uncertain. The batrachomorph clade, which gave rise to modern amphibians, was clearly differentiated from the reptilomorph clade, which gave rise to the amniotes (reptiles, birds, and mammals). After Pough, Heiser, and McFarland (1996).

roll 2000). Recent discoveries are beginning to fill in this gap, however. In addition to isolated limb and girdle bones from the Lower Carboniferous Period, there is now an articulated skeleton of *Pederpes,* the earliest known tetrapod, that appears to be adapted for walking on land (Clack 2002). This animal, which lived about 350 million years ago, may have had only five toes on the feet, although there are indications of vestigial elements of additional digits. By about 335 million years ago, a host of very distinct tetrapod lineages suddenly appear in the fossil record (fig. 1.5). Indeed, the Carboniferous Period has sometimes been characterized as the Age of Amphibians, but most amphibian fossils come from North American and European deposits, making up only about 1% of the time period encompassed by the Carboniferous (R. Carroll 2000b). Hence, the fossil record for early tetrapods is fragmentary at best.

Many of the Carboniferous tetrapods would not be recognizable as amphibians in the modern sense. While modern amphibians are mostly quite small, and all have highly permeable skin, many Carboniferous tetrapods were large and often protected by scales or even heavy dermal armor. The scaly or armored skin of these animals indicates that they probably lacked the cutaneous respiration characteristic of many living amphibians, and relied instead on well-developed lungs (Holmes 2000). These animals were the first truly successful vertebrate colonists of the land, although most are thought to have retained an aquatic mode of reproduction. At this point, all of the major continents had united into a single landmass, Pangaea, with much of Europe and North America centered near the equator. Land plant communities were much more developed than in the Devonian, with forests that eventually gave rise to the extensive coal deposits that give the period its name. The fossils of early tetrapods have been found in these coal deposits, which probably were originally warm, swampy habitats like those favored by many modern amphibians.

The Carboniferous tetrapods were much more diverse than Devonian tetrapods, and more highly derived relative to their fish ancestors, but the large gap in the fossil record makes their relationship to Devonian tetrapods obscure. They included aquatic, semiaquatic, terrestrial, and fossorial species, some of which had body forms superficially similar to modern crocodilians, lizards, snakes, and salamanders. Others were distinct from any living vertebrates. None of these early tetrapods had a body form resembling the highly derived morphology of frogs. By the late Devonian or early Carboniferous, a "batrachomorph" or "amphibian stem" lineage was well differentiated from a "reptiliomorph" or "reptile stem" lineage, represented by Anthracosaurs and Seymoriamorphs (fig. 1.5). The reptilomorph clade generally is considered to be the sister group of the amniotes (reptiles, birds, and mammals; Smithson 2000). Hence, modern amphibians and reptiles probably have not shared a common ancestor for more than 360 million years (Ahlberg and Milner 1994; Benton 1997; Clack and Carroll 2000; R. Carroll 2001; Ruta, Coates, and Quicke 2003).

The fossil tetrapods of the Carboniferous are much too diverse to discuss in detail here. Relationships among the many groups of early tetrapods are much disputed, with little agreement among various phylogenetic analyses. For recent discussions of phylogenetic relationships and accounts of the various groups, the reader should consult Ahlberg and Milner (1994), R. Carroll (1995, 2002), Laurin and Reisz (1997), J. S. Anderson (2001), Laurin (2002), Ruta, Coates, and Quicke (2003), and the books edited by Panchen (1980), Benton (1988), and Heatwole and Carroll (2000). The group that is most relevant to this book is the order Temnospondyli, considered by many paleontologists to be the likely ancestral group for the modern amphibians (Holmes 2000; Warren 2000; R. Carroll 2001; Ruta, Coates, and Quicke 2003; for contrasting views, see Laurin and Reisz 1997; Laurin 2002). This was an extremely diverse group that first appeared in the late Carboniferous or early Permian (286 million years ago), with some lineages persisting into the early Cretaceous (144 million years ago). Temnospondyls included the very large, fully terrestrial predator *Eryops* (fig. 1.6 A), probably the most frequently illustrated early amphibian. They also included other large terrestrial or semiaquatic forms, with long, crocodilian-like snouts that probably were used to capture fish in freshwater lakes (fig. 1.6 C). Others were smaller and more terrestrial, possibly feeding on insects and other invertebrates. The full extent of the terrestrial tetrapod fauna is unknown, because animals from lowland swamps or lakes are much more likely to be preserved as fossils. Hence, the fossil record is biased toward such habitats, even though tetrapods very likely were present in upland habitats as well (Boy and Sues 2000).

In the late Carboniferous and Permian, many freshwater lakes supported a diverse fauna of temnospondyls. Many of these are known only from larval stages or a few metamorphosed adults. In some cases, impressions of soft tissues, including external gills, are preserved in the fossils. The classification of these forms is somewhat confusing. The term "branchiosaurs" has been used to describe this assemblage, but this appears to represent more than one evolutionary lineage. Two groups of temnospondyls, the families Branchiosauridae and Micromelerpetonidae, are included, as is one unrelated family of Seymouriamorpha (Boy and Sues 2000). The branchiosaurids and micromelerpetonids had a superficial resemblance to modern salamanders (fig. 1.6 D), with short heads, slender trunks, and long tails. They also had three pairs of external gills, like those of modern salamander larvae. In some deposits, hundreds of larval animals have been found, but in most cases, fully metamorphosed adults are very scarce or completely absent. This could mean that adults were fully terrestrial and not preserved in the lake sediments. An alternative explanation is that some of these animals exhibited facultative paedomorphosis like that of modern ambystomatid salamanders (see chapter 13), retaining some larval features as adults when conditions were favorable to fully aquatic life (Boy and Sues 2000).

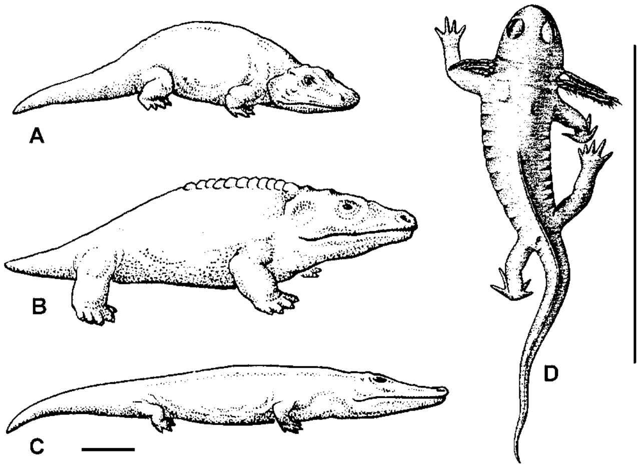

Fig. 1.6. Representative temnospondyls. (A) *Eryops,* a terrestrial dissorophid from the Permian. (B) *Cacops,* another terrestrial dissorophid from the Permian. (C) *Cyclotosaurus,* an aquatic crocodile-like capitosaur from the late Triassic. Scale lines indicate 10 cm. (D) *Branchiosaurus,* a paedomorphic or larval temnospondyl from the early Permian, with external gills similar to those of modern larval or paedomorphic salamanders. Scale line for (D) indicates 5 cm. After Pough, Heiser, and McFarland (1996).

Using evidence of food items preserved in some fossils, the functional morphology of the jaws and branchial apparatus, and inferences from modern amphibians, Boy (1993) constructed a hypothetical food web for an Early Permian lake in Germany (fig. 1.7). The smallest branchiosaurids (*Apateon*) probably fed mostly on zooplankton and other small invertebrates, although there is some evidence of cannibalism of smaller larvae as well. Somewhat larger micromelerpetonids (*Micromelerpeton*) probably fed on invertebrates and on smaller amphibians. These amphibians probably competed for food with acanthodian fishes (*Acanthodes*) and actinopterygian fishes (*Parablypterus*). All of these animals in turn were eaten by large crocodilian-like archeogosauroid amphibians such as *Sclerocephalus* and *Archegosaurus*. The smaller amphibians appeared to thrive

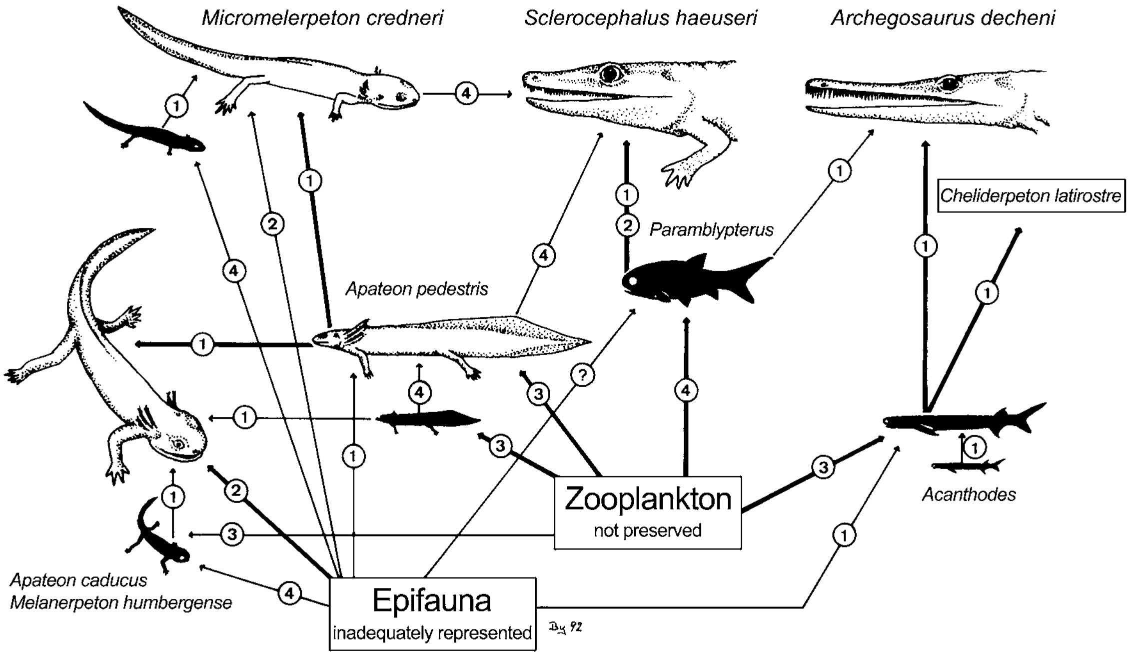

Fig. 1.7. Inferred trophic relationships among Early Permian tetrapods and fishes from the Saar-Nahe Basin in Germany. Numbers indicate the type of evidence used to infer trophic relationships: 1 = gut contents or food items stuck in throat region. 2 = coprolites (fossilized dung) that can be unambiguously assigned to their producers. 3 = functional interpretations of features of the jaw and brachial apparatus. 4 = possible predator-prey relationships based on analogies with living species. After Boy and Sues (2000).

mainly in lakes that lacked very large predatory fishes, just as modern ambystomatid salamanders do today (see chapter 14). In some lake deposits, there is evidence that the lake underwent gradual succession, with the smaller amphibians largely disappearing as large predatory fishes became more abundant (Boy and Sues 2000).

By the Triassic Period (245 million years ago), the temnospondyls were represented by a diverse monophyletic clade, the stereospondyls. These were mostly aquatic animals, although evidently derived from terrestrial ancestors. Fully terrestrial temnospondyls by this time had been largely replaced by the enormous diversity of terrestrial reptiles (Benton 1997). Like earlier lineages of temnospondyls, the Triassic forms probably all had aquatic larvae, and some are known to have undergone a rather dramatic morphological metamorphosis. Most probably were covered in some form of scales; well-preserved heavy dermal armor is known for some species. Adult body forms were extremely diverse. Many were superficially crocodile-like in appearance, with both broad-snouted generalist predators and narrow-snouted fish-eaters represented. Others did not resemble any modern vertebrates. The crocodile-like trematosaurids evidently were marine animals, indicating that Triassic nonamniote tetrapods did not all have physiological adaptations like those of modern amphibians. Most stereospondyls were extinct by the end of the Triassic, but some groups persisted in Asia and Australia into the Jurassic (Warren 2000).

A final assemblage of Carboniferous and Permian amphibians that requires brief mention is a group collectively known as lepospondyls (R. Carroll 2000c). These animals were smaller than most temnospondyls and evolved into a variety of body forms that superficially resemble those of modern salamanders, lizards, and snakes (fig. 1.8). Many apparently were terrestrial, at least as adults, and some were burrowing animals, but others were fully aquatic. Hence, in some ways these animals were ecologically more similar to modern amphibians than were the temnospondyls. The relationship of the lepospondyls to the temnospondyls has been disputed, as has the monophyly of this clade (Ruta, Coates, and Quicke 2003). At least six major lineages of lepospondyls are known, of which the most diverse and best known are the microsaurs, aïstopods, and nectrideans. Microsaurs were mostly terrestrial, with a variety of salamander-like and lizardlike body forms (fig. 1.8 A–C). Aïstopods were elongate, snakelike legless amphibians (fig. 1.8 D). They represent one of several clades of lepospondyls that exhibited a tendency toward elongation of the body and reduction of limbs. The nectrideans were a diverse group that included both aquatic and terrestrial forms (fig. 1.8 E). Most were elongate, but this was due to an elongated tail, not an elongated trunk region as in the aïstopods. Some of these amphibians had bizarre flattened heads with projecting hornlike structures, but the functional significance of this morphology is unknown (fig. 1.8 F). Others

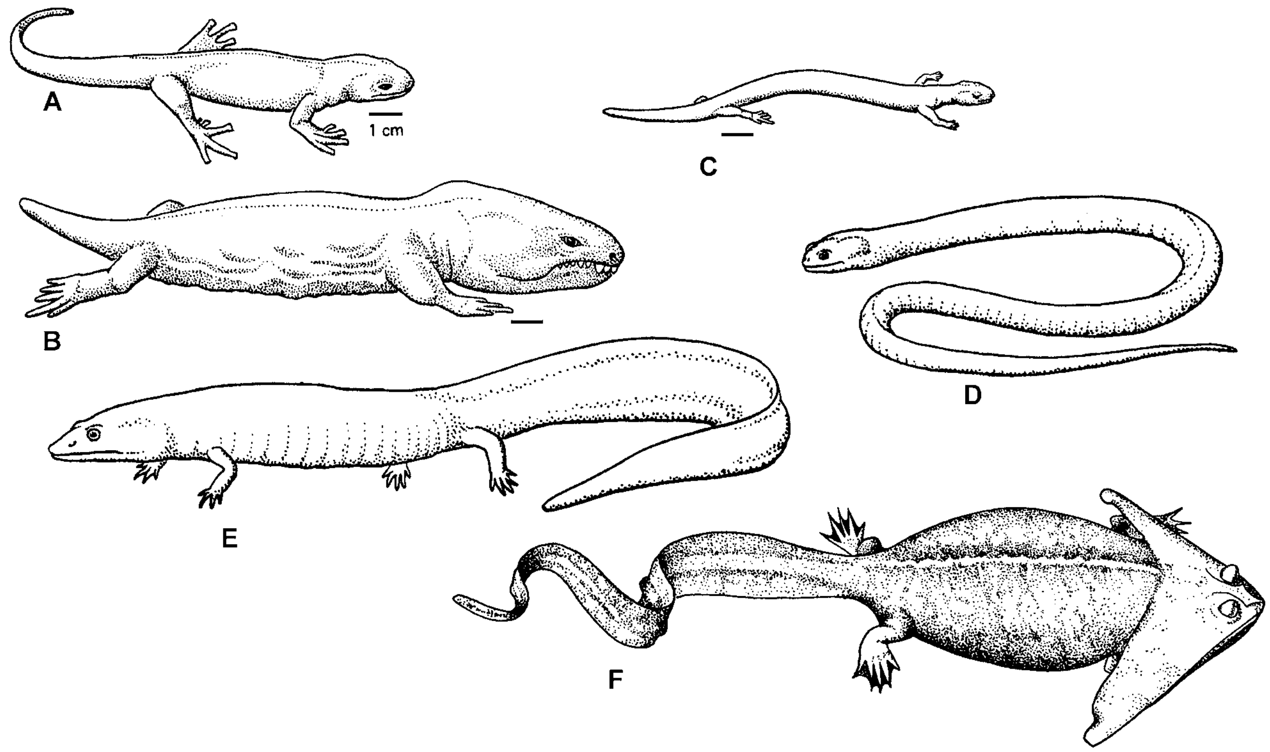

Fig. 1.8. Representative Carboniferous and Permian lepospondyls. A–C are microsaurs. (A) *Tuditanus.* (B) *Pantylus.* (C) *Goniorhynchus.* (D) *Ophiderpeton,* a snake-like aïstopod. had elongate, crocodilian-like skulls characteristic of specialized fish-eaters.

The Origin of Modern Amphibians

The general consensus among most amphibian systematists is that the three groups of living amphibians are descended from a common ancestor and therefore form a monophyletic clade, the Lissamphibia, united by a number of derived morphological characters (Duellman and Trueb 1986; Milner 1988; Bolt 1991; Trueb and Cloutier 1991a; R. Carroll 1995, 2000c, d, 2001; Ruta, Coates, and Quicke 2003). These include the presence of pedicellate teeth and the amphibian papillae, a unique sensory organ in the ear. Molecular evidence also supports the monophyly of the three living groups of amphibians (Hay et al. 1995; Feller and Hedges 1998; Zardoya and Meyer 2001; San Mauro et al. 2005; Zhang et al. 2005). Most systematists argue that this clade is most closely related to a group of terrestrial temnospondyls called dissorophoids, or possibly to the aquatic branchiosaurs, which are included in the superfamily Dissorophoidea (fig. 1.9 A; Trueb and Cloutier 1991a; Milner 1994; Roček and Rage 2000a; R. Carroll 2001; Ruta, Coates, and Quicke 2003). In contrast, Laurin and Reisz (1997) argued that lissamphibians are most closely related to lepospondyls, and these groups together form a sister clade to the amniotes (fig. 1.9 B), but most other workers have not accepted this view. It is difficult to fully resolve this controversy in the absence of key fossils linking lissamphibians with earlier clades of tetrapods. For example, Ruta, Coates, and Quicke (2003) could not identify a specific dissorophoid as the sister group to lissamphibians.

All of the modern amphibian clades are relatively small-bodied animals compared to many Permian and Triassic tetrapods. The largest living amphibians, the Asian giant salamanders (*Andrias*), are about 1.5 meters long, and would be no match for the two-meter long *Eryops* or the crocodile-like capitosaurs from the late Triassic. Indeed, as a group, amphibians are the smallest of all terrestrial vertebrates. It has been suggested that evolutionary reduction in body size was accompanied by truncation of development in many morphological features, a type of paedomorphosis known as progenesis (Bolt 1977, 1979, 1991; Roček and Rage 2000a) that is common in modern amphibian clades (see the following discussions). This process may account for the apparent convergence in morphology of small, salamander-like amphibians in a number of different clades, including the lissamphibians, nectrideans, and microsaurs (fig. 1.8; R. Carroll 1986; Milner 1988). R. Carroll (2000c) argued that the similarities between lissamphibians and lep-

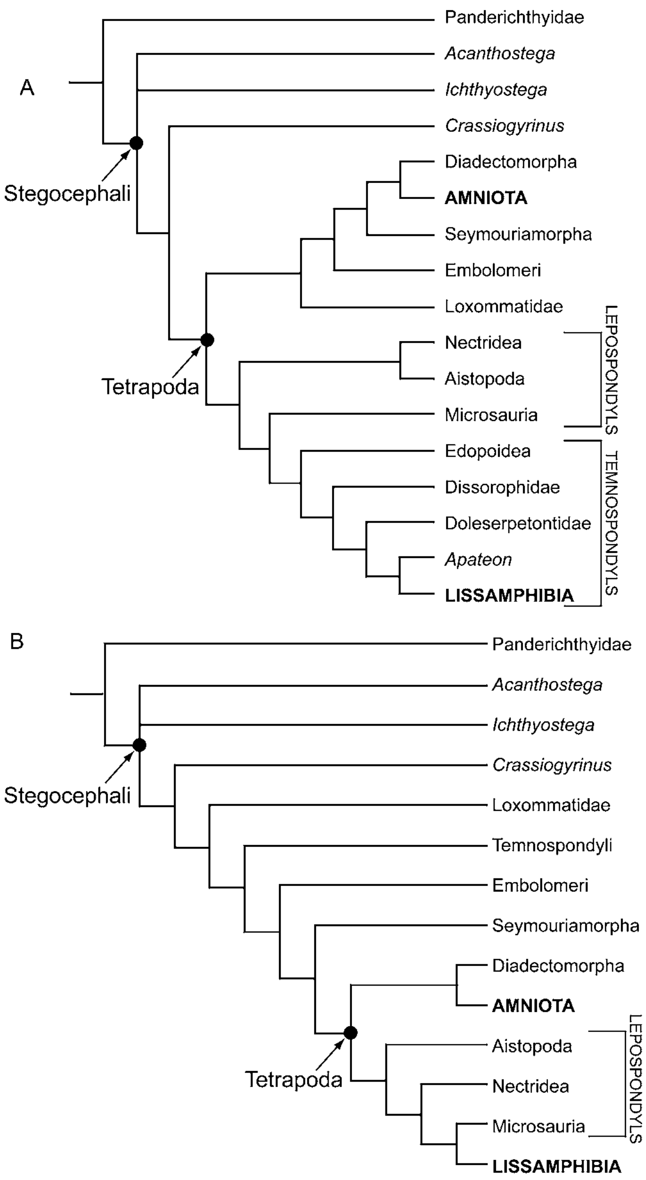

Fig. 1.9. Alternative phylogenetic hypotheses for the relationships of lissamphibians, amniotes, and early tetrapods. (A) Traditional hypothesis showing lissamphibians related to temnospondyls. (B) Hypothesis of Laurin and Reisz (1997), showing lissamphibians related to lepospondyls and to microsaurs in particular. After Pough et al. (2004).

ospondyls described by Laurin and Reisz (1997) result from convergent evolution of morphological features related to reduction in body size and therefore would not necessarily be evidence of a close relationship between these groups.

The precise relationship of the modern amphibians to Paleozoic amphibians has been hard to determine, because fossils linking these groups have not been discovered. Most paleontologists agree that anurans show the strongest affinities with Paleozoic temnospondyls, but the enormous gap in the fossil record makes it impossible to determine direct ancestry. There is little doubt that the origins of the three major clades of modern amphibians are very ancient, considerably predating the earliest existing fossils for each group. Recent attempts to apply a molecular clock analysis to genetic data indicate an origin for Lissamphibians between 330 and 367 million years ago, before the breakup of the supercontinent Pangaea (San Mauro et al. 2005; Zhang et al. 2005). This is about 100 million years before the appearance of recognizable fossils of frogs, salamanders, or caecilians, so there obviously is an enormous gap in the known fossil record of these animals.

The first froglike fossil (*Triadobatrachus massinoti*) is a single specimen from early Triassic deposits (245 million years old) in Madagascar (Roček and Rage 2000b). This animal had elongated legs compared to ancestral amphibians, as well as other froglike anatomical features, but lacked the shortened trunk and other anatomical adaptations for jumping found in modern frogs (fig. 1.10 A). A more recently discovered fossil from Poland, *Czatkobatrachus polonicus,* is incomplete, but has froglike characteristics (S. Evans and Borsuk-Białynica 1998). It is about 5 million years younger than *Triadobatrachus,* and its discovery in Europe suggests

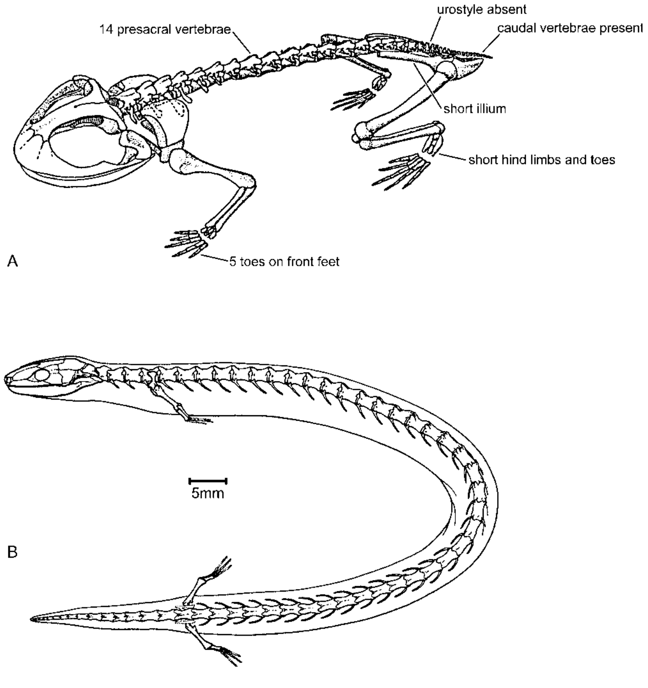

Fig. 1.10. Reconstructions of the earliest anuran and caecilian fossils. (A) *Triadobatrachus massinoti,* a froglike amphibian from an early Triassic deposit in Madagascar. This animal had 14 presacral vertebrae, compared to no more than nine for modern frogs. It also had a remnant of a tail and lacked the fused pelvic girdle, elongate illium, and urostyle of modern frogs. It also had five toes on the front feet, whereas modern frogs have four. After Roček and Rage (2000b). (B) *Eocaecilia micropodia,* a caecilian with legs from a Jurassic deposit in Arizona. The skull and lower jaw resemble those of some modern caecilians, but no modern species has limbs. After Carroll (2000c) from Jenkins and Walsh (1993).

that protoanurans were widely distributed in the Triassic (Roček and Rage 2000b).

Shubin and Jenkins (1995) reported the discovery of a fossil frog (*Prosalirus bitis*) from early Jurassic deposits in Arizona that much more closely resembles modern frogs in having a greatly shortened trunk, enlarged hind limbs, and a pelvic girdle adapted for true jumping locomotion. The North American origin of *Prosalirus,* far from the site in Madagascar where *Triadobatrachus* was found, suggests that by the early Jurassic (208 million years ago), the lineage leading to modern frogs was well established in both northern (Laurasian) and southern (Gondwanan) continents. Indeed, another early Jurassic frog, *Vieraella herbsti,* has been found in Argentina. It is sufficiently similar to modern frogs to be referred to the modern family Leiopelmatidae by some systematists, although others do not assign it to any known family. The diversity of frogs increased dramatically during the middle and late Jurassic and the Lower Cretaceous, by which time they were sufficiently modern in appearance for some fossils to be assigned to the most primitive modern clades of frogs, including the Leiopelmatidae, Discoglossidae, Rhinophrynidae, and Pipidae. By the Upper Cretaceous, several other families had made their appearance, including the Leptodactylidae and Pelobatidae, as well as several families that are now extinct (Roček 2000; Gao and Wang 2001).

The early fossil record of the other two groups of modern amphibians is less extensive than the record for frogs, although many new salamander fossils have been found in the last 20 years (Milner 2000). The first clearly recognizable fossil salamanders come from Jurassic deposits in Kazakhstan (*Karaurus*) and Kirghizstan (*Kokartus*), both of which are assigned to the extinct family Karauridae. Although these animals resemble modern salamanders, many features of the skull are more primitive than any living urodeles. Several other salamanders, known only from vertebrae, have been described from Middle Jurassic deposits in Britain. The recent discovery of hundreds of well-preserved adult and larval salamander specimens from Jurassic deposits in China may alter our ideas about salamander relationships (Gao and Shubin 2001, 2003). Two genera described from this assemblage, *Sinerpeton* and *Laccotriton,* appear to be most closely related to cryptobranchids and hynobiids, while *Chunerpeton* appears to be a cryptobranchid. Gao and Shubin argued that these fossils support an Asian origin for all salamanders, although this issue has been debated, as has the exact dating of the deposits in which the Chinese fossils were found (S. Evans et al. 2005). *Iridotriton,* another morphologically primitive salamander from the Late Jurrasic of North America, shares characteristics of both cryptobranchoid and salamandroid salamanders, but may be more closely related to the latter group (S. Evans et al. 2005). Most remaining fossil salamanders can be clearly assigned to modern families or to groups closely related to modern families. Some sirenid and cryptobranchoid salamanders have been found in the Cretaceous, as have primitive salamandroid salamanders. Many modern salamander families probably were well differentiated by the late Cretaceous or early Paleocene (65 million years ago), and fossils of many modern genera from the Paleocene, Eocene, Oligocene, and Miocene (65–23 million years ago; Gardner 2003).

The first caecilian (*Eocaecilia micropodia*) is an elongate amphibian from the same early Jurassic deposit where the anuran *Prosalirus* was found (Jenkins and Walsh 1993; R. Carroll 2000a). Unlike modern caecilians, this animal had well-developed front and back limbs, but these were smaller than in most other amphibians of this period (fig. 1.10 B). The skull, however, has many features in common with modern caecilians, and the lower jaw is nearly identical to that of modern species. There also is evidence that this species had a tentacle, a unique sensory organ found in modern caecilians (see later discussion). The skull of *Eocaecilia* was solidly roofed, as in modern genera such as *Ichthyophis,* whereas some living genera have a gap between the cheek and the rest of the skull. There has been some disagreement among systematists as to which condition is the ancestral condition for the group, but the skull of *Eocaecilia* suggests that the solidly roofed condition is primitive.

R. Carroll and Currie (1975) proposed, long before the discovery of this fossil, that a group of microsaurs in the lepospondyls was the most likely ancestral group for caecilians, and R. Carroll (2000d) argued that the morphology of *Eocaecilia* is consistent with this hypothesis. This would require that caecilians be derived from a different group of Paleozoic amphibians than are modern frogs and salamanders, with a common ancestor for all three groups going back to the Lower Carboniferous. Molecular genetic analyses provide strong support for the monophyly of living amphibians, and they generally support a closer relationship of frogs and salamanders to each other than to caecilians (Zardoya and Meyer 2001; San Mauro et al. 2004, 2005; Zhang et al. 2005). An analysis of fossils also supported this pattern of relationships and failed to find evidence for a close relationship of caecilians to microsaurs (Ruta, Coates, and Quicke 2003).

Morphological Evolution, Paedomorphosis, and Genome Size

The notion that amphibians represent an intermediate grade of evolution between fishes and reptiles is pervasive even among biologists, but in many respects, this is an inaccurate view of the evolutionary history of vertebrates. The living amphibians and reptiles have not shared a common ancestor for about 360 million years, and the lineage that gave rise to reptiles and other amniotes was well differentiated millions of years before the appearance of the first frogs, salamanders, and caecilians. In many features of their anatomy, amphibians actually have a simplified morphology, even in relation to living bony fishes. This is evident not only in the reduction of various skeletal elements, which can be seen in both fossil and living amphibians, but also in many other organ systems. For example, the nervous systems of amphibians are highly simplified, with salamanders being the most simplified and anurans the least. This is manifested in a reduction in various parts of the lateral line organs, the loss of the tympanum and middle ear cavity and the reduction of middle ear bones in salamanders and caecilians, reduction in the number of retinal cells in salamanders, and simplification of the optic tectum and cerebellum in the brains of all amphibians, especially in salamanders and caecilians (Roth, Dicke, and Nishikawa 1992; Roth et al. 1993; Roth, Blanke, and Wake 1994).

This simplification of organ systems and the loss of elements thought to be present in ancestral tetrapods has been attributed to paedomorphosis, the retention of traits in the adult stage that are present in an earlier stage of development in ancestral species. This is related to two evolutionary trends in amphibians. The first is miniaturization, an evolutionary reduction in body size, which began with the early ancestors of modern amphibians and continues to varying degrees in modern lineages (see subsequent further discussions of miniaturization in the three groups of amphibians). The second trend is the unusually large amount of DNA that amphibians have in their cells compared to other vertebrates. This is particularly true in salamanders, with neotenic forms such as amphiumids, sirens, and proteids having the largest genome sizes. The reasons for this increase in genome size are unclear, but it is correlated with increased cell size, decreased cell metabolism, and decreased rates of cell proliferation and differentiation. In short, amphibians can be expected to have lower metabolic rates, lower growth rates, and slower rates of development than other vertebrates simply because of their larger genomes (Horner and MacGregor 1983; Sessions and Larson 1987; Xia 1995). There also is a positive correlation between genome size and embryonic development time within plethodontid salamanders, after correcting for phylogeny and egg size (Jockusch 1997). Slow rates of cell proliferation and differentiation during development result in simplification of organ systems, with fewer, larger cells packed tightly into a limited space. This trend reaches an extreme in bolitoglossine salamanders, which combine very small body size with relatively large genome and cell size (Roth, Dicke, and Nishikawa 1992; Roth et al. 1993). Large cell size results in simplification of brain structure in both frogs and salamanders. Brain complexity in salamanders is affected by body size as well; larger salamander species have larger and more complex brains (the effect of small body size on brain structure is discussed in more detail in a later section). Patterns of variation in cell size and brain complexity are not correlated in obvious ways with either phylogeny or ecology, making functional interpretations difficult (Roth, Blanke, and Wake 1994).

It might seem that a trait such as large genome size would have only the most tenuous connection to the ecology and behavior of amphibians. However, it may be that many fundamental characteristics of amphibian ecology, life histories, and behavior are direct consequences of having an unusually large genome size (Sessions and Larson 1987; Roth, Dicke, and Nishikawa 1992). For example, the low metabolic rates of amphibians have important consequences for their water relations (chapter 2), temperature relations (chapter 3), modes of respiration (chapter 4), and allocation of energy to activity, growth, and reproduction (chapter 5). Low metabolic rates, low rates of cell proliferation and differentiation, and relatively large cell size could affect the number of eggs produced in a season and a lifetime, and therefore would have a major effect on the evolution of life history strategies (chapter 7). The rather slow rate of development of amphibian eggs, especially in salamanders and species with very large eggs (chapter 7; Bradford 1990), would expose the eggs to predators and other environmental dangers for relatively long periods of time, which might select for extended parental care (see chapter 8). Extended parental care might in turn select for territorial defense of sheltered oviposition sites, where both the eggs and parents are safe from predators (see chapters 8, 9, and 11). Low rates of cell proliferation and differentiation also would affect posthatching development of larvae, and therefore would have a major impact on the biology of larvae (chapter 12) and the timing of metamorphosis (chapter 13; Martin and Gordon 1995). Indeed, large genome size appears to be an evolutionary constraint that affects, directly or indirectly, nearly every aspect of amphibian biology.

Phylogeny and Classification of Anurans

Most recent taxonomic arrangements recognize about 30 families of anurans, with about 350 genera and nearly 5,300 species. The exact number of families varies because of disagreement among systematists about exactly how higher-order taxa should be arranged. In this book, I generally follow the family level taxonomy of Frost (2004), even though recent phylogenetic analyses suggest that some traditional anuran families are not monophyetic. (A new classification proposed by Frost et al. [2006] recognizes 36 families of anurans, with a substantial number of new or reconfigured genera.) Because different phylogenetic reconstructions often result in different relationships among genera, requiring different family-level classifications, there is little point in radically reconfiguring family names at this point, especially in a book not focused on systematics. One difficulty is that various morphological characters often yield conflicting results, and molecular analyses do not always agree with those derived from morphology (for more detailed discussions, see Ford and Cannatella 1993; Hillis et al. 1993; Maglia, Púgener, and Trueb 2001; Duellman 2003; García-París et al. 2003; Haas 2003; Púgener, Maglia, and Trueb 2003; Cannatella and Hillis 2004; Frost et al. 2006). Therefore, the phylogeny and classification given here should be treated as a general guide to the major lineages of anurans, subject to future revision. Indeed, the futility of considering any such arrangement the final word on the subject is shown by the recent description of an entirely new family of frogs, the Nasikabatrachidae, currently known from a single species of burrowing frog in India and thought to be most closely related to sooglossid frogs of the Seychelles Islands (Biju and Bossuyt 2003; Frost et al. 2006). The phylogeny shown in fig. 1.11 is similar to that given in Duellman (2003) and Biju and Bossuyt (2003), and reflects a general consensus, as of late 2005, of how anuran families are related to each other.

A group of 27 genera and about 200 species comprising nine anuran families (Ascaphidae, Leiopelmatidae, Discoglossidae, Bombinatoridae, Rhinophrynidae, Pipidae, Pelodytidae, Pelobatidae, and Megophryidae) generally are considered basal frogs. They sometimes have been referred to as "archaeobatrachians," but these clades do not appear to constitute a monophyletic group (Ford and Cannatella 1993; Hertwig, da Sa, and Haas 2004; Hoegg et al. 2004; Roelants and Bossuyt, 2005; Cannatella and Hillis, 2004; Frost et al. 2006). Most systematists have considered *Ascaphus* from the Pacific Northwest region of North America and *Leiopelma* from New Zealand to be the most primitive living frogs. Ford and Cannatella (1993) considered *Ascaphus* to be the sister-group to all other living anurans, whereas Duellman (2003) placed *Leiopelma* as the most basal group, largely on the basis of sperm morphology (Scheltinga and Jamieson 2003). Some systematists have placed *Ascaphus* and *Leiopelma* in the same family (Frost et al. 2006), although these genera appear to be united mostly by ancestral characters rather than shared derived characters.

An analysis based on adult and larval morphology produced a different arrangement, with the Pipoidea (Pipidae + Rhinophrynidae) being the sister group to all other frogs, including Ascaphidae (leiopelmatids do not have aquatic larvae, so were not included in this analysis; Maglia, Púgener,

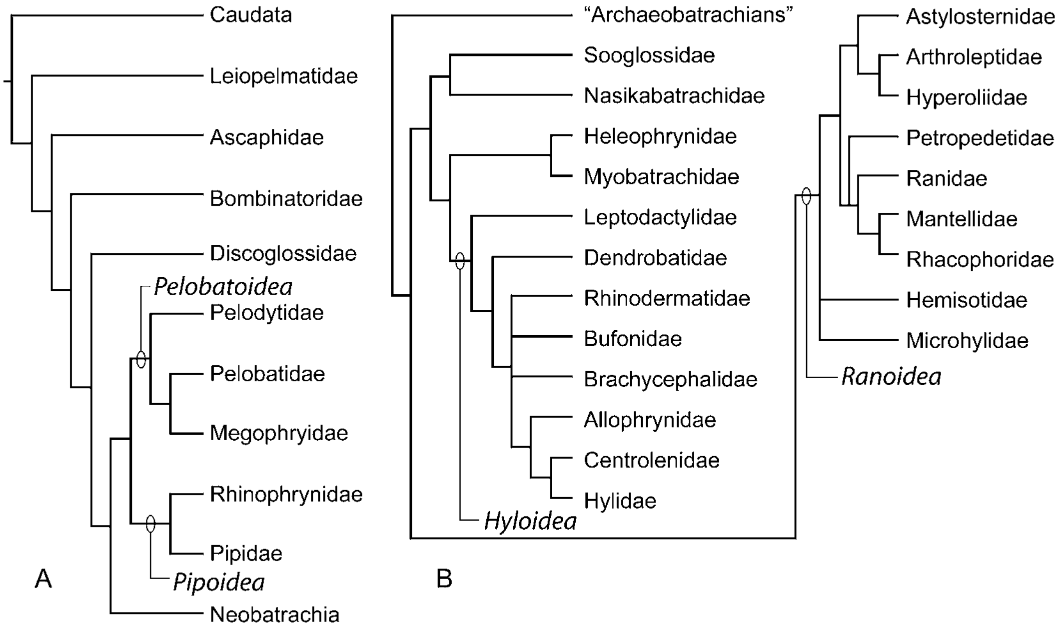

Fig. 1.11. Phylogenetic relationships of the major clades of anurans. This figure is meant to show possible relationships of families discussed in this chapter, but other arrangements are possible. Branch lengths are approximate and should not be taken as accurate representations of relative divergence times. (A) Relationships of the "archeobatrachian" anuran families, a nonmonophyletic group. Most phylogenetic analyses agree on the monophyly of the clades Pipoidea and Pelobatoidea, although there is some disagreement over relationships within the latter clade. (B) One of several possible phylogenies for the monophyletic clade Neobatrachia. The monophyly of the clades Hyloidea and Ranoidea is well supported, but relationships of families within these clades are uncertain. Some phylogenies place the hyperoliid subfamily Leptopelinae (not shown here) as more closely related to the Arthroleptidae than to the hyperoliid subfamily Hyperoliinae. After Duellman (2003), with modifications from Biju and Bossuyt (2003).

and Trueb 2001; Púgener , Maglia, and Trueb 2003). Larval morphology alone grouped *Ascaphus* with the pipoids, whereas adult morphology grouped this genus with all the other frog families. In contrast, a different analysis of larval morphology by Haas (2003) placed *Ascaphus* in its traditional position as the sister group to all other anurans, but with pipoids as the next most basal group. Whatever their placement relative to other anurans, the close relationship of pipids and rhinophrynids is well supported by both larval morphology and molecular data, despite their lack of similarity in adult morphology (see the family accounts that follow).

All phylogenetic analysis of adult morphology, larval morphlogy, and molecular characters place the families Discoglossidae and Bombinatoridae as closely related basal groups, in some cases the most basal frogs other than *Leiopelma* and *Ascaphus.* Traditionally, four genera were placed in the family Discoglossidae (*Discoglossus, Alytes, Bombina,* and *Barbourula;* e.g., Duellman and Trueb 1986), but several recent classifications have placed the last two in a separate family Bombinatoridae (Ford and Cannatella 1993; Duellman 2003; Frost et al. [2006] placed *Discoglossus* and *Alytes* in the family Alytidae). I have treated these as two separate families in this book, although studies based on adult morphology, larval morphology, molecular characters, and vocalizations do not give a consistent picture of the relationships among these four genera, in part because *Barbourula* often has been omitted from the analyses (Hay et al. 1995; Bosch and Boyero 2003a; Haas 2003; Púgener, Maglia, and Trueb 2003; Hertwig, da Sa, and Haas 2004; Roelants and Bossuyt 2005; Frost et al. 2006).

The remaining basal families (Pelodytidae, Megophryidae, and Pelobatidae) have been placed together in many phylogenetic analyses as a monophyletic clade, the Pelobatoidea. Both molecular and morphological characters support the close relationship of these groups, although their relationship to other anurans is not fully resolved (García-París et al. 2003; Haas 2003; Púgener, Maglia, and Trueb 2003; Hertwig, da Sa, and Haas 2004; Roelants and Bossuyt 2005). The relationships within this clade have been debated. Traditionally the spadefoot toads from North America (*Scaphiopus, Spea*) have been placed with Eurasian spadefoot toads (*Pelobates*) in the family Pelobatidae, but both morphological and molecular characters indicate that *Pelobates* is more closely related to the Asian megophryids than to the North American spadefoot toads. Roček (1980), Haas (2003), García-París et al. (2003), and Frost et al. (2006) all recommended placing the latter group in a separate family, Scaphiopodidae, but differed on whether the megophryids should be a separate family (García-París et al. 2003; Frost et al. 2006) or included within the Pelobatidae (Haas 2003).

All remaining frog families are placed in an even more derived assemblage, Neobatrachia (fig. 1.11). There is strong support for the monophyly of this clade (Cannatella and Hillis, 2004; Hertwig, da Sa, and Haas 2004; Hoegg et al. 2004; Frost et al. 2006), but relationships within this group, which represents about 95% of all anuran species, are poorly understood (Hillis 1991; Ford and Cannatella 1993; Hass 2003; Cannatella and Hillis 2004; Frost et al. 2006). Ford and Cannatella (1993) recognized a monophyletic clade, Ranoidea, in which they placed the Arthroleptinae, Astylosterninae, Dendrobatidae, Hemisotidae, Hyperoliidae, Mantellinae, Microhylidae, Ranidae, and Rhacophoridae, but relationships among these clades are in dispute. Ford and Cannatella (1993) considered the remaining neobatrachian families not to be a monophyletic group, but others have united these into a group variously called the Hyloidea or Bufonoidea (see later discussion). More recent molecular phylogenies have strongly supported both Ranoidea and Hyloidea as monophyletic groups (Darst and Cannatella 2004; Hoegg et al. 2004), but with the Dendrobatidae removed from Ranoidea.

Emerson et al. (2000) provided a phylogenetic analysis of ranoids using combined morphological and molecular data sets. They found strong support for a monophyletic Ranoidea, excluding the Dendrobatidae. Relationships within the group were not fully resolved, but some apparent relationships differed from traditional classifications. For example, the Arthroleptinae (represented by two species in their analysis) were nested within the Hyperoliidae, but that family did not appear to be monophyletic. Specifically, the genus *Leptopelis,* usually considered the most primitive hyperoliid, appeared to be closely related to *Arthroleptis.* Another novel result is that *Hemisus,* which was previously placed in the Ranidae and now generally treated as a separate family, was grouped with the Microhylidae in their analysis. Finally, the mantelline frogs of Madagascar appeared to be more closely related to rhacophorids than to either ranids or hyperoliids. Unfortunately, some key taxa, including African ranids and astylosternines, were not represented in this analysis, and the great diversity of microhylids also was poorly represented.

A molecular analysis of ranoid frogs from Asia and Madagascar revealed considerable convergence in morphology and ecology, both within and between these regions (Bossuyt and Milinkovitch 2000). This analysis indicates that many traditional subfamilies within the family Ranidae and Rhacophoridae do not represent monophyletic clades. For example, the subfamily Tomopterninae traditionally has been represented by a single genus of burrowing frogs, *Tomopterna,* in Africa, Sri Lanka, and Madagascar. Morphological characters support the monophyly of this genus, despite its disjunct distribution (Glaw, Vences, and Böhme

1998). However, two molecular analyses clearly indicated that the species from Madagascar, *Tomopterna labrosa,* is much more closely related to mantelline frogs from Madagascar than to Asian members of the genus (Richards and Moore 1998; Bossuyt and Milinkovitch 2000). In particular, *T. labrosa* appears to be closely related to the genus *Aglyptodactylus,* and Bossuyt and Milinkovitch (2000) proposed that this species be placed in a new genus, *Laliostoma.* According to their analysis, all of the Madagascar genera traditionally placed in the subfamilies Mantellinae (*Mantella* and *Mantidactylus*), Rhacophorinae (*Aglyptodactylus* and *Boophis*), and Tomopterninae (*Laliostoma*) form a monophyletic clade and should be placed in a separate family, Mantellidae (see also C. Richards, Nussbaum, and Raxworthy 2000). These frogs were separated from ranoid frogs on the Indian subcontinent and the future Seychelles Islands about 87.6 million years ago as the Indian-Seychelles landmass drifted northward (Bossuyt and Milinkovitch 2001). Frogs on Madagascar subsequently evolved into various ecotypes that are very similar to those found among Asian ranid and rhacophorid frogs.

Another persistent problem in interpreting relationships among neobatrachian families has been the position of the family Dendrobatidae. Some of the toxic dendrobatids are very similar to frogs of the genus *Mantella* from Madagascar in morphology, behavior, and ecology (Daly et al. 1996; Heying 2001; Vences et al. 2003; V. Clark et al. 2005), but there is no evidence that these frogs are closely related. Dendrobatids traditionally had been placed within the ranoid frogs (Ford 1993; Ford and Cannatella 1993), although some earlier workers postulated a relationship of dendrobatids to hylodine (cycloramphine) leptodactylid frogs (e.g., Lynch 1971, 1973). Recent evidence does not support a close relationship with ranoid frogs. For example, all recent molecular phylogenies place the dendrobatids outside of the ranoids and within the hyloids (Hedges and Maxson 1993; Hay et al. 1995; Ruvinsky and Maxson 1996; Vences, Kosuch et al. 2000; Darst and Cannatella 2004). Frost et al. (2006) suggested a close relationship to the leptodactylid genus *Thoropa,* which they placed in a new family, Thoropidae.

The hyloids constitute a monophyletic clade that includes the cosmopolitan family Bufonidae, the Sooglossidae of the Seychelles Islands, the Nasikabatrachidae, the Heleophrynidae of southern Africa (not included in Hyloidea by Frost et al. 2006), the Australian Myobatrachidae, and a group of mostly Neotropical families (Allophrynidae, Brachycephalidae, Centrolenidae, Hylidae, Leptodactylidae, and Rhinodermatidae). Dendrobatids appear to fit within this Neotropical group, an arrangement that makes sense biogeographically (Darst and Cannatella 2004). Cranial features of the tadpoles also support a relationship of dendrobatids with the Neotropical hyloid families (Haas 1995), while some features of the finger muscles are consistent with a close relationship between dendrobatids and leptodactylid frogs in the subfamily Cycloramphinae (Hylodinae; T. C. Burton 1998). In contrast, a peculiar morphological feature in some dendrobatids in the genus *Colostethus,* an unusual process on the tongue, supports a relationship with African ranoid frogs, but not leptodactylids (Grant, Humphrey, and Myers 1997). The molecular data indicate that these morphological features almost certainly represent convergent evolution in dendrobatids and ranoids.

There are many other problems yet to be resolved in the phylogeny of anurans. Several of the largest traditional anuran families, including the Hylidae, Leptodactylidae, and Ranidae, clearly are not monophyletic groups united by shared derived characters; these families eventually will be divided into smaller families that are monophyletic (see Frost et al. 2006 for a proposed rearrangement of these groups). Relationships within some of the other large families, including the Bufonidae and Myobatrachidae, are not fully understood, and the monophyly of the latter family has been questioned by some systematists. There also are inconsistencies between some recent molecular analyses and morphological data that must be resolved with further work. A full discussion of anuran systematics is beyond the scope of this book, but some of these issues are discussed briefly in the family accounts that follow.

Throughout the book, I have pursued a relatively conservative approach to names of families, genera, and species, using names that have been widely adopted in the literature. Since this is not a book on systematics, I have chosen not to enter into the current debate over the use of phylogenetically based taxon names, as opposed to traditional taxonomic nomenclature (De Queiroz and Gauthier 1990, 1992; Graybeal and Cannatella 1995; Frost et al. 2006). For that reason, I have retained the use of traditional family names. At lower taxonomic levels, I have largely followed Amphibian Species of the World (Frost 2004) and Amphibia Web (http://elib.cs.berkeley.edu/aw/index.html). My main criterion has been to avoid confusion and to make it possible for readers to find behavioral and ecological literature published on particular species.

Synopsis of Families of Anura

The following accounts provide a brief summary of the classification, distribution, and natural history of the currently recognized families of anurans. Families are given in alphabetical order for ease of reference and are not grouped according to higher taxonomic levels. The arrangement of families and subfamilies and numbers of genera and species generally follows Frost (2004) and is similar to the classifications in Zug, Vitt, and Caldwell (2001), Duellman (2003), and Pough et al. (2004). Numbers of genera and species should be taken as approximate figures, since the taxonomy of many groups is constantly being revised and new species are discovered every year, especially from the tropics. The taxonomy used here is one of several that are possible and has been chosen as the most widely recognized arrangement. Detailed diagnostic morphological characters of each family are not given; readers should consult Duellman and Trueb (1986), Ford and Cannatella (1993), Zug, Vitt, and Caldwell (2001), and Pough et al. (2004) for this information. For the most part, I have not provided detailed literature citations, except in cases where there has been some dispute over taxonomy. Information on distributions and general natural history come from literature cited elsewhere in the book and from standard reference sources, including Wright and Wright (1949), Liu (1950), Stebbins (1954a, 1985), Cei (1962, 1980), Okada (1966), Stewart (1967), Duellman (1970, 2001), E. N. Arnold and Burton (1978), Duellman and Trueb (1986), Inger and Stuebing (1989), Heyer et al. (1990), Conant and Collins (1991), Glasby, Ross, and Beesley (1993), Glaw and Vences (1994), Passmore and Carruthers (1995), Kuzmin (1999), Schiøtz (1999), Cogger (2000), Lescure and Marty (2000), Channing (2001), Zug, Vitt, and Caldwell (2001), Savage (2002), Pough et al. (2004), and Lannoo (2005).

Family Allophrynidae

Distribution: Guianan region of northeastern South America, including parts of Surinam, Guyana, French Guiana, Venezuela, and Brazil.

Content: A single species, *Allophryne ruthveni* (fig. 1.12 A). The relationship of this frog to other anurans has long been a puzzle to systematists. Since it was described in the 1920s, this frog has been variously placed in the families Bufonidae, Centrolenidae, and Hylidae. Ford and Cannatella (1993) failed to find derived characters uniting this species with hylids. They left its placement in a higher taxon unresolved, but Savage (1973) had previously placed it in a monotypic family, and this is the taxonomy currently used by most systematists (Caldwell and Hoogmoed 1998). Analyses using DNA sequences indicated that *Allophryne* is either the sister group to the Centrolenidae (Austin et al. 2002), or is a member of that family (Frost et al. 2006), although it does not resemble centrolenids in general morphology or breeding behavior. An analysis based on hind foot muscle morphology also showed a close relationship to centrolenids, with both families closely related to hylids (T. C. Burton 2004).

Natural History: The natural history of this frog is poorly known, but it seems to be a typical treefrog that calls from vegetation around ponds, streams, and rivers, and lays eggs in water.

Family Arthroleptidae

Distribution: Tropical Africa.

Content: Three genera, about 50 species. These frogs traditionally were treated as a subfamily of ranids, although Laurent (1986) placed arthroleptines in the family Hyperoliidae. Dubois (1981) united the subfamilies Arthroleptinae and Astylosterninae into the family Arthroleptidae, which was included in Duellman's (1993a) checklist. Ford and Cannatella (1993) could not identify any shared derived characters uniting the two subfamilies and therefore considered the monophyly of the family to be questionable. Following Dubois (1999), Frost (2004) grouped the genera *Arthroleptis* (16 species), *Cardioglossa* (16 species), and *Schoutedenella* (19 species; fig. 1.12 B) in the family Arthroleptidae *sensu stricto,* whereas Duellman (2003) retained the earlier classification uniting arthroleptines and astylosternines into a single family. Frost et al. (2006) placed the arthroleptine and astylosternine genera, along with the genus *Leptopelis* (often placed in the family Hyperoliidae) in an expanded family, Arthroleptidae.

Natural History: The natural history of this family is poorly studied. Most arthroleptids are small to medium-size forest-floor or savanna frogs that lay terrestrial eggs that undergo direct development, except for *Cardioglossa,* which has tadpoles.

Family Ascaphidae

Distribution: Pacific Northwest region of North America.

Content: One genus, two species. Until recently, only one species, *Ascaphus truei* (fig. 1.12 C), was recognized. Nielson, Lohman, and Sullivan (2001) presented a phylogeographic analysis based on mitochondrial DNA and concluded that inland Rocky Mountain populations should be considered a separate species, *A. montanus.* This genus sometimes has been included in the family Leiopelmatidae (Duellman and Trueb 1986; Duellman 1993a), but *Ascaphus* and *Leiopelma* are united only by shared ancestral characters, not shared derived characters. Ford and Cannatella (1993) considered *Ascaphus* to be a separate clade that is the sister group to all remaining anurans. Mitochondrial DNA data place the ascaphids and leiopelmatids as sister taxa (Hay et al. 1995; Roelants and Bossuyt 2005; Frost et al. 2006). As discussed previously, several other molecular and morphological analyses place these as the most basal frogs.

Natural History: These so-called "tailed" frogs live in cold mountain streams and are unique in that males have a copulatory organ that is used to fertilize eggs internally. It

Fig. 1.12. Diversity of anurans (Allophrynidae to Brachycephalidae). (A) *Allophryne ruthveni* (Allophrynidae) from South America. (B) *Schoutedenella xenodactyla* (Arthroleptidae) from West Africa. (C) *Ascaphus truei* (Ascaphidae) male, showing copulatory organ, from Washington. (D) *Trichobatrachus robustus* (Astylosternidae) from West Africa. (E) *Bombina orientalis* (Bombinatoridae) from Asia. (F) *Brachycephalus ephippium* (Brachycephalidae) from Brazil; male giving foot-waving display. Photos by Walter Hödl (A, B), William P. Leonard (C), Wayne Van Devender (D), Martha L. Crump (E), and Celio F. B. Haddad (F). For additional photos of these families, see fig. 7.6 E, 14.29 A (*Bombina*), and 10.1 C, D (*Brachycephalus*).

is derived from the cloaca, but has its own skeleton and musculature. Mating sometimes takes place several months before oviposition, with sperm being stored in the female's reproductive tract (Sever et al., 2001, 2003). Eggs are laid in rosary-like strings attached to rocks. The tadpole has an oral disc that allows it to hold onto rocks in swift currents.

Family Astylosternidae

Distribution: Tropical Africa.

Content: Five genera, 29 species. These frogs were traditionally treated as a subfamily of ranids, although Laurent (1986) placed astylosternines in the family Hyperoliidae. Dubois (1981) united the subfamilies Arthroleptinae and Astylosterninae into the family Arthroleptidae, which was included in Duellman's (1993a) checklist. Ford and Cannatella (1993) could not identify any shared derived characters uniting the two subfamilies and therefore considered the monophyly of the family to be questionable. Following Dubois (1999), Frost (2004) (http://research.amnh.org/cgi-bin/herpetology/amphibia_tree) grouped the genera *Astylosternus* (11 species), *Leptodactylodon* (15 species), *Nyctibates* (one species), *Scotobleps* (one species), and *Trichobatrachus* (one species; fig. 1.12 D) in the family Astylosternidae, whereas Duellman (2003) retained the earlier classification uniting arthroleptines and astylosternines into a single family. Frost et al. (2006) combined the arthroleptine and astylosternine genera with the genus *Leptopelis* (traditionally placed in the family Hyperoliidae) into an expanded family, Arthroleptidae.

Natural History: The natural history of this family is poorly studied. Most astylosternids are riparian, living along rivers and streams. The most famous species is the hairy frog (*Trichobatrachus*), which gets its name from the long hair-like projections that males develop during the breeding season, apparently as auxiliary respiratory organs. All members of this family have aquatic larvae.

Family Bombinatoridae

Distribution: Europe and Asia.

Content: Two genera, *Bombina* (eight species) and *Barbourula* (two species). These two genera are sometimes included in the family Discoglossidae. They are united by a number of derived characters that have led taxonomists to place them in a separate family (Lanza, Cei, and Crespo 1976; Cannatella 1985, 1989; Clarke 1987; Ford and Cannatella 1993), although the debate about the relationships among the discoglossoid frogs continues (Haas 2003; Púgener, Maglia, and Trueb 2003; Hertwig, da Sa, and Haas 2004; Roelants and Bossuyt 2005; Frost et al. 2006).

Natural History: Species of *Bombina* (fig. 1.12 E) are marked with conspicuous red, yellow, or orange aposematic coloring, mainly on the ventral surface, and have highly distasteful and toxic skin secretions. They lay eggs in shallow ponds and are relatively aquatic as adults, but do venture onto land and readily move between ponds. *Barbourula,* from Borneo and the Philippines, is adapted for living in fast-moving streams, and also has a partially tropical distribution. It feeds in part on freshwater crabs and lays large, unpigmented eggs under rocks in streams.

Family Brachycephalidae

Distribution: Humid coastal forests of southern Brazil.

Content: A single genus, *Brachycephalus* (fig. 1.12 F), with eight species, including two species formerly placed in the genus *Psyllophryne.* This small family is endemic to the Atlantic coastal forests of Brazil. Brachycephalids are generally toadlike in appearance and are among the smallest living anurans. The relationships of these very small anurans to other families are unclear, but there is some evidence that they are related to small terrestrial frogs in the genus *Euparkerella,* which are classified as leptodactylids (Giaretta and Sawaya 1998). Darst and Cannatella (2004) found these frogs to be most closely related to eleutherodactylines, and suggested that recognition of the group as a separate family was not warranted. Frost et al. (2006) recommended greatly expanding this family to include the genus *Eleutherodactylus* and its relatives, all previously placed in the family Leptodactylidae. If this change is adopted, the family Brachycephalidae would go from being one of the smallest anuran families to one of the largest, with 16 genera and hundreds of species, all of which apparently produce terrestrial eggs that undergo direct development.

Natural History: Very little is known about the natural history of this family. They appear to be typical forest-floor anurans that feed on small insects. One species, *Brachycephalus ephippium,* is bright orange and has highly toxic skin secretions. It is diurnally active and lays eggs in the soil under leaf litter, where they undergo direct development (Pombal, Sazima, and Haddad 1994; Pombal 1999). The other species are cryptically colored, but details of their breeding biology and ecology are unknown.

Family Bufonidae

Distribution: Worldwide, except for Madagascar, Australia, New Guinea, and oceanic islands (*Bufo marinus,* a South American species originally thought to be useful in controlling sugar cane beetles, has been introduced into many Caribbean islands, Australia, and many Pacific islands, including Hawaii and the Philippines).

Content: About 33 genera, 480 species. There is no doubt that this family is a monophyletic group, but relationships within the family are poorly understood. The largest genus is *Bufo,* with more than 250 species (fig. 1.13 A, B). Recent analyses based on molecular characters indicate that this genus probably is not monophyletic as presently constituted, because some species share presumed derived characters not found in most members of the genus (Graybeal and Cannatella 1995; Graybeal 1997). On the other hand, some other small bufonid genera actually may belong in the genus *Bufo.* For example, Asian toads from the Himalayas that were placed in the genus *Torrentophryne* because of their unusual morphology and stream-adapted tadpoles appear to be nested within a clade of Asian *Bufo* (Liu et al., 2000). Indeed, Graybeal and Cannatella (1995) found clear evidence of monophyly for only 12 of 33 bufonid genera. The origin of the many species of *Bufo* in North America has been much debated, with various systematists arguing for a close relationship of some or all of these species to African, South American, or Eurasian species. The molecular phylogeny of Pauly, Hillis, and Cannatella (2004) strongly supported a monophyletic clade of North American *Bufo* derived from a Neotropical ancestor.

The Neotropical genus *Atelopus* (fig. 1.13 D), with about 70 species, is the only other genus in the family with more than 25 species. Molecular data suggest that this genus and other Neotropical bufonids not included in *Bufo* (*Osornophryne, Melanophryniscus*) split off relatively early from other bufonids (Graybeal, 1997). Many named genera in this family are very small, with only one to five described species, and have restricted ranges (examples in fig. 1.13 C, F). Several African species originally placed in the genus *Nectophrynoides* (fig. 1.13 E) were placed in separate genera (*Altiphrynoides, Nimbaphrynoides, Spinophrynoides*) by Dubois (1986) because of differences in reproductive biology. These names are used in Frost (2004) but have not been universally adopted by other authors. Nevertheless, egg pigmentation and several morphological characters provide some evidence that the two viviparous species (placed in the genus *Nimbaphrynoides* by Dubois) do in fact form a monophyletic clade, while *Nectophrynoides* in the broad sense does not (Graybeal and Cannatella 1995; Frost et al. 2006). The genera *Altiphrynoides* and *Spinophrynoides* have only one species each, but together appear to form a monophyletic group.

Natural History: The so-called true toads (*Bufo*) are found on all major continents except Australia (where one species has been introduced), in both temperate and tropical regions. Despite considerable variation in size, many toads are similar in general morphology and natural history. Most are relatively heavy-bodied, squat anurans with short legs, rough skin, and conspicuous parotoid glands on the head that produce distasteful and sometimes highly toxic secretions containing bufotoxin. These secretions are produced in smaller glands all over the body as well. Many toads feed heavily on ants, which may provide them with at least some of the toxic or distasteful chemicals in their skin. Despite these secretions, most toads are not aposematically colored, probably because of their largely nocturnal habits. Some toads, however, are brightly colored and exhibit marked sexual differences in color, with males being much brighter than females. Most of these species, which include the bright orange *Bufo periglenes* from Costa Rica and *B. canorus* from North America, are active during the day. Most species are terrestrial as adults and are capable of burrowing in soft soils or sand. Toads are moderately active foragers that move by hopping or walking rather than jumping. All species of *Bufo* lay aquatic eggs, usually deposited in long strings in ponds, ditches, and other still bodies of water. Most have aquatic larvae that feed throughout development, but a few species have nonfeeding tadpoles.

The genus *Atelopus* is found mainly along streams in tropical and montane forests of South and Central America (Lötters 1996). These terrestrial anurans have thin bodies, long legs, and slender toes, and generally have bright aposematic markings of red, orange, yellow, and black that advertise their toxic skin secretions. They are largely diurnal and tend to move by walking, rather than hopping like most *Bufo.* They lack a tympanum and a middle ear, yet many species have well-developed vocalizations and can hear airborne sounds. Species of *Atelopus* are stream breeders, usually laying large, unpigmented eggs attached to rocks. The tadpoles have ventral suckers that enable them to hold onto rocks in swift currents. Similar tadpole adaptations are found in several small Old World genera, including the Asian genus *Ansonia* (about 20 species) and the African genus *Werneria* (four species). Arboreal habits are uncommon in bufonids, but some species of *Ansonia, Bufo,* and *Pelophryne* climb onto low vegetation. The brown tree toad of Borneo (*Pedostibes hosii*) is a forest-dwelling arboreal species.

A number of bufonid genera include species with unusual reproductive modes, such as terrestrial oviposition with direct development of eggs in *Oreophrynella,* arboreal oviposition with nonfeeding tadpoles in *Pelophryne,* terrestrial nonfeeding larvae in *Altiphrynoides malcolmi,* ovoviviparity in *Nectophrynoides,* and viviparity in *Nimbaphrynoides liberiensis* and *N. occidentalis.* The last two genera have internal fertilization, as does another African bufonid, *Mertensophryne micranotis.*

Family Centrolenidae

Distribution: Wet tropical forests from southern Mexico through Central America to Argentina.

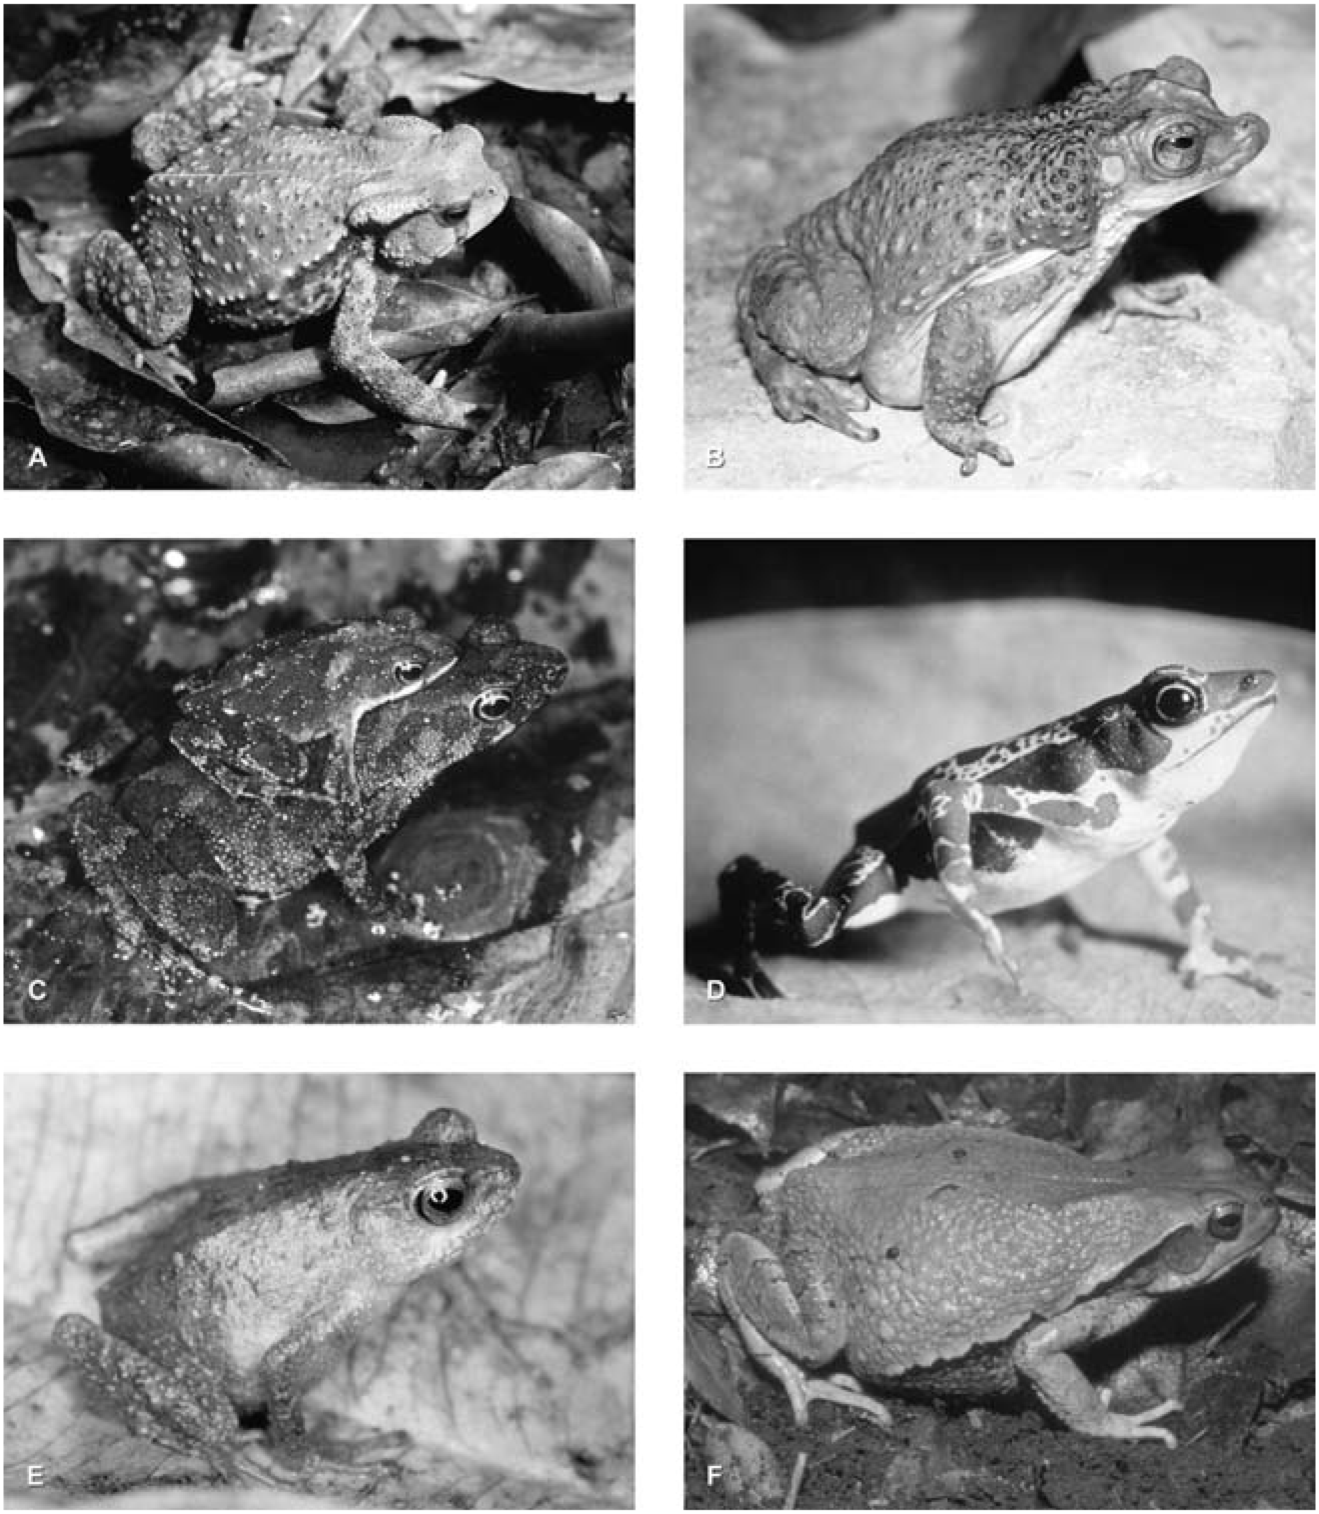

Fig. 1.13. Diversity of anurans (Bufonidae). (A) *Bufo bankorensis* from Taiwan. (B) *Bufo lemur* from Puerto Rico. (C) *Dendrophryniscus minutus* from South America; small male in amplexus with a very large female. (D) *Atelopus varius* from Central America; male giving leg-waving display. (E) *Nectophrynoides tornieri* from East Africa, a viviparous toad. (F) *Schismaderma carens* from South Africa. Photos by Kentwood D. Wells (A), Wayne Van Devender (B), Walter Hödl (C–E), and Alan Channing (F). For additional photos of bufonids, see fig. 1.22 D (*Mertensophryne*); 2.3 B, 8.6 A–C, 14.26 D, 16.5 C, 16.8 A, C, 16.10 C (*Bufo*); and 14.32 D (*Atelopus*).

Content: Three genera, about 135 species (the inclusion of *Allophryne ruthveni* in this family would add one genus and one species to the total; Frost et al. 2006). Most of these frogs are associated with streams in lowland and montane tropical forests, but *Centrolene geckoideum* is found in paramo swamps at altitudes of more than 4,000 m in the Andes of Colombia. Centrolenids appear to be closely related to hylids and to *Allophryne* (Austin et al. 2002; T. C. Burton 2004; Darst and Cannatella 2004). Traditionally, many members of the family were placed in the very large genus *Centrolenella,* but Ruiz-Carranza and Lynch (1991a) redistributed its species among the genera *Centrolene, Cochranella,* and *Hyalinobatrachium* (fig. 1.14 A). However, the name *Centrolenella* continued to be widely used until recently, and much of the behavioral and ecological literature on these frogs is published under that name. The genera *Centrolene* and *Cochranella* may not be monophyletic groups as currently constituted (Frost et al. 2006). Frogs in this family often have restricted ranges, and many new species have been described from South America in recent years.

Natural History: Most species in this family are treefrogs, with enlarged toe pads that allow them to climb on branches and leaves of plants overhanging streams; a few live on rocks in and around streams. Many species are translucent green, with the internal organs visible through the transparent underside, a feature that gives these frogs the common name “glass frogs.” Eggs are laid out of water, usually on the undersides of leaves overhanging streams. In some species the eggs are attended by the male. Tadpoles of at least some species are fossorial, burrowing into the mud at the bottoms of streams. Some species of *Centrolene* lay eggs on rocks next to streams where the tadpoles complete their development.

Family Dendrobatidae

Distribution: Tropical South and Central America, some islands in West Indies.

Content: Nine to eleven genera, more than 240 species. The systematics of this family has been much disputed. Many previously unrecognized or undescribed species are known to exist in several major genera (Symula et al. 2003), so the total number of species is unknown. The relationship of dendrobatids to other anurans has been unclear, but now seems reasonably well resolved. This family traditionally was placed among the ranoid frogs (e.g., Ford and Cannatella 1993), but recent morphological and molecular studies clearly support a close relationship with other Neotropical hyloid families, especially leptodactylids in the subfamily Hylodinae (Cycloramphinae; Hedges and Maxson 1993; Haas 1995, 2003; Hay et al. 1995; Ruvinsky and Maxson 1996; T. C. Burton 1998; Vences, Kosuch et al. 2000; Garda et al. 2002; Duellman 2003; Darst and Cannatella 2004). Frost et al. (2006) considered the genus *Thoropa* to be the sister group to dendrobatids.

The taxonomy and relationships of major clades within the family have been in dispute as well. Traditionally the large, cryptically colored and nontoxic genus *Colostethus* has been considered the most basal lineage of dendrobatids, with various genera of toxic frogs being more derived. Myers, Paolillo O., and Daly (1991) argued that the groups with toxic skin secretions and aposematic coloration (*Dendrobates, Epipedobates,* and *Phyllobates*) represent a derived monophyletic clade, and this was supported by an analysis of DNA sequences in which relatively few species of nontoxic *Colostethus* were included (Clough and Summers 2000). In contrast, more complete molecular studies suggest that aposematic coloration and toxicity have evolved independently as many as five times, and cryptically colored species traditionally placed in the genus *Colostethus* actually belong to a number of separate clades that are not closely related to each other (Santos, Coloma, and Cannatella 2003; Vences, Kosuch et al. 2003). Furthermore, some species of *Colostethus,* such as the Central American species *C. pratti,* appear to be deeply nested within a clade of *Epipedobates* (Santos, Coloma, and Cannatella 2003) or more closely related to species of *Epipedobates* than to other *Colostethus* (Vences, Kosuch et al. 2003).

La Marca (1992, 1995) placed nine species of *Colostethus* (the *Colostethus collaris* group) from Venezuela, Trinidad, and Tobago, which have dark collars around the throat, in a separate genus, *Mannophryne* (several more species have since been assigned to this genus; Mijares-Urrutia and Arends 1999). This name has been disputed by other systematists, and the original description criticized for lack of detail (Kaiser and Altig 1994; Kaiser, Coloma, and Gray 1994; T. Grant, Humphrey, and Myers 1997). Chromosomal studies are not helpful in resolving the issue, because *Mannophryne* (*M. trinitatis, M. herminae, M. olmonae*) and some *Colostethus* (*C. leopardalis*) have the same number of chromosomes (Kaiser et al. 2003). One molecular phylogenetic study supported the validity of the genus *Mannophryne* (Vences, Kosuch et al. 2003), while another did not include any of these species in the analysis (Santos, Coloma, and Cannatella 2003). La Marca (1994) placed nine species from the Venezuelan Andes in a new genus, *Nephelobates* (corresponding to the *Colostethus albogularis* group), but again, the validity of this genus has been disputed. The molecular analysis of Vences, Kosuch et al. (2003) supported the monophyly of this genus, whereas the study by Santos, Coloma, and Cannatella (2003) did not address the issue.

The large genus *Epipedobates* has been considered a relatively basal group, but unlike *Colostethus,* has toxic skin

Fig. 1.14. Diversity of anurans (Centrolenidae to Mantellidae). (A) *Hyalinobatrachium fleischmanni* (Centrolenidae) from Panama; pair in amplexus. (B) *Dendrobates virolinensis* (Dendrobatidae) from Colombia. (C) *Heleophryne purcelli* (Heleophrynidae) from South Africa. (D) *Hemiphractus proboscieis* (Hemiphractinae) from Ecuador. Crump (D), Harold Cogger (E), and Wayne Van Devender (F). For additional photos of these families, see fig. 11.2 D (*Hyalinobatrachium*); 1.22 A, 11.7 C, D; 14.32 C (*Dendrobates*); 8.13 B, 14.33 D (*Allobates*); 8.14, 11.7 B (*Mannophryne*); 2.8 A, 10.1, 11.7 A (*Colostethus*); 14.32 A (*Phyllobates*); 14.33 E, F (*Epipedobates*); 11.3 (*Stefania*); 11.4 (*Flectonotus, Gastrotheca*); and 14.32 B (*Mantella*). For a photo of the family Hemisotidae, see fig. 11.5 (*Hemisus*).

secretions. Several molecular phylogenies indicate that this genus consists of an assemblage of unrelated lineages, so eventually the taxonomy of the genus will need to be revised (Vences, Kosuch et al. 2000, 2003; Santos, Coloma, and Cannatella 2003; Frost et al. 2006, recommended eliminating the name *Epipedobates* and placed most species in the genus *Ameerega,* which itself may not be monophyletic). Two genera, *Allobates* and *Phobobates,* proposed by Zimmermann and Zimmermann (1988) on the basis on differences in reproductive biology, were considered to be synonyms of *Epipedobates* by Myers, Paolillo O., and Daly (1991), and they have not been universally recognized as separate genera. Originally the genus *Allobates* included only a single species, *A. femoralis,* but other authors have continued to treat this species as a member of the genus *Epipedobates* (e.g., Aguiar-Junior et al. 2003; Narins, Hödl, and Grabul 2003). The molecular analyses of Santos, Coloma, and Cannatella (2003) and Vences, Kosuch et al. (2000, 2003) placed this species closer to several species of *Colostethus* than to other species of *Epipedobates,* as did analyses of chromosome structure (Aguiar-Junior et al. 2002) and sperm morphology (Aguiar-Junior et al. 2003). Both Vences, Kosuch et al. (2003) and Santos, Coloma, and Cannatella (2003) added another species to this genus, *A. zaparo* (previously *Epipedobates zaparo*) and found support for *Allobates* as a monophyletic clade closely related to one lineage of *Colostethus.* Vences, Kosuch et al. (2000, 2003) and Santos, Coloma, and Cannatella (2003) found the two species of *Phobobates* (*P. trivittatus* and *P. silverstonei*) to be nested within the genus *Epipedobates,* and the genus *Phobobates* is not generally recognized.

Lötters, Jungfer, and Widmer (2000) removed another species, *Epipedobates azureiventris,* from the genus *Epipedobates* and placed it in a new genus, *Cryptophyllobates.* The molecular phylogenies of Vences, Kosuch et al. (2000, 2003) indicated that this species is most closely related to *Colostethus bocagei,* whereas the analysis of Santos, Coloma, and Cannatella (2003) placed it deeply nested within a clade of *Colostethus,* so its generic status is uncertain.

Frogs in the genera *Phyllobates* (five species) and *Dendrobates* (about 37 species; fig. 1.14 B) appear to form a derived monophyletic group that has aposematic coloration and highly toxic skin secretions (Clough and Summers 2000; Vences, Kosuch et al. 2000, 2003; Santos, Coloma, and Cannatella 2003). These secretions give the family the name dart-poison frogs, although only three species of *Phyllobates* actually are known to have been used by tribes in South America to poison blowgun darts. *Phyllobates* clearly appears to be monophyletic (Widmer, Lötters, and Jungfer 2000). *Dendrobates* and several very small frogs often placed in the genus *Minyobates* appear to be closely related. All recent molecular studies have indicated that species formerly placed in *Minyobates* actually belong within the genus *Dendrobates* (Clough and Summers 2000; Vences, Kosuch et al. 2000, 2003; Santos, Coloma, and Cannatella 2003), making that genus monophyletic as well.

An unusual dendrobatid is *Aromobates nocturnus* (Myers, Paolillo O., and Daly 1991), the only species in the family that is active mainly at night. It lacks aposematic coloration and the toxic skin secretions typical of the family, although it produces another type of defensive secretion with an obnoxious odor. It appears to be the most primitive living dendrobatid and the sister group of all other members of the family, but it has never been included in any molecular phylogenetic analysis. The apparent close relationship between dendrobatids and hylodine leptodactylids, which are diurnal, raises questions about whether the nocturnal habits of this species are ancestral or derived.

Natural History: Except for *Aromobates,* these frogs are largely diurnal. Many species of *Colostethus, Mannophryne,* and *Nephelobates* are associated with rocky streams. The other genera are mostly forest-floor frogs, but *Allobates* and *Epipedobates* exhibit a variety of habitat preferences. Some species have considerable climbing ability and may regularly ascend into trees to deposit tadpoles in bromeliads and water-filled tree holes. These frogs are very active and can be seen hopping about the forest floor in search of food. Males of many species are highly territorial and engage in prolonged fights with one another. Most members of the family lay terrestrial eggs that hatch into tadpoles that are carried by either the male or female (depending on the species) to water, where they complete their development. In some *Dendrobates,* females place tadpoles in bromeliads and feed them with unfertilized eggs. In a few species of *Colostethus,* the tadpoles are not carried to water, but complete their development in a terrestrial nest, where they do not feed.

Family Discoglossidae

Distribution: Europe, the Middle East, and North Africa.

Content: Two genera, 12 species. The two genera, the largely terrestrial midwife toads (*Alytes*) and the more aquatic *Discoglossus,* are quite distinct from each other. Some classifications, including Duellman's (1993a) checklist, placed the genera *Bombina* and *Barbourula* in this family as well. The two genera are united by a number of derived skeletal and molecular characters and are now generally considered a separate family (see Bombinatoridae; Lanza, Cei, and Crespo 1976; Cannatella 1985, 1989; B. T. Clarke 1987; Ford and Cannatella 1993). Frost et al. (2006) used the name Alytidae for the family designated as Discoglossidae in this book.

Natural History: The European midwife toads (*Alytes*) are terrestrial species that mate on land. Males wrap strings of eggs around their hind legs and carry them until they are ready to hatch. Tadpoles are then deposited in ponds. Frogs in the genus *Discoglossus* are pond-breeders that lay small, pigmented eggs individually or in small clusters on the bottoms of shallow ponds.

Family Heleophrynidae

Distribution: Southern Africa.

Content: One genus, *Heleophryne,* with six species (fig. 1.14 C). These frogs often have been considered closely related to Australian myobatrachids or to leptodactylids, but there are no shared derived morphological characters uniting *Heleophryne* with these families (Ford and Cannatella 1993). Two analyses based on DNA sequences place *Heleophryne* as the sister group to myobatrachids (Hay et al. 1995; Biju and Bossuyt 2003). San Mauro et al. (2005) and Frost et al. (2006) placed this family as the sister group to all remaining neobatrachians.

Natural History: These so-called ghost frogs are found in the mountains of South Africa, where they breed in fast-flowing streams. They have flattened bodies, long legs, and expanded toe pads for clinging to wet rocks. The skin is covered with small hooks or spines that may facilitate climbing on wet rock surfaces. Eggs are laid attached to rocks underwater. Tadpoles have suckerlike mouths that allow them to cling to rocks, where they graze on algae. They are unique among anuran larvae in having relatively large mouths without horny beaks, but they do have many rows of small denticles. Very little is known about the natural history of these frogs.

Subfamily Hemiphractinae

Distribution: Panama and South America; one species in Trinidad and Tobago.

Content: Five genera, about 80 species. The so-called "marsupial frogs" have long been treated as a subfamily of Hylidae. Morphologically they are treefrogs (fig. 1.14 D), but are distinguished by their unusual modes of reproduction, with eggs being carried in various ways on the female's body. Recent phylogenetic studies have shown that this clade probably is more closely related to leptodactylids than to hylids, but there is not a clear agreement on the proper taxonomic treatment of the group. Taxon sampling, characters, and methods of analysis differed among recent phylogenetic studies. Darst and Cannatella (2004) included only two genera, *Cryptobatrachus* and *Gastrotheca,* in their analysis, which was based entirely on two mitochondrial genes. They found these genera to be more closely related to leptodactylids than to hylids, but not necessarily closely related to each other. Faivovich et al. (2005) included all five genera in an analysis based mostly on molecular characters. Their analysis showed all hemiphractines to be nested within a paraphyletic assemblage of leptodactylids, but not necessarily as a monophyletic group. Wiens et al. (2005) also included all five genera in their analysis, but used different statistical methods to analyze their data. In their analysis, both morphological and molecular data alone, and morphological and molecular data combined, supported the monophyly of hemiphractines, with this clade again being most closely related to leptodactylids. They recommended elevating the group to full family status. A more recent analysis suggested that hemiphractines constitute several independent clades that are not closely related to each other (Frost et al. 2006). Given the lack of clear consensus among these studies, I have retained the subfamilial name, without allocating these frogs to a particular family.

Natural History: These frogs are unique in that all members of the group have unusual reproductive modes, with eggs being carried in pouches or exposed on the back of the female. In some cases, eggs hatch into tadpoles that are deposited in bromeliads or other bodies of water, but in others, embryos undergo direct development on the female, In at least some species in the genus *Stefania,* tiny froglets are transported on the back of the female for a period of time after hatching (see chapters 10 and 11 for more details). If the hemiphractines actually comprise several different clades, as suggested by Frost et al. (2006), then their unusual reproductive modes would have evolved independently, and indeed, there are major differences in modes of development among the various genera.

Family Hemisotidae

Distribution: Tropical and subtropical sub-Saharan Africa.

Content: A single genus, *Hemisus,* with nine species (fig. 1.25 A). These frogs were formerly treated as a subfamily of ranids, but they are very different morphologically and ecologically from most ranids. The combined morphological and molecular analysis of Emerson et al. (2000) grouped these frogs with microhylids, but their analysis did not include key genera of African ranid frogs and did not fully represent the diversity of microhylids. Frost et al. (2006) retained this genus in its own family, closely allied to the brevicepitine microhylids, which they found not to be closely related to other subfamilies of Microhylidae.

Natural History: These are burrowing frogs with a morphology resembling that of some burrowing microhylids. They have narrow snouts that allow them to burrow head-first into soil. They feed mainly on ants and termites. Eggs are laid in a terrestrial burrow near ponds and temporary pools, where they are attended by the female. When the eggs hatch, the female digs a tunnel that allows the tadpoles to reach the water, where they complete their development.

Family Hylidae

Distribution: North, Central, and South America, West Indies, Europe, North Africa, Asia north of the Himalayas, Japan, Australia, New Guinea, Solomon Islands.

Content: About 42–45 genera, more than 800 species. Traditionally four subfamilies were recognized: Hemiphractinae, Hylinae (fig. 1.15 A, B), Phyllomedusinae (fig. 1.15 C), and Pelodryadinae (fig. 1.15 E, F), but with the removal of the hemiphractines from the family, only the other three subfamilies remain (see "Subfamily Hemiphractinae," discussed earlier). Duellman (2001, 2003) placed the semiaquatic genera *Pseudis* (fig. 1.15 D) and *Lysapsus,* which traditionally were treated as a separate family Pseudidae, within the hylids as the subfamily Pseudinae. Zug et al. (2001) and Pough et al. (2004) continued to treat these frogs as a separate family. Most recent phylogenetic analyses place these two genera as nested within the subfamily Hylinae, despite considerable differences in morphology (Darst and Cannatella 2004; Faivovich et al. 2005; Wiens et al. 2005; Frost et al. 2006). Salducci et al. (2002) placed the Centrolenidae nested within the subfamily Hylinae, but their analysis included only one species of *Hyalinobatrachium.* The more complete analyses of Darst and Cannatella (2004), Faivovich et al. (2005), Wiens et al. (2005), and Frost et al. (2006) did not support this arrangement. Two of the major clades of hylids are centered in the Neotropics (Hylinae, Phyllomedusinae), but hylines also are found in North America and Eurasia. All of the North American and Eurasian hylids appear to be part of a large Middle American clade and probably are relatively recent invaders of these continents. The subfamily Pelodryadinae is found in Australia, New Guinea, and the Solomon Islands. Despite their geographic separation, most recent phylogenetic analyses support a close relationship between the Phyllomedusinae and the Pelodryadinae.

The exact number of genera in this family has yet to be determined. Faivovich et al. (2005) erected a number of new genera for clades within the Hylinae. Wiens et al. (2005) did not consider all of these taxonomic changes to be necessary, but suggested some new generic assignments of their own. Given the fluid state of the taxonomy of the subfamily Hylinae, I have not attempted to replace the name *Hyla* with new genus names in the rest of this book, even though this large genus does not appear to be monophyletic as traditionally constituted.

Natural History: Most hylids are tree frogs that have enlarged toe pads for climbing on vegetation ranging from low grasses and shrubs to the top of the canopy in tropical rainforests. Some genera, such as the North American cricket frogs (*Acris*) and chorus frogs (*Pseudacris*), have smaller toe pads or lack them altogether, and are largely terrestrial or semiaquatic (fig. 1.15 A). The New World hylids are very diverse morphologically and ecologically and exhibit a wide range of reproductive modes (see chapter 10). Members of the very large genus *Hyla* are mostly arboreal and are the dominant tree frogs in the Neotropics, North America, and Eurasia. Some species of *Hyla* exhibit limited burrowing ability, as do several species of *Pseudacris,* while other hylids, such as the New World genus *Pternohyla,* are specialized burrowers. *Pseudis* and *Lysapsus* are highly aquatic, with fully webbed feet and very large hind legs. In the so-called paradoxical frog (*Pseudis paradoxa*), there is relatively little growth after metamorphosis, so the tadpole, including the tail, is longer than the adult frog (Emerson, 1988b). All phyllomedusines are arboreal, and some live high in the canopies of tropical rainforests, but they descend to ground level to breed and place their eggs on vegetation, tree trunks, and other substrates over water.

The large genus *Litoria* (fig. 1.15 E) and several smaller genera are the tree frogs of Australia and New Guinea. Many *Litoria* are similar to *Hyla* in appearance and ecology, but there is considerable morphological and ecological diversity within the genus. Some species are pond-breeders, whereas others are stream-breeders. Other species, such as *L. raniformis,* are semiaquatic frogs that look more like ranids than typical hylids. Others, such as *L. latopalmata, L. nasuta,* and *L. nigrofrenata,* are ranidlike terrestrial inhabitants of the forest floor. At least one species, *L. alboguttata,* is fossorial. All of these frogs lack the enlarged toe pads characteristic of tree frogs. Another genus of pelodryadines, *Cyclorana* (fig. 1.15 F), is so divergent that it once was classified in the family Myobatrachidae. Most species in this genus are globular, burrowing frogs that are capable of surviving long dry periods underground. Despite these major morphological differences, Frost et al. (2006) proposed to include this genus within the genus *Litoria* because it appears to have evolved from within that genus.

Family Hyperoliidae

Distribution: Sub-Saharan Africa, Madagascar, and the Seychelles Islands.

Content: About 19 genera, 260 species. Like other ranoid frogs, the systematics of hyperoliids has been much debated in the literature. Some authors have included the African astylosternine and arthroleptine frogs in this family (Laurent 1986), but others have placed them in the Ranidae or in one or more separate families (Dubois 1981). Different classifications group the hyperoliids into either two or

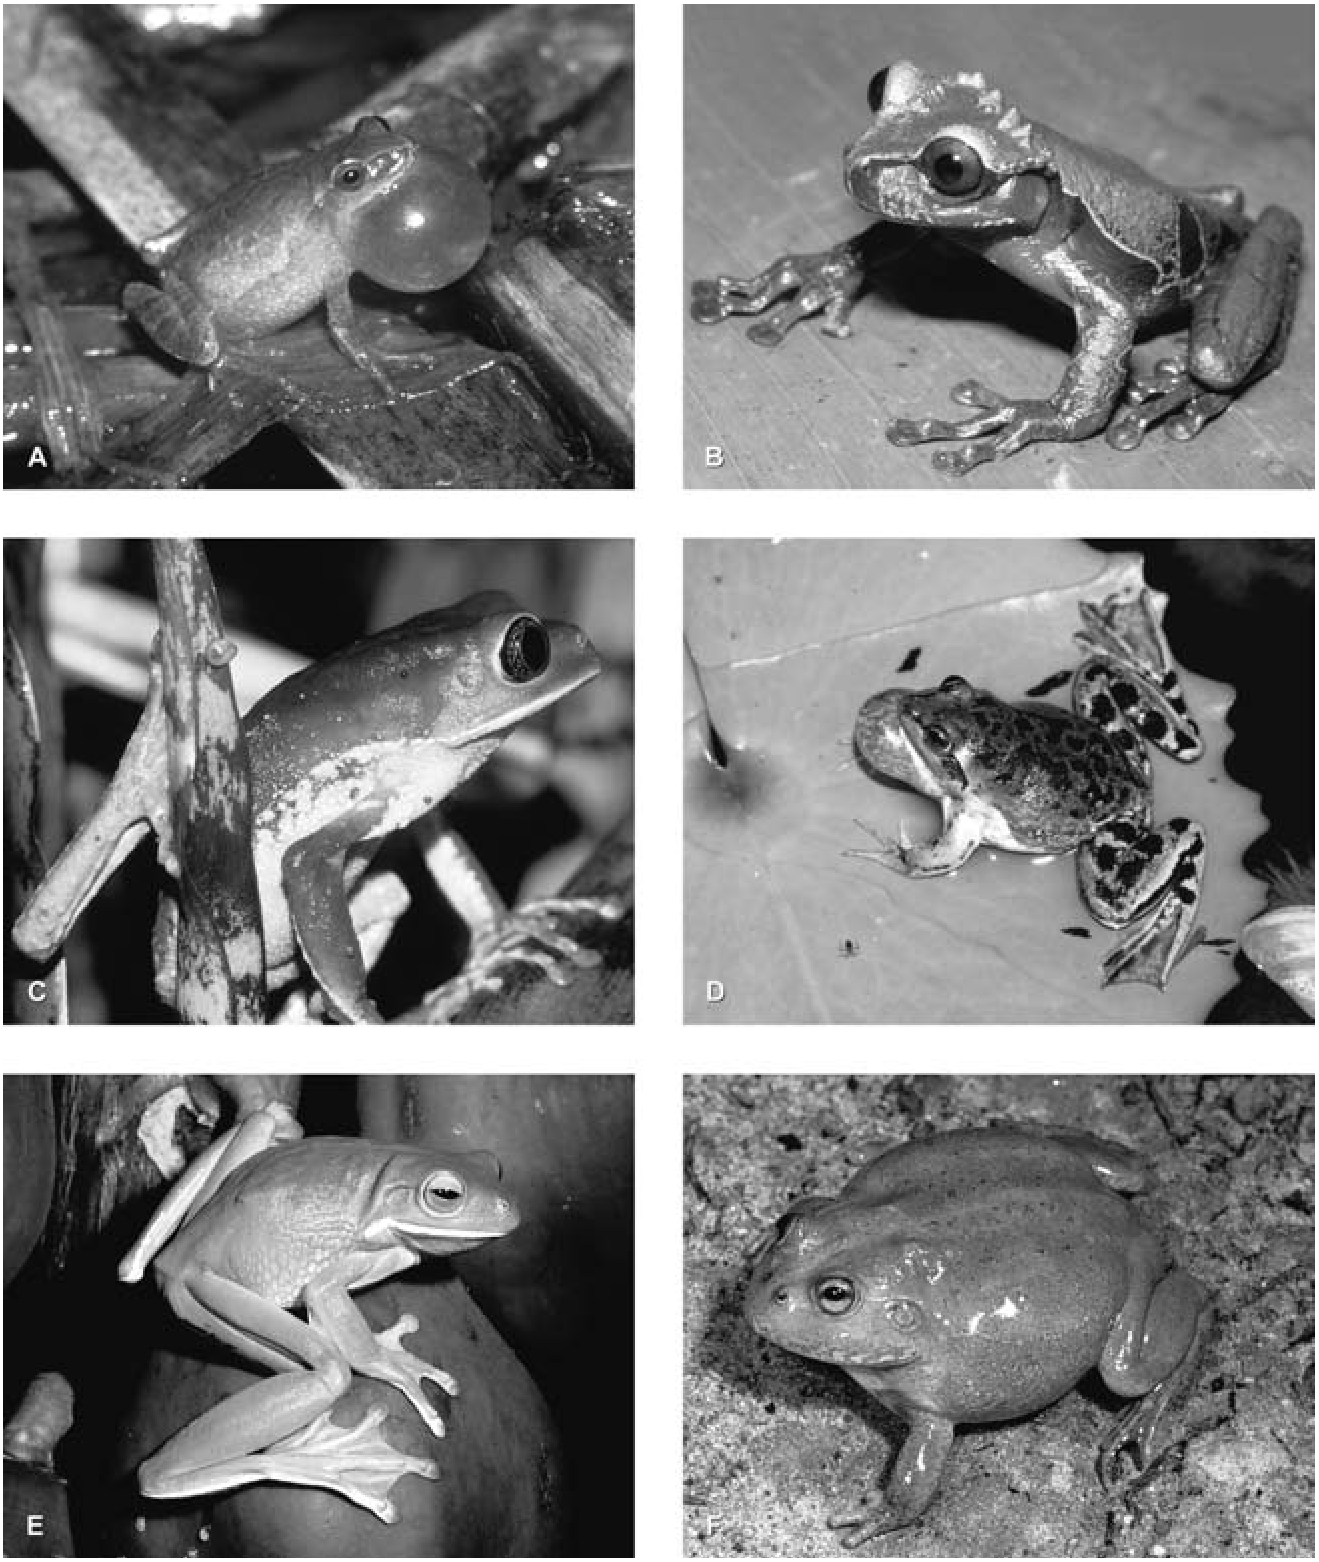

Fig. 1.15. Diversity of anurans (Hylidae). (A) *Pseudacris crucifer* from Connecticut. (B) *Anotheca spinosa* from Central America. (C) *Phyllomedusa trinitatis* from Trinidad. (D) *Pseudis paradoxa* from Trinidad. (E) *Litoria infrafrenata* from Australia. (F) *Cyclorana platycephalus* from Australia. Photos by Kentwood D. Wells (A, C, D), Karl Heinz Jungfer (B), and Harold Cogger (E, F). For additional photos of hylid frogs, see fig. 1.1 A (*Agalychnis*); 2.6 (*Phyllomedusa*); 5.17 (*Scinax*); 7.6 D (*Phrynohyas*); 7.21, 7.23, 10.1 B, 11.1, 16.12 (*Hyla*); 8.6 D (*Triprion*); 14.25 A (*Osteocephalus*); and 14.25 B, C (*Litoria*).

four subfamilies. The subfamily Leptopelinae includes the single genus *Leptopelis,* with about 50 species (fig. 1.16 D). Both morphological and molecular data indicate that this genus is the basal lineage within the family (Drewes 1984; Richards and Moore 1996), and some analyses place it as more closely related to other African ranoids than to the other hyperoliids (Biju and Bossuyt 2003), or actually in the family Arthroleptidae (Frost et al. 2006). The largest clade is the subfamily Hyperoliinae, comprised mostly of species in the genera *Hyperolius* (about 120 species; fig. 1.16 B) or *Afrixalus* (about 30 species; fig. 1.16 A). One genus, *Heterixalus*, with about 12 species, is endemic to Madagascar. Some classifications place the endemic Seychelles Island species, *Tachycnemis seychellensis,* in a separate subfamily Tachycneminninae, but this species appears to be very closely related to *Heterixalus* and may belong in the same genus (Richards and Moore 1996). The morphologically distinctive running frogs in the genus *Kassina* (fig. 1.16 C) sometimes have been placed with four other small genera in the subfamily Kassininae, but other classifications place all hyperoliids except *Leptopelis* in the subfamily Hyperoliinae.

Most hyperoliids are relatively small arboreal or terrestrial frogs with well-developed toe pads. The largest genus, *Hyperolius,* includes many species that are similar to Neotropical hylid tree frogs in their appearance and general ecology. These frogs exhibit extraordinary variation in color pattern, but otherwise are morphologically similar. This has led to a very confused taxonomy, with many forms being given specific names within a *Hyperolius viridiflavus* "superspecies" complex (Richards and Moore 1996; Schiøtz 1999; Wieczorek, Channing, and Drewes 1998; Wieczorek, Drewes , and Channing 2001). The literature on the behavior of these frogs is confusing as well, with the name *Hyperolius marmoratus* being applied to populations that have been studied in southern Africa and *H. viridiflavus* to those studied in more northern populations. Other workers have used the name *H. marmoratus* only for populations from the east central coast of South Africa.

Natural History: Most species of *Hyperolius* lay small eggs in standing water, but some species place their eggs on vegetation over water, as do species in the genus *Afrixalus.* Members of the latter genus are known as leaf-folding frogs, because they often fold leaves around their eggs, presumably to protect them from predators or desiccation. Another hyperoliine frog, *Acanthixalus,* lays eggs in water-filled tree holes. Most members of the genus *Leptopelis* are larger arboreal or terrestrial frogs. They lay nonaquatic eggs on the ground near water; tadpoles of at least one species move to water to complete development. Although often called tree frogs, some species of *Leptopelis* are capable of burrowing and have well-developed metatarsal tubercles. Frogs in the genus *Kassina* are terrestrial frogs that sometimes climb into low vegetation. They have elongated bodies and short legs and tend to move by walking rather than hopping. Most species are brightly colored and are protected by noxious skin secretions.

Family Leiopelmatidae

Distribution: New Zealand.

Content: One genus, *Leiopelma,* with four species (fig. 1.14 E). These frogs, all endemic to New Zealand, are considered among the most primitive (basal) living frogs because they retain many ancestral morphological traits. Some aspects of their life histories, however, are thought to be derived.

Natural History: All *Leiopelma* live in relatively cool, moist habitats. Two species, *L. archeyi* and *L. hamiltoni,* lay eggs in terrestrial nests. These hatch into advanced-stage tadpoles that complete development without feeding. A third species, *L. hochstetteri,* lays aquatic eggs in water-filled depressions on the ground. The eggs hatch into tadpoles at an earlier stage of development than the species that remain in the nest, but do not feed before metamorphosis.

Family Leptodactylidae

Distribution: Texas, Florida, Mexico, Central and South America, West Indies.

Content: About 50 genera, more than 1,100 species (fig. 1.17). This enormous family is not clearly defined by a set of shared derived characters and clearly does not represent a monophyletic assemblage (Ford and Cannatella 1993; Darst and Cannatella 2004; Wiens, Bonett, and Chippindale 2005). The number of monophyletic clades, the placement of genera within these clades, and the placement of species within genera are all subjects of current debate (Faivovich et al. 2005; Lehr, Fritzsch, and Müller 2005; Nuin and do Val 2005). Consequently, it is not yet possible to give a definitive picture of leptodactylid phylogeny or classification. The new classification proposed by Frost et al. (2006) is radically different from that given here, with major rearrangements of genera and subfamilies and the elevation of several clades to family status.

Leptodactylids are the dominant frogs in much of South and Central America and the Caribbean. They are morphologically and ecologically diverse, with fully aquatic, semiaquatic, terrestrial, fossorial, and arboreal species. They are found from the cold temperate regions of far southern South America to subtropical regions of North America, but are most diverse in lowland and montane tropical forests. Currently five subfamilies are recognized. The Leptodactylinae include about 150 species found throughout South and Central America. The largest genera are *Leptodactylus* (68

Haddad (A, C, D), Ivan Sazima (B), Walter Hödl (E), and Kentwood D. Wells (F). For additional photos of leptodactylid frogs, see fig. 2.11 (*Lepidobatrachus*); 4.7 (*Telmatobius*); 7.1, 10.5 A, 14.29 E, F (*Physalaemus*); 7.6 B (*Hylodes*); 8.13 A, 10.1 D, 14.28, 16.10 D (*Eleutherodactylus*); 8.29, 10.5 C, 11.6, 14.29 C, D (*Leptodactylus*); 14.33 C (*Lithodytes*); 16.10 A (*Paratelmatobius*); and 16.10 B (*Holoaden*).

species), *Physalaemus* (about 50 species), *Pleurodema* (12 species; fig. 1.17 E), and *Pseudopaludicola* (12 species). The subfamily Eleutherodactylinae, also very widely distributed, includes the largest genus of vertebrates, *Eleutherodactylus,* with over 700 described species (fig. 1.17 F). Crawford and Smith (2005) argued that one large clade within the genus, with about 105 species, should be recognized as a separate genus, *Craugastor.* The only other genus in this subfamily with more than six species is *Phyrnopus,* with about 30 species. A recent phylogenetic analysis indicated a close relationship to the genus *Eleutherodactylus,* with several species probably belonging in that genus. The smaller genus *Phyllonastes* was nested within *Phrynopus* (Lehr, Fritzsch, and Müller 2005). Another widespread subfamily, the Telmatobiinae, includes the large genus *Telmatobius* (about 54 species; see fig. 4.7 in chapter 4) and *Alsodes* (16 species), along with nine other genera with fewer than eight species each. The subfamily Cycloramphinae (sometimes called Hylodinae, depending on which genera are included) is centered in eastern Brazil and northern Argentina and includes *Cycloramphus* (26 species), *Hylodes* (20 species; fig. 1.17 B), *Crossodactylus* (10 species), and several smaller genera (fig. 1.17 A). The small subfamily Ceratophryinae, with six genera, is found in tropical and subtropical South America. This group includes *Proceratophrys* (18 species), *Odontophrynus* (10 species), *Ceratophrys* (eight species; fig. 1.17 D), and *Lepidobatrachus* (three species), and *Macrogenioglottus* (one species fig. 1.17 C).

Natural History: Most of the leptodactylines are terrestrial or semiaquatic frogs that breed in ponds. They vary greatly in size from moderately small to very large species of *Leptodactylus,* some of which regularly prey on tadpoles and adults of other frogs. Most species lay eggs in foam nests, which float on the surface of the water or are placed in cavities and burrows near standing water. Most species also have free-living, pond-type tadpoles, but in the genus *Adenomera,* tadpoles remain in a foam nest inside a burrow throughout development and do not feed. The ceratophryines are all relatively large terrestrial frogs, some of which feed on other frogs. They are capable of burrowing into the ground during the dry season and form skin cocoons to reduce water loss. The hylodines are found mainly in and around streams. The tadpoles of some species have morphological adaptations for holding onto rocks in the spray zones near waterfalls.

The telmatobiines are more diverse morphologically and ecologically. Relatively primitive species, many of which are found in the cool regions of southern South America, have aquatic eggs and tadpoles, although some have unusual breeding habits, such as placing eggs in small water-filled depressions where the tadpoles develop without feeding. Species in the genus *Telmatobius* are largely or entirely aquatic and include stream-dwelling species and others found in high-altitude Andean lakes. The best known species is *T. culeus* from Lake Titicaca, a fully aquatic frog with unusual adaptations for breathing through its skin.

The genus *Eleutherodactylus* and other eleutherodactylines are small to medium-sized terrestrial and arboreal frogs, most of which are cryptically colored. This group has been very successful in colonizing tropical and subtropical habitats from South America to the southern United States; the derived reproductive mode of these frogs undoubtedly has facilitated their dispersal onto most Caribbean islands. All eleutherodactylines except one species of *Eleutherodactylus* lay terrestrial or arboreal eggs that undergo direct development into miniature froglets, thus freeing these frogs from dependence on aquatic breeding sites. Some species have extensive parental care, especially clades found on Caribbean islands. *Eleutherodactylus jasperi,* from Puerto Rico, is the only known ovoviviparous frog in the New World, but unfortunately now appears to be extinct.

Family Mantellidae

Distribution: Madagascar and the Comoro Islands

Content: Five genera, 157 species. The largest genus is *Mantidactylus,* with about 85 species, followed by *Boophis* with more than 50 species, *Mantella* with 15 species (fig. 1.14 F), *Aglyptodactylus* with three species, and *Laliostoma* with one species. These genera have all been considered endemic to Madagascar, with one species of *Boophis* and one of *Mantidactylus* found on Mayotte in the Comoro Islands, introduced by humans from Madagascar. Recent work by Vences, Vieites et al. (2003) indicated that these actually are distinct species endemic to Mayotte, apparently derived from overseas dispersal from Madagascar within the last five to seven million years. These five genera represent a monophyletic lineage, but their relationship to other anurans has been much debated. They often have been treated as a subfamily of Ranidae (Blommers-Schlösser 1979), but other analyses have placed them within the family Rhacophoridae (Channing 1989; Ford and Cannatella 1993; J. Wilkinson, Drewes, and Tatum 2002) or in a separate family. Blommers-Schlösser (1993) considered both the Mantellinae and Rhacophorinae to be subfamilies of Ranidae. An analysis of combined morphological and molecular data indicated that mantellines are more closely related to rhacophorids than to other ranoid frogs (Emerson et al. 2000), a conclusion supported by recent molecular data (Bossuyt and Milinkovitch 2000; C. Richards et al. 2000; J. Wilkinson et al. 2002; Frost et al. 2006). The genera *Boophis* and *Aglyptodactylus* previously were placed in the family Rhacophoridae. The molecular phylogenetic analyses of Bossuyt and Milinkovitch (2000), C. Richards, Nussbaum, and

Raxworthy (2000), Vences and Glaw (2001), and Vences, Glaw et al. (2002) placed these genera as sister taxa to other mantellid frogs. These authors placed these genera, along with the burrowing frog *Laliostoma* (= *Tomopterna*) *labrosa,* in the family Mantellidae. These conclusions are generally consistent with an earlier molecular phylogeny of Richards and Moore (1998), which showed that the Madagascar frogs are united as a monophyletic group, but they treated the genera *Mantella* and *Mantidactylus* as a subfamily of Rhacophoridae. The mitochondrial DNA phylogeny of J. Wilkinson et al. (2002) also confirmed the monophyly of the Madagascar frogs, including *Boophis* and *Aglyptodactylus,* but they chose to include this clade within the family Rhacophoridae. I have followed recent summaries of anuran taxonomy in treating this clade as a separate family (Duellman 2003; Frost 2004; Pough et al. 2004; Frost et al. 2006).

Natural History: Mantellid frogs have undergone an extensive radiation on Madagascar, evolving into terrestrial, fossorial, riparian, and arboreal species that exhibit considerable morphological, ecological, and behavioral convergence with frogs in other families. The genus *Mantella* has aposematic coloration and toxic skin secretions that are convergent with those of dendrobatid frogs (Daly et al. 1996; Schaefer, Vences, and Veith 2002; see fig. 1.14 F and fig. 14.32 in chapter 14). Members of this genus also resemble dendrobatids in general body morphology and behavior, being conspicuous diurnal forest-floor dwellers that probably are active foragers for small insects. They exhibit complex courtship behavior and nonaquatic reproduction like that of dendrobatids (Heying 2001), but they do not carry tadpoles to water as dendrobatids do. Although these frogs are very distinct from other mantellids, some molecular phylogenies show the genus *Mantella* nested with the genus *Mantidactylus* (Vences, Vieites et al. 2003). The latter is very diverse, with terrestrial, arboreal, and semiaquatic species. This genus has species that closely resemble Neotropical hylids or *Eleutherodactylus* in general body form and coloration. The genus *Aglyptodactylus* resembles terrestrial members of the genus *Mantidactylus,* while the closely related *Laliostoma labrosa* is fossorial. The large genus *Boophis* consists of arboreal frogs very similar to many Asian rhacophorids, but they do not lay eggs in foam nests, as do many Asian and African rhacophorids. Most species lay eggs in ponds or attached to rocks in streams (Andreone et al. 2002). Many aspects of the mating behavior and reproductive biology of this family are unusual, with both terrestrial and arboreal oviposition being represented, sometimes with extensive parental care. Unfortunately, the natural history of most species is very poorly known, and many are endangered by extensive habitat destruction in Madagascar.

Family Megophryidae

Distribution: Northern Indian subcontinent to China, Southeast Asia, the Philippines, and islands of the Sunda Shelf.

Content: 11 genera, about 130 species. This group often has been treated as a subfamily of the Pelobatidae (Dubois 1980a; Dubois and Ohler 1998), but recent analyses indicate that it is more appropriately treated as a separate family (Ford and Cannatella 1993; Lathrop 1997; Maglia 1998). The number of valid genera has been the subject of some debate. Dubois (1980a) and Dubois and Ohler (1998) recognized four subgenera within *Megophrys: Atympanophrys* (two species), *Brachytarsophrys* (four species), *Ophryophryne* (three species), and *Xenophrys* (27 species). Frost (2004) treated all of these groups as separate genera, because he chose not to recognize subgenera, leaving only six species in *Megophrys sensu stricto* (fig. 1.16 E). Because the original subgeneric classification is noncladistic, however, the monophyly of the various subgroups within *Megophrys sensu lato* is unclear. On the basis of differences in karyotypes, Rao and Yang (1997) argued that several species of *Megophrys* (*Xenophrys*) should be placed in a new genus *Panophrys,* and they recognized *Brachytarsophrys* and *Ophryophryne* as valid genera. They also recognized *Atympanophrys,* but with a modified species content, and they indicated that a new diagnosis of the genus was required. All of these frogs, regardless of genus-level classification, often are united into the subfamily Megophryinae.

The remaining genera often are placed in the subfamily Leptobrachiinae. This group includes the genera *Leptobrachella* (seven species), *Leptobrachium* (12 species), *Leptolalax* (17 species), *Oreolalax* (17 species), and *Scutiger* (17 species), with the last two being very closely related. This subfamily also includes five species in the genus *Vibrissaphora* from Southeast Asia, characterized by bizarre keratinized spines projecting from the upper jaw and face of the male (see fig. 8.33 in chapter 8). These frogs sometimes have been treated as a subgenus of *Leptobrachium,* but are clearly differentiated from other members of that genus by several shared derived characters (see Ho et al. 1999, for a discussion).

Most megophryids are terrestrial forest-floor frogs. Frogs in the genus *Megophrys* and their close relatives are mostly relatively large terrestrial frogs that often have striking cryptic coloration and structures on the skin that make them resemble dead leaves on the forest floor (fig. 1.16 E). Those in the genera *Leptobrachella, Leptobrachium, Leptolalax,* and *Vibrissaphora* are smaller frogs found in leaf litter on the forest floor. Frogs in the genera *Scutiger* and *Oreolalax* also are terrestrial, but tend to be closely associated with rocky mountain streams. All megophryids for which reproductive biology is known deposit eggs in streams.

They lay eggs in quiet pools, or in nests under rocks, as in *Vibrissaphora.*

Tadpoles of several genera, including *Leptobrachella, Leptobrachium, Leptolalax,* and *Vibrissaphora,* have elongate bodies and muscular tails with narrow tail fins (see fig. 12.17 B in chapter 12). They live mostly in spaces between rocks in riffles of rocky streams (Haas, Hertwig, and Das 2006). Tadpoles of *Scutiger* and *Oreolalax* also have muscular tails, as well as clasping or suctorial mouthparts for holding onto rocks in flowing water. Some of tadpoles in these genera are at least partially carnivorous, feeding on other tadpoles and aquatic invertebrates (see fig. 12.20 in chapter 12). The tadpoles of *Megophrys* (including species sometimes placed in the genus *Xenophrys*) have peculiar inverted umbrella-like mouths adapted to feeding at the water's surface (see fig. 12.16 C in chapter 12).

Family Microhylidae

Distribution: North, Central, and South America, sub-Saharan Africa, Madagascar, Asia, the Australo-Papuan region, Indonesia, Philippines.

Content: About 70 genera, 430 species (fig. 1.18). This large and very diverse family usually is divided into nine subfamilies, although Frost et al. (2006) proposed some major rearrangements, with the brevicipitines elevated to full family status. The Asterophryinae and Genyophryinae are centered in the Australo-Papuan region, especially New Guinea. The Brevicipitinae, Melanobatrachinae, and Phrynomerinae are found in Africa. The Scaphiophryinae and Cophylinae are found exclusively in Madagascar. The Dyscophinae are found in Madagascar and Southeast Asia. The Microhylinae are found in the New World and in East and Southeast Asia. Wassersug and Pyburn (1987) placed the genus *Otophryne,* which differs from other South American microhylids in a number of adult and larval characters, in its own subfamily, Otophryinae. A phylogenetic analysis by Wild (1995), however, indicated that this genus belongs in the subfamily Microhylinae. Some phylogentic analyses put the burrowing frogs of the genus *Hemisus* within the family Microhylidae (Emerson et al. 2000; Loader et al. 2004), but the relationship of this genus to microhylids remains unclear, and most authors treat this genus as a separate family.

Many genera of microhylids have only a few species. For example, most genera of microhylines contain less than five species, and many are monotypic (Zweifel 1986; Wild 1995; Frost 2004). Wild (1995) attributed the proliferation of genera to an unusual degree of morphological variation in the family, especially in osteological characters. The reason for such variation is unclear, but it may be related to the burrowing habits of many microhylids. A high degree of morphological variation also could be related to widespread miniaturization in the group (Hanken and Wake 1993). Some microhylids, such as members of the genus *Stumpffia* from Madagascar, are among the World's smallest anurans (see further discussion of "Miniaturization").

The genera with the largest number of species are *Microhyla* (about 30 species) from southern and eastern Asia, *Chiasmocleis* (about 20 species; fig. 1.18 B) from South America and Panama, and *Kalophrynus* (15 species) from eastern Asia, all in the subfamily Microhylinae. The only other subfamilies with more than 20 species are the Cophylinae (seven genera, 38 species) and the Genyophryninae (11 genera, about 140 species). Microhylids in North America are restricted to Mexico and the southern and central United States (*Gastrophryne,* five species; *Hypopachus,* two species).

Natural History: Microhylids are morphologically diverse and include arboreal, terrestrial, and burrowing species. Several distinct reproductive modes are represented in this family. Most microhylines from Asia and the New World are narrow-mouthed, burrowing frogs with narrow, pointed heads and small mouths that feed mostly on ants and termites (fig. 1.18 A, B). Most genera in this subfamily have aquatic eggs and tadpoles that are midwater suspension feeders, but tadpoles of *Otophryne* burrow into the substrate and may feed on organic material found in the sand. One South American microhyline, *Syncope antenori,* breeds in bromeliads, and the tadpoles develop without feeding, a reproductive mode that is similar to that of some species of *Kalophrynus* from Borneo and several genera in the subfamily Cophylinae from Madagascar. Another species of *Syncope* is thought to have direct development. Terrestrial oviposition also has been reported in the South American microhylines *Myersiella* and *Synapturanus;* eggs either undergo direct development or hatch into nonfeeding tadpoles that remain in a terrestrial nest.

All microhylids from New Guinea (fig. 1.18 E, F) and surrounding regions are either terrestrial or arboreal and lay nonaquatic eggs that undergo direct development. Some of these, such as the genus *Cophixalus* and *Oreophryne* and *Austrochaperina,* are ecologically similar to Neotropical leptodactylids in the genus *Eleutherodactylus,* while others are fossorial species that spend most of their lives in root mats beneath the forest floor. Most species of the genus *Xenorhina* are fossorial; they have wedge-shaped heads adapted for burrowing and lack enlarged toe disks. One recently described species, *Xenorhina arboricola,* is arboreal. Although it retains the wedge-shaped head characteristic of burrowing species, it also has enlarged toe disks. It lives in leaf litter that accumulates in large ferns and in moss on trees and epiphytes (Allison and Kraus 2000). A similar shift to arboreal habits has occurred in the genus *Calulops.* One species, *C. slateri,* lives in the axils of trees or in epiphytes high above the forest floor, but all others are terrestrial. The genus *Cho-*

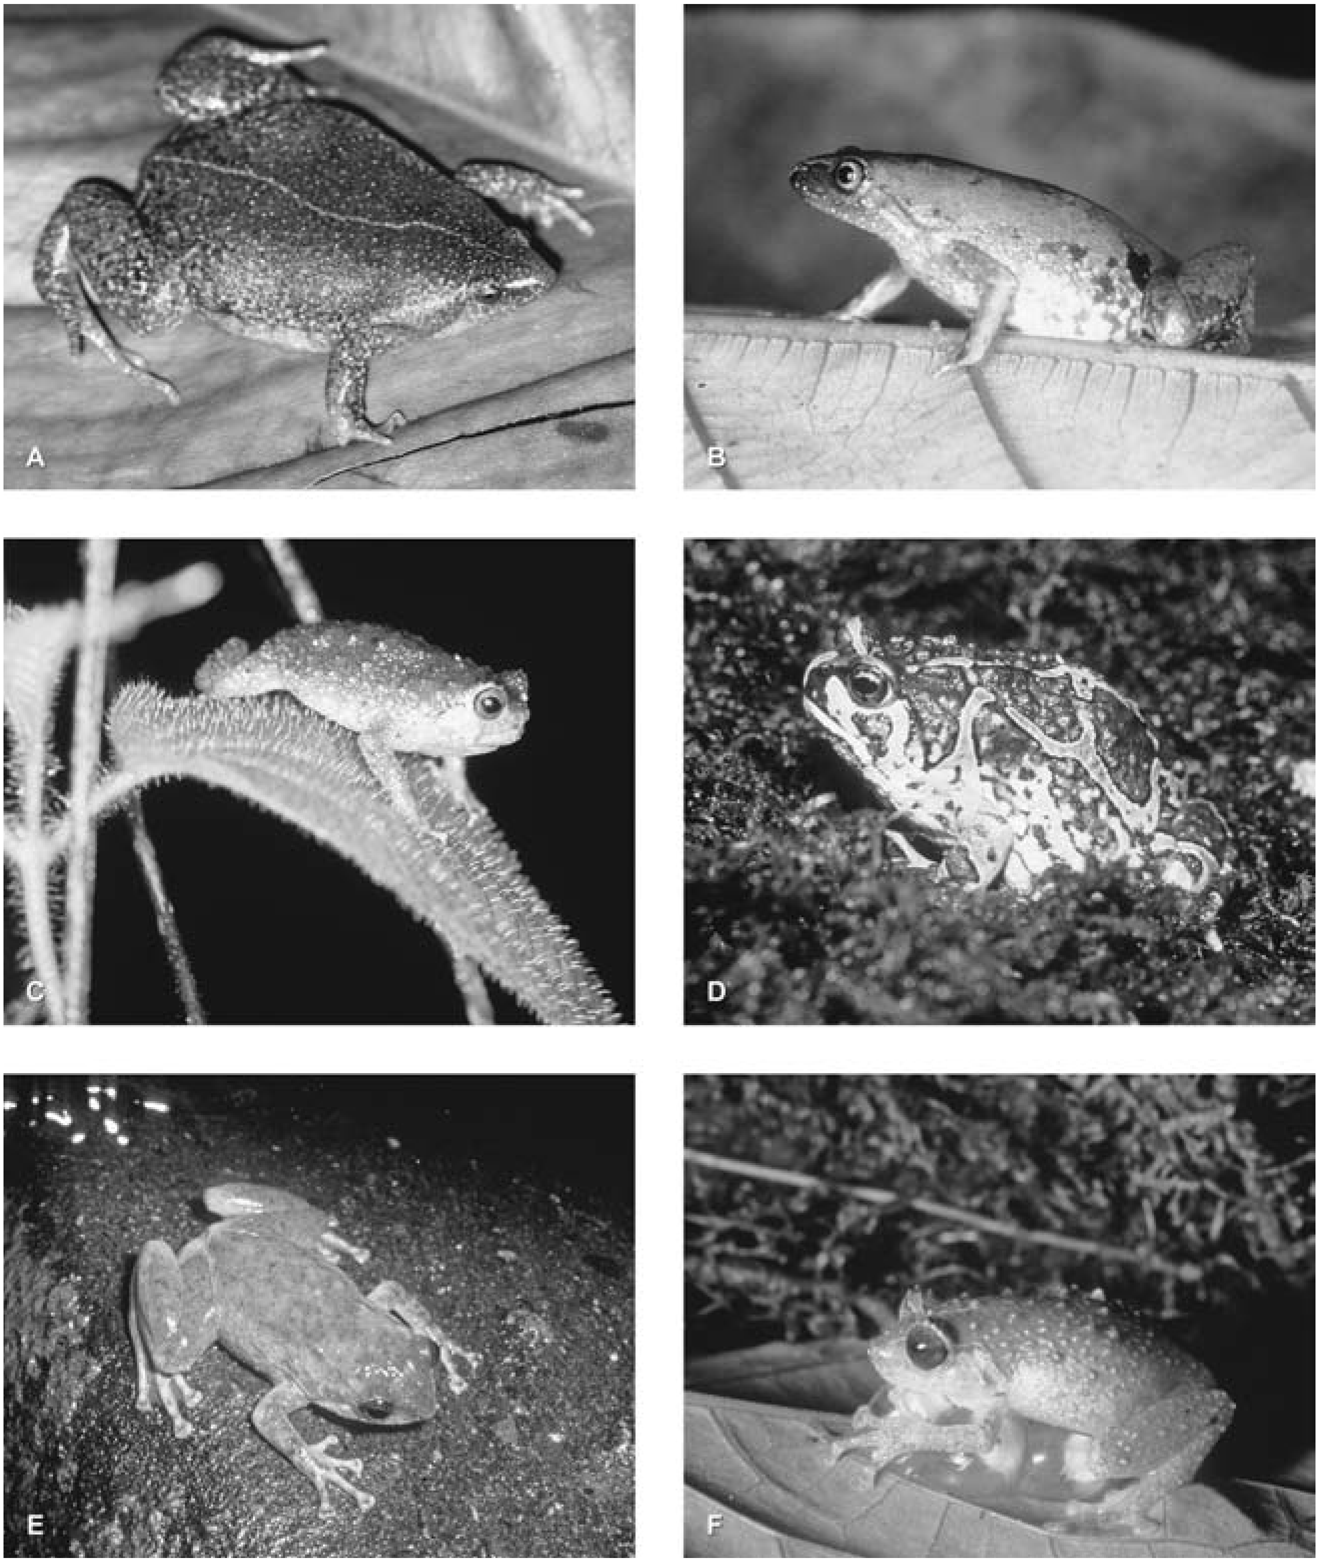

Fig. 1.18. Diversity of anurans (Microhylidae). (A) *Elachistocleis ovalis* from Trinidad. (B) *Chiasmocles shudicarensis* from French Guiana. (C) *Callulina kreffti* from Tanzania. (D) *Scaphiophryne pustulosa* from Madagascar. (E) *Austrochaperina palmipes* from New Guinea. (F) *Oreophryne* sp. from New Guinea; male brooding eggs. Photos by Kentwood D. Wells (A), Walter Hödl (B, C), Martha L. Crump (D), and David Bickford (E, F). For additional photos of microhylid frogs, see fig. 1.22 B (*Austrochaperina*); 1.22 C (*Choerophryne*); 10.4 (*Kalophryne*); 11.2 A (*Albericus*); 11.2 B (*Oreophryne*); 11.9 A (*Cophixalus*); 11.9 B (*Liophryne*); 14.26 B (*Otophryne*); and 14.26 C (*Chiasmocles*).

erophryne also is partially arboreal, with males sometimes calling from vegetation up to two meters above the ground, although they are primarily terrestrial inhabitants of the forest floor (Kraus and Allison 2001). This genus is characterized by an extremely elongated snout (fig. 1.22 C). The elongated snout probably enables these frogs to move through root mats below the forest floor and probably restricts their diet to tiny prey, such as mites and termites. This genus may be closely related to another obscure group of small terrestrial frogs in the genus *Albericus* (Menzies 1999).

The microhylids of Madagascar have occupied a variety of habitats and include arboreal, terrestrial, and fossorial species. Several arboreal species in the subfamily Cophylinae lay eggs in water-filled tree holes, but the tadpoles develop without feeding. In the genus, *Plethodontohyla,* some species breed in tree holes, while others breed in shallow terrestrial nests where the tadpoles develop without feeding. The tiny terrestrial frogs of the genus *Stumpffia* apparently also have nonfeeding tadpoles that develop in a terrestrial nest. These frogs are unique among microhylids in producing a foam nest. A molecular phylogenetic analysis of the subfamily showed considerable convergent evolution of similar ecological adaptations in different genera, with multiple shifts between terrestrial and arboreal breeding (Andreone et al. 2005). Scaphiophrynine microhylids from Madagascar (*Scaphiophryne* and *Paradoxophyla*) are small terrestrial or fossorial frogs (fig. 1.18 D), although some *Scaphiophryne* are at least partly arboreal. All of these frogs breed in temporary ponds and have aquatic tadpoles. Species in the genus *Dyscophus* are larger terrestrial frogs, some of which have bright red or orange coloration and produce copious noxious skin secretions. These frogs also breed in temporary water, and their tadpoles are midwater suspension feeders like those of many other microhylids.

Burrowing microhylids in the genus *Breviceps* from southern Africa also lay terrestrial eggs, which are placed in subterranean burrows, where tadpoles develop without feeding. The so-called rubber frogs of southern Africa (*Phrynomantis*) are elongate, terrestrial frogs that tend to hold their bodies close to the ground and move mainly by walking or running. They eat mostly ants. They are aposematically colored and protected by noxious skin secretions. Eggs are laid in ponds.

Family Myobatrachidae

Distribution: Australia and New Guinea.

Content: 23 genera, about 120 species. This family, which is centered in Australia, confused taxonomists for many years. It once was considered a subfamily of Leptodactylidae, but later work showed that myobatrachids are no more closely related to leptodactylids than they are to several other anuran clades. Indeed, Ford and Cannatella (1993) found no derived characters that unite the two subfamilies of myobatrachids, the Myobatrachinae and the Limnodynastinae, and suggested that the former may be more closely related to sooglossids than to limnodynastines. Indeed, Duellman (2003) treated these as separate families, as do some other authors (Frost et al. 2006), but most other authors have treated them as subfamilies. Lee and Jamieson (1992) reported that two shared characteristics of sperm ultrastructure unite these subfamilies into a monophyletic clade. The gastric-brooding frogs (*Rheobatrachus*) are especially problematic, having been regarded by different authors as most closely related to limnodynastines, myobatrachines, or placed in their own subfamily or family. Unfortunately, the apparent extinction of this genus makes resolution of this issue difficult. It is astonishing that in a continent as well studied by herpetologists as Australia, new species of myobatrachids continue to be discovered; two entirely new genera (*Bryobatrachus* from Tasmania and *Spicospina* from Western Australia) were described in the 1990s (Rounsevell et al. 1994; Roberts et al. 1997; Read et al. 2001, placed *Bryobatrachus* within the larger genus *Crinia*).

Natural History: All myobatrachids are fossorial, terrestrial, or semiaquatic frogs; there are no arboreal species. The family is morphologically diverse and lives in a variety of habitats, from extremely dry deserts to tropical rainforests and mountain streams. Because much of Australia is a desert, frogs in both subfamilies have repeatedly evolved adaptations for desert life, including a rotund body form, spades on the hind feet for burrowing, nocturnal habits, and specialized diets of ants and termites, all of which are convergent with adaptations of North American spadefoot toads in the family Pelobatidae. Frogs with one or more of these adaptations include limnodynastines in the genera *Heleioporus* (fig. 1.19 A), *Neobatrachus, Notaden* (fig. 1.19 D), and some species of *Limnodynastes.* Burrowing, desert-dwelling myobatrachines include *Arenophryne rotunda,* a rotund frog that superficially resembles spadefoot toads, but burrows headfirst rather than feet first. It lays terrestrial eggs that undergo direct development. An even more peculiar headfirst burrower is *Myobatrachus gouldii* (fig. 1.19 C), a frog with a turtle-like appearance that spends virtually its entire life underground, even mating and laying eggs in underground burrows.

Many limnodynastines that breed in temporary ponds and swamps lay eggs in foam nests that float on the water's surface or are deposited in burrows at the edges of bodies of water; these include *Adelotus, Lechriodus* (fig. 1.19 B), *Limnodynastes,* and some species of *Heleioporus.* Frogs in the genus *Philoria* are found in wet, mossy environments, where they lay large eggs in a foam nest; tadpoles develop to metamorphosis without feeding. Another unusual myobatrachine

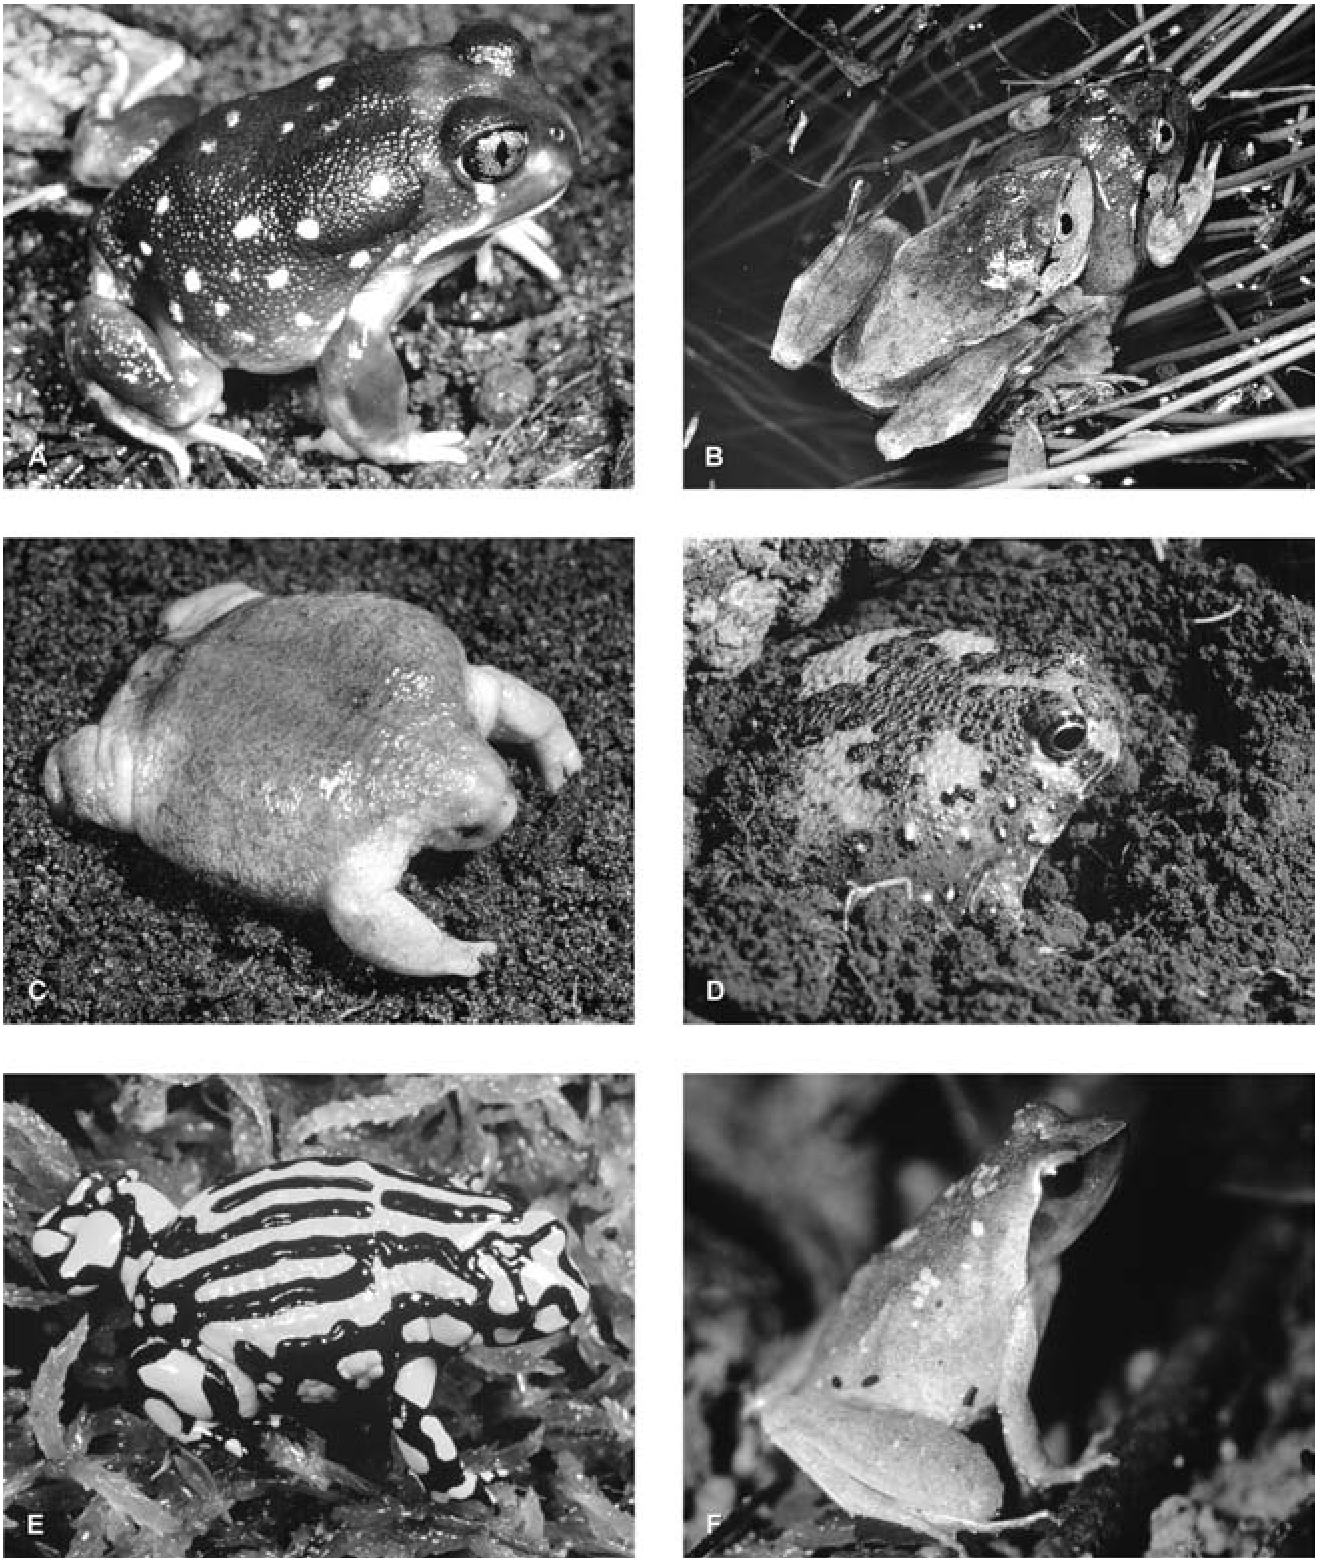

Fig. 1.19. Diversity of anurans (Myobatrachidae and Petropedetidae). (A) *Heleiporus albopunctatus* (Myobatrachidae) from Australia. (B) *Lechriodus fletcheri* (Myobatrachidae) from Australia. (C) *Myobatrachus gouldii* (Myobatrachidae) from Australia. (D) *Notaden bennettii* (Myobatrachidae) from Australia. (E) *Pseudophryne corroboree* (Myobatrachidae) from Australia. (F) *Phrynobatrachus plicatus* (Petropedetidae) from West Africa. Photos by Harold Cogger (A–E) and Ulmar Grafe (F). For additional photos of these families, see fig. 16.11 A (*Taudactylus*) and 16.11 B (*Rheobatrachus*). See fig. 8.31 for a drawing of *Petropedetes.*

is *Megistolotis lignarius,* an inhabitant of boulder fields. Its somewhat flattened head may enable it to retreat into crevices. It lays eggs in foam nests in stream pools.

Foam nesting is not found in myobatrachines, but there are a number of unusual reproductive modes in this group as well. Small terrestrial frogs in the genera *Geocrinia* and *Pseudophryne* (fig. 1.19 E) lay eggs on land, while in *Assa darlingtoni,* males carry tadpoles in special inguinal pouches (see fig. 11.8 in chapter 11). Most other myobatrachines are relatively small, terrestrial or semiaquatic frogs that lay small batches of eggs in ponds and slow-moving streams. The genus *Crinia* resembles North American cricket frogs (*Acris*) and chorus frogs (*Pseudacris*) in morphology and habits. The genus *Uperoleia* is more toadlike in appearance, having rough, glandular skin and prominent parotoid glands. Some species in this genus, especially those found in deserts, are burrowers. A few myobatrachids live near swift streams, including *Taudactylus* (see fig. 16.11 A in chapter 16), which resembles Neotropical dendrobatids in the genus *Colostethus* in general appearance and their diurnal habits. *Rheobatrachus,* the gastric-brooding frogs, had perhaps the most peculiar reproductive habits of any frogs, with eggs and tadpoles carried in the stomach of the female (see fig. 16.11 B in Chapter 16).

Family Nasikabatrachidae

Distribution: Western Ghats of India

Content: One species, *Nasikabatrachus sahyadrensis.* This peculiar burrowing frog was described as an entirely new family by Biju and Bossuyt (2003) and is known from only a few specimens. A phylogenetic analysis based on both mitochondrial and nuclear DNA placed this frog as the sister group of the Sooglossidae from the Seychelles Islands. It may represent an ancient Cretaceous lineage that was more widespread before India and the Seychelles separated.

Natural History: The natural history of this frog is essentially unknown, although it is fossorial and probably eats mostly ants or termites. It appears to have inguinal amplexus.

Family Pelobatidae

Distribution: North America, Europe, western Asia, North Africa.

Content: Three genera, 11 species. The North American spadefoot toads were traditionally placed in a single genus, *Scaphiopus.* Most recent authors have placed only three species in this genus, *S. holbrookii, S. hurterii,* and *S. couchii* (fig. 1.16 F), allocating all others (*S. bombifrons, S. hammondii, S. multiplicata,* and *S. intermontana*) to the genus *Spea.* Other investigators have argued that splitting the spadefoot toads into two genera is not justified and have used the name *Scaphiopus* for all North American species (J. A. Hall, Larsen, and Fitzner 1997). Literature on the ecology and behavior of these species has been published under both names. A phylogenetic analysis based on morphological characters supported the monophyly of both *Spea* and *Scaphiopus* (Maglia 1998). This analysis also suggested that *Scaphiopus* might be more closely related to Old World *Pelobates* than to *Spea,* but Maglia (1998) argued that this might be due to convergent evolution of morphological characters. More recent analyses indicate that *Spea* and *Scaphiopus* are not closely related to *Pelobates,* and several authors have recommended placing these two genera in a separate family, Scaphiopodidae (García-París et al. 2003; Haas 2003; Frost 2004; Frost et al. 2006).

Natural History: The spadefoot toads of North America (*Scaphiopus* and *Spea*) are rotund anurans with conspicuous spade-shaped tubercles on their hind feet that enable them to burrow backward into soil. They spend much of their lives underground and have special physiological adaptations for prolonged periods of dormancy. Most species emerge after heavy summer rains to form explosive breeding aggregations in temporary ponds. They retain the ancestral behavior of inguinal amplexus. The tiny eggs of desert-dwelling species hatch more rapidly than do those of most other anurans, and tadpole development is very fast as well. While above ground, adults are nocturnal and feed on insects. Eurasian spadefoot toads (*Pelobates*) share morphological adaptations for burrowing seen in the North American species, but are less restricted to arid regions and lack the highly explosive breeding periods and rapid tadpole development of desert spadefoots.

Family Pelodytidae

Distribution: Western Europe and southwestern Asia.

Content: A single genus, *Pelodytes,* with three species. The current disjunct distribution of the three living species suggests they are a remnant of a group that once was more widespread. Indeed, fossil remains of this family have been found in North America, where it no longer occurs (Henrici 1994; Sánchez-Herráiz et al. 2000).

Natural History: These are relatively small, agile, terrestrial frogs that frequent damp habitats. They lay eggs in short strings in ponds. Amplexus is inguinal, like that of all relatively primitive frogs. Most aspects of their natural history have not been intensively studied.

Family Petropedetidae

Distribution: Sub-Saharan Africa

Content: 13 genera, about 100 species. By far the largest genus is *Phrynobatrachus,* with nearly 70 species (fig. 1.19

F; placed in a separate family by Frost et al. 2006). The only other genera with more than two species are *Cacosternum* (nine species; placed in the family Pyxicephalidae by Frost et al. 2006), *Arthroleptella* (eight species), and *Petropedetes* (seven species). Most species are small frogs of African forests and savannas that lay eggs in temporary pools during the rainy season, but some have unusual reproductive modes. *Anhydrophryne* has direct development of eggs laid in a terrestrial nest, whereas *Arthroleptella* has nonfeeding tadpoles that complete development in wet moss. Frogs in the genus *Petropedetes* are larger and lay eggs on wet rocks in forest streams, where the tadpoles develop while clinging to vertical rockfaces.

Family Pipidae

Distribution: Tropical South America and Africa.

Content: Five genera, 30 species. This is an ancient lineage that originated before the breakup of Gondwanaland. There is an extensive fossil record, going back to the Lower Cretaceous (120 million years ago; Báez 1996). Currently the family has a disjunct distribution in Africa and South America. Recent phylogenetic analyses place two African genera, *Hymenochirus* and *Pseudhymenochirus,* closer to the only South American genus, *Pipa* (fig. 1.20 A), than to the other African genera, *Xenopus* and *Silurana* (Cannatella and Trueb 1988a, b; de Sa and Hillis 1990; Cannatella and de Sa 1993). These two genera are very ancient, having diverged about 64 million years ago, and probably most closely resemble the ancestral morphology of the group (Evans et al. 2004). *Xenopus*-like fossils from the middle Cretaceous have been found in southern South America (Báez 1996; Báez and Púgener 2003). Despite their early appearance in the fossil record, pipids cannot be considered morphologically primitive frogs. Indeed, most morphological features of this family are highly derived and are related to their aquatic life style (Trueb 1996). Because pipids stay in the water as adults, there is less radical remodeling of the skull during metamorphosis than in other frogs. In addition, adults lack a tongue, a feature unique to this family, resulting in a different mode of feeding from that seen in most anurans. Pipids produce calls, as do most other anurans, but the mechanism of sound production is completely different (see chapter 7). There also are derived features of the pelvic girdle related to swimming (Cannatella and de Sa, 1993).

Natural History: All members of this family are strictly aquatic frogs that seldom venture onto land. All have flattened bodies and large hind legs with extensive foot webbing. The African genera have relatively narrow snouts, whereas the South American *Pipa* have wide heads and mouths. These frogs often live in turbid water and detect prey with a well-developed lateral-line system (absent in *Hymenochirus* and *Pseudhymenochirus*). The frogs ingest prey organisms by pushing them into the mouth with the front feet. The African species all lay small eggs attached to submerged aquatic plants or scattered individually at the surface of ponds. Tadpoles are midwater suspension-feeders. The seven species of *Pipa* have one of the most peculiar reproductive modes of any frog. After eggs emerge from the female's vent and are fertilized by the male, the male then maneuvers them onto the back of the female, where they stick to the skin. The skin then swells around the eggs, leaving each one in its own cavity (see fig. 10.12 in chapter 10). In some species, eggs undergo direct development in these brood chambers and hatch into miniature frogs, but in other species, the eggs hatch into aquatic tadpoles that are midwater suspension-feeders like those of other species in the family.

Family Ranidae

Distribution: Worldwide, except for southern South America, the West Indies, Australia, and most oceanic islands (ranids are found on islands such as Japan, the Philippines, New Guinea, Borneo, the Indonesian Archipelago, and the Solomon Islands).

Content: About 38 genera, 650+ species (fig. 1.21). It is clear that the family Ranidae as traditionally recognized by most systematists is not a monophyletic group. There has been considerable debate about the relationships of ranoid frogs, which include ranids, petropedetids, hyperoliids, rhacophorids, arthroleptids, astylosternids, mantellids, hemisotids, and microhylids (Ford and Cannatella 1993; Emerson et al. 2000; Frost et al. 2006). Several clades, such as the mantellid frogs of Madagascar and the arthroleptid and astylosternid frogs of Africa, have been treated by different authors as subfamilies of ranids, rhacophorids, or hyperoliids, or as separate families (Dubois 1981, 1983b, 1984, 1986, 1992; Duellman and Trueb 1986; Laurent 1986; Ford and Cannatella 1993; see also separate accounts of these groups).

There also is considerable confusion about the relationships among the groups usually included in the family Ranidae. Traditionally, many genera of New World, Eurasian, and African ranids have been lumped into a huge subfamily, Raninae, which almost certainly does not represent a monophyletic group. Dubois (1992) split off several Old World groups into the subfamilies Dicroglossinae, Ptychadeninae, Pyxicephalinae, Ranixaline, and Tomopterninae, with subfamilies further subdivided into tribes. He placed 13 African genera in a separate family, Petropedetidae, but not all systematists have followed this classification. Unfortunately, the groupings proposed by Dubois (1992) were based on overall similarity in morphology, not on shared derived characters. Subsequent work has shown

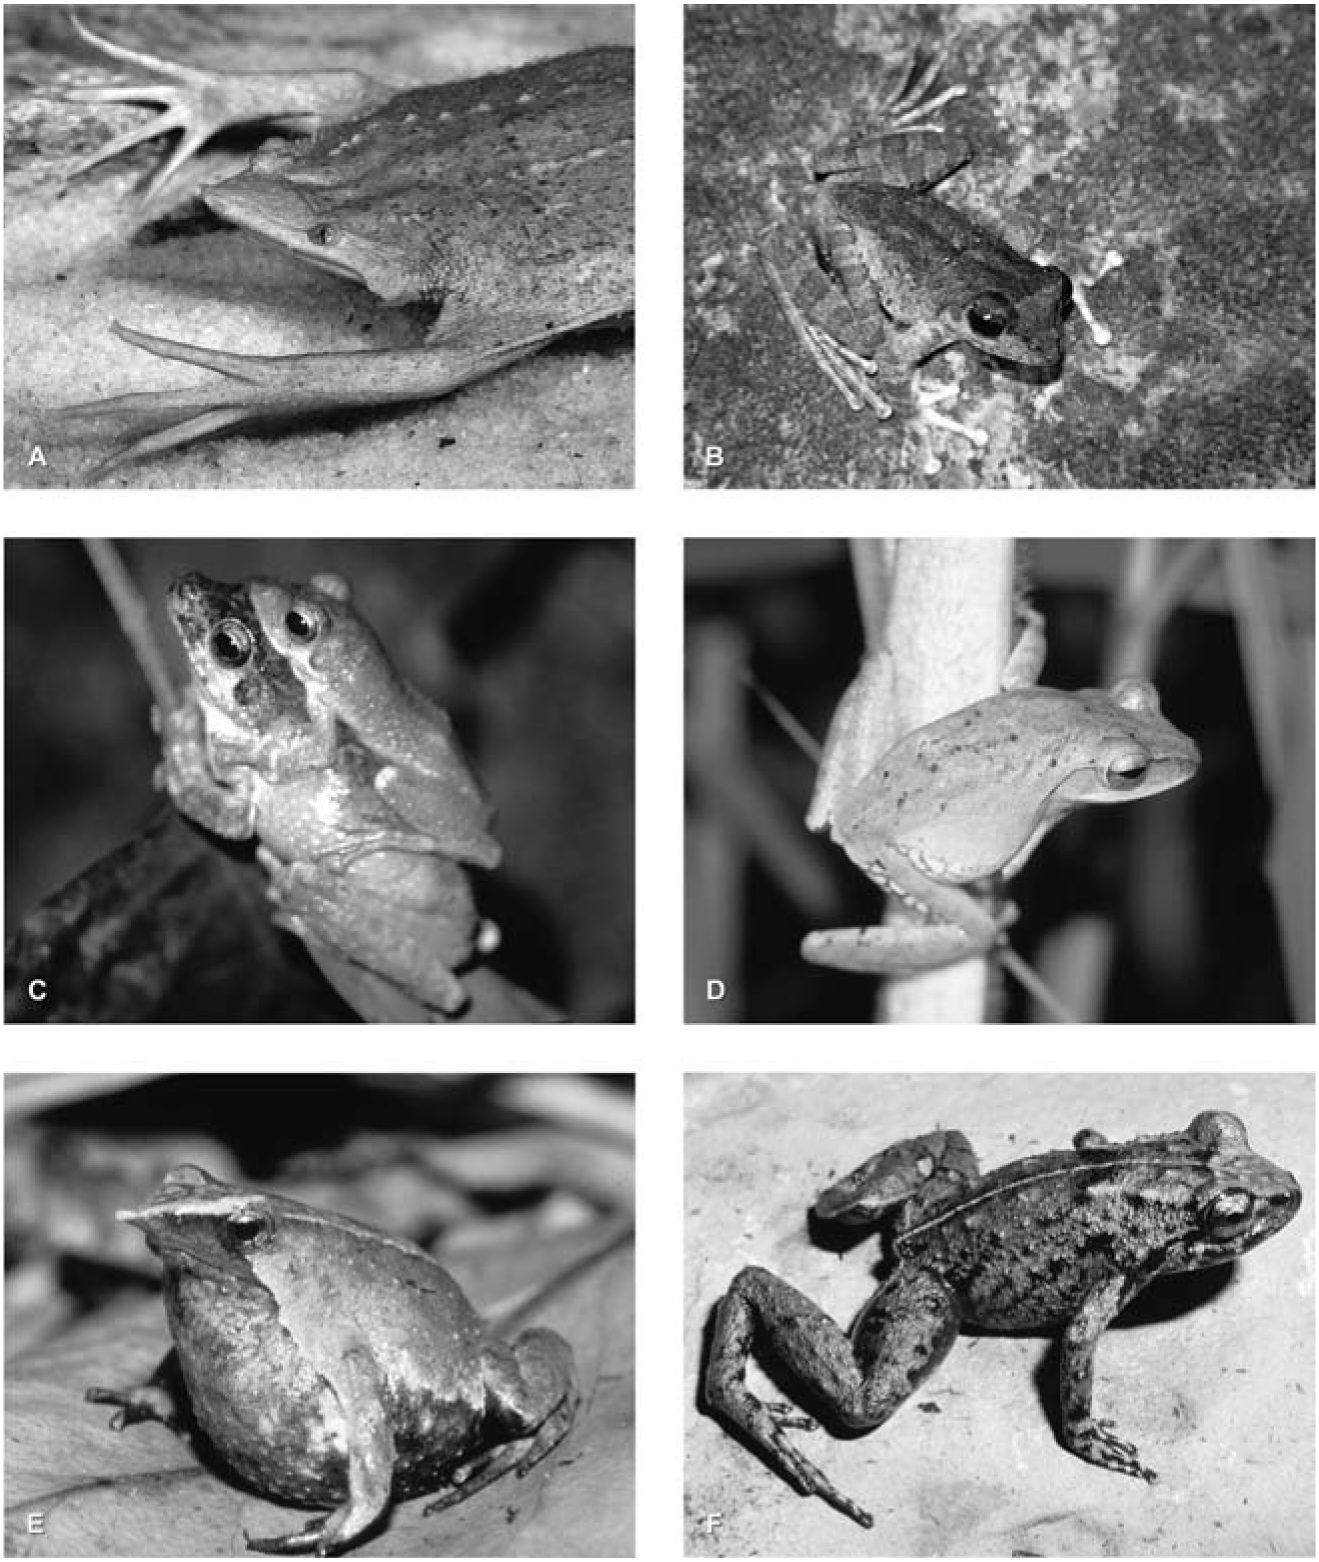

Fig. 1.20. Diversity of anurans (Pipidae to Sooglossidae). (A) *Pipa pipa* (Pipidae) from South America. (B) *Buergeria robusta* (Rhacophoridae) from Taiwan. (C) *Chiromantis rufescens* (Rhacophoridae) from West Africa. (D) *Polypedates megacephalus* (Rhacophoridae) from Taiwan. (E) *Rhinoderma darwinii* (Rhinodermatidae) from Chile; male carrying tadpoles in vocal sac. (F) *Nesomantis thomasseti* (Sooglossidae) from the Seychelles Islands. Photos by Wayne Van Devender (A, F), Kentwood D. Wells (B, D), Ulmar Grafe (C), and Martha L. Crump (E). For additional photos of these families, see fig. 10.7 A (*Chiromantis*); 10.7 B (*Rhacophorus*); and 10.7 C, 11.2 F, 11.11 C (*Chirixalus*). For a photo of the family Rhinophyrnidae, see fig. 10.1 A (*Rhinophrynus*).

(D) *Pyxicephalus adspersus* from southern Africa; juvenile. (E) *Rana banaorum* from Vietnam. (F) *Staurois natator* from Borneo; pair in amplexus. Photos by Alan Channing (A), Wayne Van Devender (B–E), and Walter Hödl (F). For additional photos of ranid frogs, see fig. 3.18, 7.6 C, F, 7.7, 8.11, 8.20, 10.2, 14.27, 16.5 D, 16.8 D (*Rana*); 10.3 (*Nyctibatrachus*); and 14.26 A (*Ceratobatrachus*).

that convergent evolution in morphology is common among ranoid frogs, and many of the subfamilies, tribes, genera, and subgenera recognized by Dubois (1992) are not monophyletic groups (Emerson and Berrigan 1993; Inger 1996; Bossuyt and Milinkovitch 2000; van der Meijden et al. 2005; Frost et al. 2006). Much more phylogenetic work is required to clarify the relationships among major lineages of ranoid frogs. The genus *Rana* (fig. 1.21 E) is the most widely distributed, but probably is not a monophyletic group. There is much dispute over the relationships of major clades within this genus (Inger 1996), and a number of schemes to partition this group into multiple genera have been proposed (Hillis and Wilcox 2005; Frost et al. 2006).

Members of the genus *Rana* within North America do not constitute a monophyletic group. A clade of western species that includes *R. aurora, R. boylii, R. cascadae,* and several other species, it is more closely related to Eurasian members of the *R. temporaria* group than to *Rana* in eastern North America. The latter are part of a larger clade that includes species from Middle America, Mexico, the southwestern United States, and eastern North America. *Rana sylvatica,* which resembles *R. temporaria* in appearance and ecology, is not closely related to that species or to any other Eurasian ranids (Hillis and Wilcox 2005). Because all of the very extensive literature on the ecology and behavior of these frogs uses the name *Rana,* I have not attempted to update the names in this book.

Natural History: Most species are medium to large aquatic or semiaquatic frogs, usually found near lakes, ponds, marshes, and swamps. The gopher frogs (*Rana capito*) and crawfish frogs (*R. areolata*) of the southeastern United States are semifossorial and often are associated with burrows constructed by other animals. There also are stream-dwelling ranids in North America, including *R. aurora* and *R. boylii.* There are other stream-dwelling *Rana* in Central America (e.g., *R. maculata*) and the Himalayas (stream-dwelling Himalayan species are sometimes placed in the genus or subgenus *Paa*). Other stream-adapted ranids include Asian species in the genera *Amolops* and *Staurois* (fig. 1.21 F) and the African genus *Conraua,* which includes the so-called African giant frog (*Conraua goliath*). All of these have tadpoles with sucker-like mouths or abdominal suckers for holding onto rocks in swift currents. The Southeast Asian crab-eating frog (*Fejervarya cancrivora*) is unusual in frequenting salty mud flats where it feeds on marine crabs and other invertebrates. Some ranid frogs have expanded toe pads and resemble hylid tree frogs (e.g., *R. chalconata* of Borneo). Another Bornean frog, *R. hosii,* has expanded toe pads that are used to climb on rocks and vegetation near streams.

Some ranids are burrowing frogs, including African species in the genera *Tomopterna* and *Pyxicephalus* (fig. 1.21 D), both of which are relatively rotund, and the African genus *Aubria,* which has a more elongate body form. African frogs in the genus *Ptychadena* are semiaquatic frogs similar to *Rana.* The genus *Platymantis* is found in New Guinea, the Philippines, the Solomon Islands, and nearby islands. These frogs are terrestrial or arboreal inhabitants of tropical rainforests. They lay nonaquatic eggs that undergo direct development. Direct development also is found in several other genera closely related to *Platymantis.*

Family Rhacophoridae

Distribution: Tropical Africa, China, Southeast Asia, Japan, Taiwan, Philippines, Greater Sunda Islands.

Content: Ten genera, about 270 species. Although several clades of frogs, such as the mantellid frogs of Madagascar, have sometimes been included in this family (see Mantellidae), most classifications include only 8–10 genera. Recent molecular data suggest that the Madagascar frogs in the genera *Boophis* and *Aglyptodactylus,* which traditionally had been placed in the subfamily Rhacophorinae, actually are part of a monophyletic Madagascar mantellid clade (Bossuyt and Milinkovitch, 2000; C. Richards, Nussbaum, and Raxworthy 2000; Vences and Glaw 2001; Vences et al. 2002; J. Wilkinson, Drewes, and Tatum 2002). The subfamily Rhacophorinae now includes the genera *Chirixalus, Chiromantis* (fig. 1.20 C), *Nyctixalus, Philautus, Polypedates* (fig. 1.20 D), *Rhacophorus,* and *Theloderma,* with about 200 species, although some of these genera, including *Chirixalus* and *Polypedates,* appear not to be monophyletic (J. Wilkinson, Drewes, and Tatum 2002). Two species of *Chirixalus* from Taiwan, China, and the Ryukyu Islands sometimes are placed in a separate genus with a confusingly similar name, *Kurixalus,* which may be related to another species in Vietnam (Matsui and Orlov 2004). All of the published literature on the ecology and behavior of these frogs uses the original name, however. The remaining five species of rhacophorids are stream-breeding frogs in the genus *Buergeria* (fig. 1.20 B), in a separate subfamily Buergeriinae. Removal of the Madagascar genera from the family Rhacophoridae makes the family almost exclusively an Asian clade, with only the genus *Chiromantis* being found in Africa.

Natural History: Most rhacophorids are tree frogs, convergent with hylids in appearance and general ecology. However, unlike hylids, many rhacophorids produce foam nests that are placed in trees, attached to rocks, or laid at the water's surface (the genera *Rhacophorus, Polypedates,* and *Chiromantis*). In some species, the outer surface of the foam nest hardens and protects the tadpoles from desiccation. Frogs in the Asian genus *Buergeria* lay eggs under rocks in streams. Deposition of nonaquatic eggs is known in *Philautus* and *Chirixalus.* In the former, eggs may undergo direct development into small froglets, whereas in the latter, they hatch into tadpoles that feed on conspecific eggs provided by the female. Members of the genus *Chirixalus* exhibit a variety of reproductive modes and sometimes lay eggs in treeholes, although some of this reproductive diversity actually may reflect a lack of close relationship among different members of this group (Frost et al. 2006). Frogs in the genera *Theloderma* and *Nyctixalus* also breed in treeholes and have tadpoles that develop without feeding.

Family Rhinodermatidae

Distribution: Cool temperate forests in the Andes of southern Chile and Argentina.

Content: A single genus, *Rhinoderma,* with two species. The first species described in this family, *R. darwinii* (fig. 1.20 E), was discovered by Charles Darwin on the voyage of the *Beagle.* The relationship of *Rhinoderma* to other anurans is unclear. Frost et al. (2006) placed this genus in the family Cycloramphidae.

Natural History: These are small, largely terrestrial frogs that live near cold streams in the southern beech (*Nothofagus*) forests of Chile and Argentina. They have a unique reproductive mode. Tadpoles hatch from terrestrial eggs and are taken into the vocal sac of the male and carried for some time. In *R. darwinii,* the nonfeeding tadpoles emerge from the vocal sac as miniature frogs, whereas in *R. rufum,* tadpoles are deposited in small pools to complete development.

Family Rhinophrynidae

Distribution: Lowland areas from southern Texas through Mexico to Costa Rica.

Content: Only one living species, *Rhinophrynus dorsalis,* the Mexican burrowing frog (see fig. 10.1 A in chapter 10). Phylogenetic analyses place this frog as the sister group of the pipids on the basis of both larval morphology and molecular data (Ford and Cannatella 1993; Hay et al. 1995; Haas 2003; Púgener, Maglia, and Trueb 2003).

Natural History: This peculiar-looking frog has an egg-shaped body, a pointed snout, and short legs with spade-like hind feet. They are almost completely subterranean, coming to the surface only after heavy rains to feed and breed. Eggs are laid in shallow temporary ponds and quickly hatch into tadpoles that are midwater suspension feeders. Adults feed mainly on termites.

Family Sooglossidae

Distribution: Seychelles Islands.

Content: Two genera, *Sooglossus* (three species) and *Nesomantis* (one species) (fig. 1.20 F). The members of this family are all endemic to the Seychelles Islands in the Indian Ocean. This archipelago is a remnant of the supercontinent Gondwanaland and probably was connected to India about 75 million years ago (Nussbaum 1984; Bossuyt and Milinkovitch 2001). Because of their long isolation, both the continental affinities and the relationships of sooglossids to other anuran families have been a matter of some debate. Traditionally they were thought to be closely related to ranoid frogs, but a number of derived morphological characters are shared with the myobatrachines of Australia, suggesting these are their closest relatives (Ford and Cannatella 1993). Hay et al. (1995) could not resolve their relationships to other anurans based on mitochondrial DNA and placed them in a lineage separate from all other families. They retain the ancestral condition of inguinal amplexus (Nussbaum 1980), but other aspects of their reproductive biology are thought to be derived. A recently discovered burrowing frog from India (*Nasikabatrachus sahyadrensis*) now appears to be the sister group of sooglossids (Biju and Bossuyt, 2003; see "Family Nasikabatrachidae"). Relationships within the family are uncertain, and it may be that *Nesomantis* belongs within the genus *Sooglossus* (Gerlach and Willi 2002).

Natural History: All four species are small, nondescript terrestrial frogs that are most common in moist upland forests on the larger islands. A recently described species, *S. pipilodryas,* was found most commonly in the leaf axils of one species of palm tree (Gerlach and Willi 2002). All apparently lay terrestrial eggs, although the life history of *Nesomantis* is essentially unknown. In *Sooglossus gardineri,* eggs undergo direct development in a hidden terrestrial nest, where they are attended by the female (see fig. 10.10 B in chapter 10. In contrast, the terrestrial eggs of *S. seychellensis* hatch into nonfeeding tadpoles that are carried on the back of a parent, apparently the male, until they metamorphose (Nussbaum, 1984).

Morphological Evolution and Ecology in Anurans

All frogs share certain morphological characteristics that make them immediately distinguishable from other vertebrates, most notably their shortened bodies, extremely large hind legs, and relatively large heads and eyes. Nevertheless, anurans are morphologically diverse and occupy a variety of habitats, from ponds and streams to tropical rainforests, grasslands, high-altitude heaths, and hot deserts. Some species are strictly aquatic, while others are equally at home on land or in the water, or are specialized for terrestrial, fossorial, or arboreal life. The following sections provide an overview of the ecological context of morphological evolution in anurans, with special emphasis on the relationship of body size to ecology, modes of locomotion, adaptations for burrowing and arboreal life, and the functional morphology of feeding.

Habitat Associations of Adult Anurans

Some lineages of anurans are essentially uniform in their habitat associations. *Ascaphus,* pipids, and *Pseudis* are aquatic; *Leiopelma, Brachycephalus,* and *Rhinoderma* are terrestrial; *Hemisus, Nasikabatrachus,* pelobatids, and *Rhinophrynus* are fossorial; and *Heleophryne* occupies riparian habitats along streams. All of these clades, however, contain relatively few species, and in several cases, only a single species. Larger lineages invariably exhibit much greater variation in habitat use, although one or two lifestyles may predominate. Adult habitat associations of major anuran lineages are listed in table 1.1. I have followed Menzies (1976) in differentiating between scansorial species that live near the ground, but climb into low vegetation, and arboreal species, which seldom come near the ground except to breed. However, other authors have treated arboreal species as a subset of scansorial frogs (Zweifel and Tyler 1982; Zweifel 1985), which adheres to the strict definition of scansorial as "climbing." Clearly these categories blend into one another, as do scansorial and terrestrial, terrestrial and fossorial, terrestrial and riparian, and riparian and aquatic lifestyles. Associations with certain unusual habitats, such as caves, boulders, rock crevices, and bromeliads, are not listed separately because they are rare, but they often are correlated with distinctive morphological traits (e.g., large eyes in cave-dwelling frogs and flattened bodies in crevice and bromeliad-dwellers).

In some groups, the most common habitat association may represent the ancestral condition for the entire clade. For example, terrestrial habits probably are ancestral for adult bufonids, with only a few species having secondarily evolved fossorial, arboreal, or riparian habits. Terrestrial, fossorial, and riparian hylids almost certainly evolved from

Table 1.1 Habitat associations of some major clades of anurans

Family	Major habitats	Minor habitats
Arthroleptidae	Terrestrial	Scansorial
Astylosternidae	Riparian	Terrestrial
Bufonidae	Terrestrial	Fossorial, arboreal, riparian
Centrolenidae	Arboreal	Riparian
Dendrobatidae	Terrestrial	Scansorial, arboreal, riparian
Hemiphractinae*	Arboreal	Terrestrial
Hylidae		
Hylinae	Arboreal	Scansorial, fossorial, riparian, aquatic (*Pseudis*)
Pelodryadinae	Arboreal	Scansorial, terrestrial, fossorial, semiaquatic
Phyllomedusinae	Arboreal	Terrestrial
Hyperoliidae*	Arboreal	Scansorial, terrestrial, riparian, fossorial
Leptodactylidae*		
Ceratophryinae	Terrestrial	Fossorial
Cycloramphinae	Riparian	
Eleutherodactylinae	Terrestrial	Scansorial, arboreal, fossorial
Leptodactylinae	Terrestrial	Fossorial, riparian, aquatic
Telmatobiinae		
Alsodini	Terrestrial	Semiaquatic, fossorial
Telmatobiini	Semiaquatic	Aquatic, terrestrial
Mantellidae	Terrestrial	Scansorial, arboreal, fossorial
Megophryidae	Terrestrial	Fossorial, riparian
Microhylidae		
Asterophryinae	Terrestrial	Fossorial
Brevicipitinae	Fossorial	Terrestrial
Cophylinae	Terrestrial	Arboreal, scansorial, fossorial
Dyscophinae	Terrestrial	Fossorial
Genyophryinae	Terrestrial	Arboreal, scansorial, fossorial, riparian
Microhylinae	Terrestrial	Fossorial
Scaphiophryinae	Terrestrial	Fossorial
Myobatrachidae*		
Limnodynastinae	Terrestrial	Fossorial, riparian
Myobatrachinae	Terrestrial	Fossorial, riparian
Pelobatidae	Fossorial	Terrestrial
Pelodytidae	Terrestrial	Fossorial
Petropedetidae	Terrestrial	Riparian, aquatic
Ranidae*	Semiaquatic, terrestrial	Fossorial, aquatic, scansorial
Rhacophoridae	Arboreal	Scansorial, terrestrial, riparian

Sources: Habitat classification modified from Duellman (1993b), with additional information from Inger (1954), Menzies (1976), Zweifel and Tyler (1982), Ameit (1989), Heyer et al. (1990), Cogger (1992), Glaw and Vences (1994), and other standard references.

Notes: Groups that may not be monophyletic clades are marked with an asterisk (*). Very small clades or those with little variation in habitat associations are omitted. Scansorial refers to species that live near the ground, but climb into low vegetation. Arboreal refers to species that spend most of their lives above the ground. Fossorial refers to burrowing species. Riparian species live along the shores of bodies of water.

arboreal ancestors. In other cases, however, the most common habitat association may simply reflect the lifestyles of a single highly successful derived lineage. For example, among leptodactylids, terrestrial or arboreal species are by far the most common, but this is due almost entirely to the success of the genus *Eleutherodactylus* and its close relatives (Duellman, 1993b).

Within more restricted groups, the evolution of habitat associations can go in different directions, even in closely related species. For example, the *Eleutherodactylus* of Hispaniola belong to two separate lineages, one primarily arboreal, with some secondarily derived terrestrial species, the other mainly terrestrial, with secondarily derived arboreal species. The result is convergent evolution of similar ecomorphs in the two lineages, but with evolution proceeding in opposite directions (Hedges 1989). Extensive convergent evolution of similar ecomorphs also is evident in the ranoid frogs of Madagascar and South Asia, which have independently evolved into terrestrial, fossorial, arboreal, rock-dwelling, and riparian species that are so similar morphologically that they have been considered to be closely related (Bossuyt and Milinkovitch 2000).

Evolutionary transitions from one type of habitat to another appear to be constrained by morphological features acquired in the ancestral habitat. For example, there are few lineages of frogs that include both highly aquatic and highly arboreal species (table 1.1), and those that do are large and diverse groups that may not be monophyletic, such as ranids (Ford and Cannatella 1993). In general, adaptive radiation in habitat use appears to occur along either horizontal or vertical habitat gradients. That is, largely semiaquatic or riparian lineages may also have some terrestrial or highly aquatic species, while largely terrestrial lineages usually also include scansorial, arboreal, or fossorial species (table 1.1). For example, in the cophyline microhylid frogs of Madagascar, there have been multiple evolutionary transitions between terrestrial and arboreal habits (Andreone et al. 2005).

The data in table 1.1 also show that the popular impression that most frogs are closely associated with water is incorrect. In fact, most major anuran clades are largely terrestrial or arboreal as adults, and only a few are strictly aquatic. This pattern is particularly evident in the wet tropics (Duellman 1990). About 75% of frogs in sub-Saharan Africa are either terrestrial or arboreal as adults, and for South America, the figure is closer to 90%. Only 4% of the frogs in these regions are strictly aquatic (Duellman 1993b), and these belong to a very small number of clades (Caldwell 1996a).

Body Size and Ecology

Anurans come in a wide range of body sizes. The largest frog in the world is a ranid from West Africa, *Conraua goliath*, with an adult body length of about 300 mm and a mass exceeding 3 kg (Duellman and Trueb 1986), but there are many other species that exceed 100 mm in length. There is some disagreement over which species is the world's smallest. A tiny Cuban frog, *Eleutherodactylus limbatus* (11.5 mm), is frequently cited, but the Brazilian frog *Brachycephalus didactylus* (9.8 mm), *Sooglossus gardineri* (Sooglossidae) of the Seychelles Islands (10.5 mm), *Stumpffia pygmaea* (Microhylidae) from Madagascar (10–12 mm), *Syncope carvalhoi* (Microhylidae) from Amazonian Brazil (10 mm), and *Aphantophryne minuta* (Microhylidae) from New Guinea (12 mm) are in the same size range (see the following discussion of miniaturized frogs; S. L. Mitchell and Altig 1983; Nussbaum 1984; Duellman and Trueb 1986; Zweifel and Parker 1989; Glaw and Vences 1994; Caldwell 1996a).

There has never been a detailed quantitative study of the relationship of body size to ecology in anurans. If we consider all anurans together, there is no obvious relationship between body size and habitat. For example, the largest toads, *Bufo marinus* (240 mm) and *Bufo blombergi* (250 mm), are terrestrial as adults, while other very large frogs, such as *Rana catesbeiana* (up to 200 mm), are semiaquatic. Nevertheless, within certain lineages, some general relationships between body size and ecology are evident. I will give only a few examples. Note that these patterns tell us nothing about the direction of evolution in body size in a particular clade; that is, we cannot say whether large or small body size is ancestral or derived without a thorough phylogenetic analysis of the group.

Among ranid frogs in the northern hemisphere (North America, Europe, and northern Asia), there is a consistent relationship between body size and association with aquatic habitats. On all three continents, the largest species are found primarily in permanent lakes, ponds, rivers, and streams. These include *R. catesbeiana* and *R. grylio* in North America, *Rana ridibunda* and its relatives in Europe and the Middle East, and *Hoplobatrachus tigerinus, Paa boulengeri,* and *Paa yunnanensis* in Asia. At the other end of the size scale are the North America woodfrog (*Rana sylvatica*) and the ecologically similar, but unrelated, Eurasian woodfrogs (*R. temporaria, R. japonica,* and their relatives), all of which are primarily terrestrial outside of the breeding season. Ranids of intermediate size span a wide range of habitats, from relatively terrestrial (*Rana pipiens*) to semiaquatic species that frequent the margins of ponds, streams, flooded rice fields, and marshes (*Rana palustris, R. arvalis, R. graeca, Fejervarya limnocharis*) to more aquatic species that are seldom far from water (*Rana septentrionalis, R. pretiosa, R. nigromaculata*). Even in local species assemblages, these patterns are sometimes evident. For example, bullfrogs (*Rana catesbeiana;* 98 mm), green frogs (*R. clamitans;* 73 mm), and leopard frogs (*R. pipiens;* 62 mm) living together at a site in eastern Canada occupied a habitat gradient from ponds to pond margins to terrestrial habitats that paralled differences in body size (McAlpine and Dilworth, 1989). At a site in Spain, the larger *R. perezi* occupied pond and marsh habitats, whereas the smaller *R. iberica* lived in terrestrial habitats close to water (Lizana, Perez-Mellado, and Ciudad 1987, 1990; see chapter 15 for further discussion of niche partitioning in frogs).

In several groups that include both terrestrial and arboreal species, there is a general tendency for the smallest species to be the most terrestrial and the largest species the most arboreal, with intermediate species often climbing into low vegetation. For example, the smallest North American hylids, *Acris* and *Pseudacris,* all live near the ground or in low vegetation. Larger species of *Hyla,* such as *H. versicolor, H. chrysoscelis,* and *H. gratiosa* often move high into the forest canopy outside the breeding season. Among Neotropical hylids, the smallest species, such as *Hyla minuta* and *H. microcephala,* tend to be found on low vegetation in grassy habitats, while intermediate size species occupy a variety of habitats from ground level to mid-level canopy. The largest species, such as *Hyla boans, H. rosenbergi, H. miliaria, Trachycephalus venulosus, Agalychnis calcarifer, A. craspedopus,* and several species of *Phyllomedusa,* invariably are canopy-dwellers that are seen near the ground only during the breeding season (Duellman 1970; Toft and Duellman 1979; Zimmerman and Rodrigues 1990; Hoogmoed and Cadle 1991). This pattern may be related to the advantages of large body size in an environment exposed to drying winds during the day (see chapter 2; these frogs probably limit their activity to nighttime hours). Exceptions are bromeliad-dwelling hylids, which often live high in the canopy, but also are quite small, presumably because they live in small microhabitats that are protected from drying winds.

Similar patterns are sometimes seen in *Eleutherodactylus.* In Puerto Rico, where members of this genus belong to a single monophyletic clade, the smallest species (*E. locustus, E. eneidae, E. wightmanae*) are the most terrestrial, while several of the largest species (*E. coqui, E. hedrecki, E. portoricensis*) are more arboreal, although *E. coqui* utilizes the entire vertical structure of the forest, from leaf litter to the canopy. Juveniles of this species are largely terrestrial. Again, species associated with bromeliads tend to be smaller than other arboreal species (*E. gryllus, E. cochranae, E. jasperi;* Rivero 1978; Hedges 1989; Joglar 1998). The tendency for larger species to be more arboreal was not evident at a site in Costa Rica (Miyamoto 1982), but the *Eleutherodactylus* there probably do not represent a single closely related lineage. Among the microhylid frogs of Australia and New Guinea, which resemble *Eleutherodactylus* in ecology and breeding biology, the patterns are less clear. Most species are small and terrestrial, but some relatively small species are scansorial. One of the largest species, *Cophixalus riparia,* is arboreal. Species in the genus *Oreophryne* are relatively small, but also arboreal. They tend to shelter in the leaf axils of banana plants and water-holding epiphytes, and therefore are ecological equivalents of Neotropical bromeliad-dwellers (Menzies 1976; Zweifel and Tyler 1982; Zweifel 1985).

Despite these general relationships between body size and habitat within certain lineages, it is clear that there is not a single body size that is most suited to a particular habitat. For example, nearly all bufonids are terrestrial, yet the family includes species that span almost the entire range of body sizes in anurans. Within particular habitats, frogs of different sizes frequently live together. Tiny cricket frogs (*Acris*) often share the shoreline of a pond with much larger green frogs (*Rana clamitans*). The floor of the Brazilian rainforest is inhabited not only by tiny frogs in the family Brachycephalidae, but also large leptodactylid frogs such as *Ceratophrys,* which often prey on other frogs. In the rainforests of New Guinea and northern Australia, tiny terrestrial microhylids share the forest floor with much larger microhylids, ranids, and myobatrachids. No doubt these frogs living in the same general habitat differ in their use of microhabitats, but detailed ecological studies are scarce (see chapter 15).

Miniaturized Anurans

One evolutionary trend in body size among anurans that deserves special mention is miniaturization (Hanken and Wake 1993; Clarke 1996; Yeh 2002). In several lineages, some species have evolved adult body sizes of less than 20 mm. Miniaturized frogs include the following: *Brachycephalus* (fig. 1.12 F); very small dendrobatid frogs in the genus *Dendrobates* (those formerly placed in the genus *Minyobates;* fig. 1.14 B and 1.22 A), along with a few species of *Colostethus* and *Epipedobates;* Neotropical microhylids in the genus *Syncope* and *Synapturanus;* microhylids from Australia and New Guinea in the genera *Cophixalus, Austrochaperina* (fig. 1.22 B), *Choerophryne* (fig. 1.22 C), and *Aphantophryne;* microhylids from Madagascar in the genus *Stumpffia;* very small *Eleutherodactylus,* such as *E. limbatus* from Cuba and *E. griphus* from Jamaica; small leptodactylids in the genera *Adelophryne, Phyllonastes, Phrynopus,* and *Phyzelaphryne;* African bufonids in the genera *Mertensophryne* (fig. 1.22 D) and *Didynamipus;* Neotropical bufonids in the genus *Dendrophryniscus* (fig. 1.13 C); the sooglossid frog *Sooglossus gardineri* from the Seychelles Islands; and the North American hylid *Pseudacris ocularis* (S. L. Mitchell and Altig 1983; Nussbaum 1984; Alberch and Gale 1985; Zweifel 1985; Crombie 1986; Myers 1987; Zweifel and Parker 1989; Simon and Toft 1991; Vences and Glaw 1991; Glaw and Vences 1994; B. T. Clarke 1996; de la Riva and Köhler 1998; Zweifel 2000; Kraus and Allison 2001; Lehr, Aguilar, and Lundberg 2004).

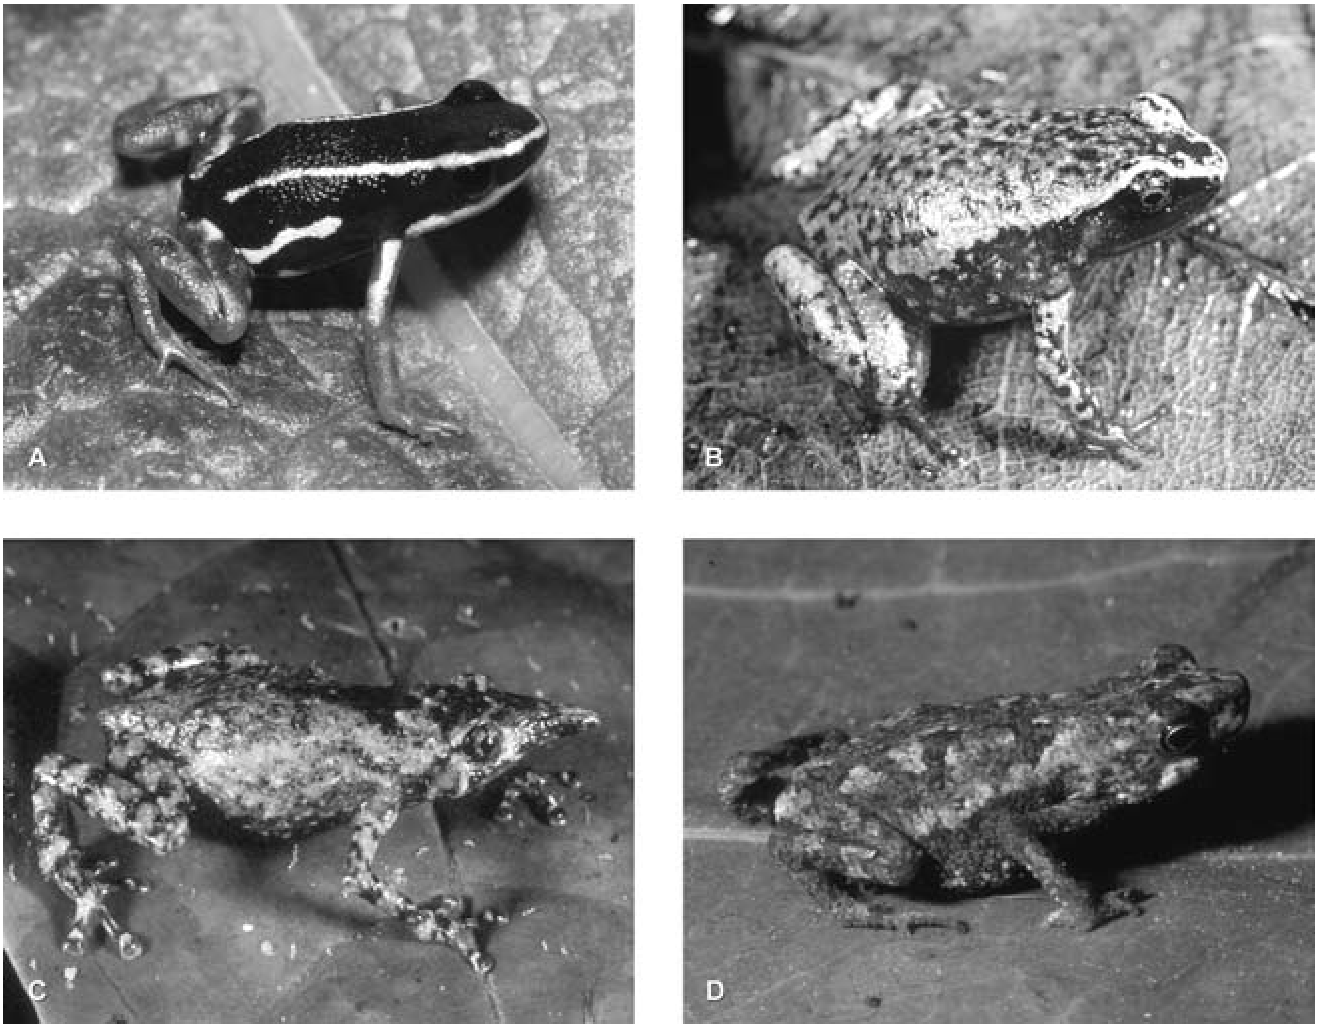

Fig. 1.22. Miniaturized frogs have evolved in several unrelated families. Most of these are terrestrial forest floor frogs from the tropics and have adult body sizes as small as 10 mm. These include many Neotropical dendrobatid frogs, such as *Dendrobates claudiae* from Panama (A), microhylid frogs from Australia and New Guinea such as *Austrochaperina pluvialis* (B), and *Choerophryne longirostris* (C), and the tiny East African bufonid *Mertensophryne micronotus* (D). Photos by Karl Heinz Jungfer (A), Harold Cogger (B), Allen Allison (C), and Robert Drewes (D).

Reduction in body size in these miniaturized frogs is correlated with retardation in the development of certain morphological features, resulting in morphological traits that are paedomorphic relative to those of less derived relatives. This has been attributed to a process known as progenesis, the truncation of development at an early stage relative to the pattern seen in ancestral species. Without detailed ontogenetic studies, it often is difficult to determine exactly what process has been involved in miniaturization (Hanken and Wake 1993). Many of the miniaturized frogs listed here have undergone reductions in skull elements and in the number and size of the digits, with the missing or reduced elements being those that appear latest in development (Alberch and Gale 1985; Trueb and Alberch 1985; Yeh 2002). Similar patterns are seen in other small frogs as well, such as the small terrestrial Australian myobatrachids in the genus *Uperoleia,* most of which are slightly larger (20–30 mm; M. Davies 1989).

The highly miniaturized frogs share a number of ecological traits, some of which also are characteristic of other small frogs. Most are found in wet tropical regions, primarily in forested habitats, where they are terrestrial or scansorial inhabitants of the forest floor litter. Most have some unusual mode of reproduction involving deposition of terrestrial eggs that undergo direct development or hatch into tadpoles that remain in the nest or are carried to water by a parent (see chapter 10). In most cases, these unusual reproductive modes are characteristic of the entire clade to which the miniature species belong, although this is not true of the bufonids. When the diets of these frogs are known, they are almost always specialists on tiny prey such as ants, termites, mites, and collembolans, items that are scarce in the diets of larger frogs, even in the same family or genus (Inger and Marx 1961; Toft 1980a, b, 1981, 1995; S. L. Mitchell and Altig 1983; Zweifel 1985; Crombie,1986; Simon and Toft 1991). All of these miniature frogs are members of neobatrachian clades that have the ability to project the tongue well beyond the tips of the jaws, probably a prerequisite for feeding on very small prey (Nishikawa et al. 1992). It is not clear whether the ability to specialize on small but very abundant prey is a selective force favoring the evolution of miniaturization, or simply a constraint imposed by small size (see further discussion of the functional morphology of feeding). What is clear is that miniaturization has evolved independently in diverse lineages of anurans.

The Anuran Body Plan and Modes of Locomotion

Anurans are, first and foremost, animals built for jumping, and many features of their bodies are highly derived compared to ancestral amphibians (Zug 1972, 1978). Locomotion in early terrestrial amphibians presumably was similar to that found in living salamanders. Both front and back legs move in alternating fashion, coupled with lateral undulations of the body. In contrast, jumping locomotion utilizes simultaneous movement of the hind legs, which are much larger than the front legs. Nearly all of the force for jumping comes from the hind legs (Calow and Alexander 1973; R. Marsh 1994; Gillis and Biewener 2000), while the front legs and pectoral girdle serve mainly to support the frog at rest and to absorb the shock of landing after a jump (Emerson 1983). Several features of hindlimb muscle morphology and physiology provide the rapid burst of power needed for jumping (Lutz and Rome 1994). The power output generated during a frog's jump is impressive relative to the size of the leg muscles and is enhanced by stored elastic energy in tendons and muscle fibers (R. Marsh 1994; Marsh and John-Alder 1994). Across a range of phylogentically unrelated species, the mass of the thigh musculture was positively correlated with take-off speed, with jumping frogs such as *Eleutherodactylus fitzingeri* having a take-off speed about 2.5 times greater than that of hopping toads such as *Bufo alatus* (= *B. typhonius;* Choi, Shim, and Ricklefs 2003). All jumping anurans can achieve rapid takeoffs from land, but some frogs, such as the so-called "skipper frogs" of the ranid genus *Euphlyctis,* also can jump from a floating position in the water. This ability is enhanced by large and convex webbing on the hind feet, which allow for a greater take-off velocity than can be achieved by frogs with more typical convex webbing (Nauwelaerts, Scholliers, and Aerts 2004).

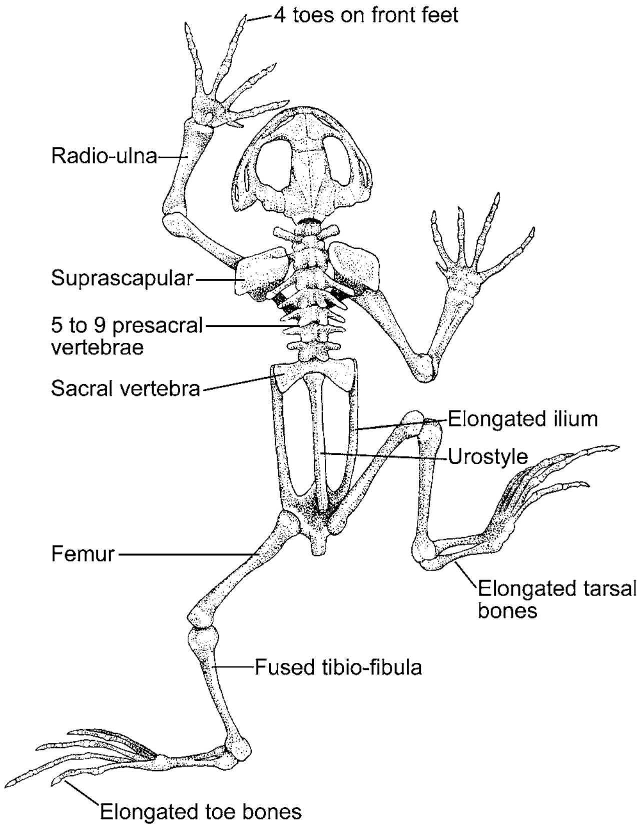

Fig. 1.23. Skeleton of a frog, showing features important in jumping locomotion. After Pough, Janis, and Heiser (2001).

In addition to the elongated, muscular hind legs, a number of other morphological features enhance the jumping ability of frogs (Zug 1972; Emerson 1983). One obvious feature, which gives the order its name, is the loss of the tail. In addition, the vertebral column is greatly shortened through reduction in number of vertebrae (fig. 1.23). Salamanders typically have at least 20 vertebrae anterior to the sacrum (the vertebra that articulates with the pelvic girdle), whereas frogs have less than 10, and sometimes as few as five. The vertebral column is stiffened by fusion of the postsacral vertebrae into a single bone, the urostyle, and by overlapping processes on the presacral vertebrae that reduce lateral movement. The rear half of the body consists of the pelvic girdle, which has a somewhat triangular shape, with the two hind legs articulating with the girdle very close together. This provides a single focal point for force distribution during jumping. The hind limb is strengthened through fusion of the tibia and fibula. The tarsal bones are fused and elongated, and the toes of the hind foot are elongated as well, providing a broad platform for jump takeoffs. The skulls of anurans also are highly derived relative to ancestral amphibians. Bony elements and teeth are reduced in most species, leaving a skull that is little more than a supporting framework for the brain case and relatively large sense organs, especially the eyes and ears. Presumably the reduction in skull elements serves to reduce the mass of the skull, thereby enhancing jumping performance. Some frogs have secondarily evolved increased or decreased ossification of the skull as adaptations to particular environments (Trueb 1993).

Jumping is the most common mode of locomotion in frogs and is characteristic of frogs from a wide range of habitats. The frogs familiar to most people are semiaquatic species that live around lakes, ponds, swamps, marshes, or the margins of streams. These have moderately streamlined bodies, elongate pelvic girdles, and relatively long, muscular hind legs with extensive webbing on the hind feet. Other jumping frogs live on rocks in fast-moving streams and usually are equipped with expanded toe pads to hold on to the rocks. Most arboreal frogs also are very good jumpers. Some terrestrial frogs are powerful jumpers as well, including species in the Neotropical genus *Eleutherodactylus.* Most jumping frogs are sit-and-wait predators that feed on relatively large prey items. They escape from predators by leaping into the water or disappearing into leaf litter after one or two long jumps. Each jump can be equivalent to several body lengths, but jumping frogs generally have a limited capacity for sustained locomotor activity and therefore tire quickly (see chapter 5).

Other forms of terrestrial locomotion seen in frogs, including hopping, walking, and burrowing, are modifications of jumping. Hopping is similar to jumping, but movement occurs in a series of short leaps, rather than a few long ones. Hopping is characteristic of many terrestrial anurans, including toads (*Bufo*) found throughout the world, desert-dwelling spadefoot toads (*Scaphiopus*) of the southwestern United States, Neotropical leptodactylid frogs in the genus *Physalaemus,* which inhabit the floor of tropical rainforests, and microhylid frogs from Australia and New Guinea (*Cophixalus, Austrochaperina*), also found in forest-floor leaf litter. Hopping anurans typically have relatively short, stout bodies with shorter pelvic girdles and shorter hind legs than jumping frogs (Emerson 1978). Many of these frogs are active foragers, moving about the forest floor in a series of short hops, each equivalent to or less than one body length. Hopping frogs generally have greater capacities for sustained locomotion than jumping frogs, but they move at relatively slow speeds (see chapter 5). Because they cannot escape from predators by suddenly leaping away, most hopping frogs rely on crypsis or on distasteful skin secretions and aposematic coloration to discourage predators (see chapter 14).

Some frogs move mainly by walking, which involves movement of both front and back legs, alternating from side to side, but without the extensive lateral movement of the trunk seen in walking salamanders. Examples of walking frogs include microhylids such as *Kaloula pulchra* from Southeast Asia, Neotropical bufonids in the genus *Atelopus,* and the so-called running frogs (*Kassina,* Hyperoliidae) of southern Africa. Some arboreal frogs, such as Neotropical phyllomedusine hylids (*Agalychnis, Phyllomedusa*) walk while on the ground, and they also engage in hand-over-hand vertical climbing. Walking frogs share some characteristics of hopping frogs, including relatively short hind legs and feet, but species such as *Kassina* and *Atelopus* have more elongate bodies than do hopping frogs. These two modes of locomotion tend to grade into one another, with some frogs switching from hopping to walking gaits. Hopping and walking frogs both have modifications of the iliosacral joint and associated musculature that change the direction of movement in the pelvic girdle relative to that seen in jumping frogs. In jumping frogs, movement of the pelvic girdle is mainly in the vertical plane, whereas in walking and hopping frogs movement is either front-to-back or involves lateral rotation of the pelvic girdle. Anurans with an iliosacral joint that allows for lateral rotation appear to be faster walkers than those with vertical or front-to-back pelvic movements, although only a few species have been compared (Emerson 1979; Emerson and De Jongh 1980).

Most frogs can swim, even those that do not normally live in water. General patterns of limb movement are similar in swimming and jumping (Calow and Alexander 1973; Emerson and De Jongh 1980; Gal and Blake 1988a, b; Peters, Kamel, and Bashor 1996), although the actions of individual muscles differ to some extent (Gillis and Biewener 2000). Most frogs swim by extending their hind limbs synchronously while keeping the front legs pressed against the body, although some species that have hopping or walking modes of locomotion may paddle with the front feet while pushing through the water with the hind legs. Most authors have considered swimming to be derived from jumping locomotion, since both involved synchronous movements of the hind legs. This view was challenged by Abourachid and Green (1999), who found that the most primitive frogs, *Leiopelma* and *Ascaphus,* always swim with alternating movements of the hind legs. These frogs jump like all other frogs, with synchronous movements of the hind legs. This suggests that the motor patterns involved in jumping and swimming may have evolved independently.

A few frogs have become almost entirely aquatic and consequently are poorly equipped for locomotion on land. The most fully aquatic frogs are members of the family Pipidae, but others, including South American frogs in the genera *Pseudis* (Pseudidae) and *Telmatobius* (Leptodactylidae), are largely aquatic. Other frogs, including *Ascaphus* (Ascaphidae), *Bombina* and *Barbourula* (Bombinatoridae), the North American pig frog (*Rana grylio,* Ranidae), and other ranids, spend most of their time in the water, but can move onto land or rocks in streams. Aquatic frogs typically have streamlined bodies, large, muscular hind legs, and hind feet with webbing extending to the tips of the toes. Some, such as *Bombina, Telmatobius,* and all pipids, are dorsoventrally flattened, with the hind legs oriented more to the sides of the body than underneath. Some aquatic frogs also have well-developed lateral line systems (e.g., *Xenopus*).

Burrowing Frogs

Many anurans that move mainly by hopping or walking also are capable of burrowing, whereas burrowing is uncommon in jumping anurans (Zug 1972; Emerson 1976; Taigen, Emerson, and Pough 1982). Anurans often burrow in loose soil or sand to escape cold winters (see chapter 3), hot summers, or long dry seasons (see chapter 2). Some species use burrows opportunistically in particularly hot or dry weather, while others use them as regular daytime retreats. Others lead a largely subterranean life, emerging only for short periods to feed or reproduce (e.g., spadefoot toads). A few species are almost completely subterranean, finding food and laying eggs underground and seldom, if ever, emerging at the surface.

The most common mode of burrowing involves digging with the hind feet, which often are equipped with special tubercles or spades. The animals descend backward into the soil, sometimes rotating in a circle as they do so (fig. 1.24). This mode of burrowing is not found in any other vertebrates, but has evolved repeatedly in many different families of anurans, including arthroleptids, bufonids, hylids, hyperoliids, leptodactylids, microhylids, myobatrachids, pelobatids, ranids, and rhinophrynids (Emerson 1976; Sanders and Davies 1984). The large, muscular hind legs of frogs require only minor modification to be useful in burrowing, and indeed, many nonfossorial frogs are facultative burrowers (Emerson 1976). Highly fossorial frogs that burrow backward typically have relatively short legs, with the tibio-fibula especially shortened relative to jumping anurans, a feature that could be an adaptation for walking as well as burrowing.

Some burrowing frogs have relatively short toes on the hind feet compared to those of jumping anurans, as in *Breviceps* (Microhylidae; Poynton and Pritchard 1976) and *Pyxicephalus* (Ranidae; Passmore and Carruthers 1979). Often there is a considerable amount of fleshy webbing between the toes, as in *Scaphiopus* (Pelobatidae; Stebbins 1954a), *Neobatrachus* (Myobatrachidae; Cogger 2000), and *Tomopterna* (Ranidae; Passmore and Carruthers 1979). Presumably all of these features enhance the animal's ability to push soil to the side while digging. In addition, various modifications of the hind-limb muscles serve to orient the digging tubercles on the hind feet in the proper position for pushing against the soil and increase the force of the lower leg during digging (see Emerson, 1976, for details of functional morphology). Burrowing also involves asynchronous movement of the hind legs, as in walking, not the synchronous movement used in jumping.

Many burrowing frogs have relatively short, globular bodies (e.g., figs. 1.15 F; 1.16 F; 1.17 C, D; 1.18 D; 1.19 A, C, D; 1.21 D). This is associated less with digging than with water conservation. A globular body reduces the surface area exposed to evaporation relative to body volume, an important adaptation for frogs in arid regions, where burrowing species are particularly common (see chapter 2). Many burrowing frogs also have distinctive diets, relying more heavily on ants and termites than do many other anurans. Termites are especially good food for a burrowing frog because they contain a lot of fat, which provides energy stores for a long dry season (see chapter 5). These frogs typically engage in active foraging, hopping or walking relatively long distances in search of prey, in contrast to the sit-and-wait foraging modes of most jumping anurans (Emerson

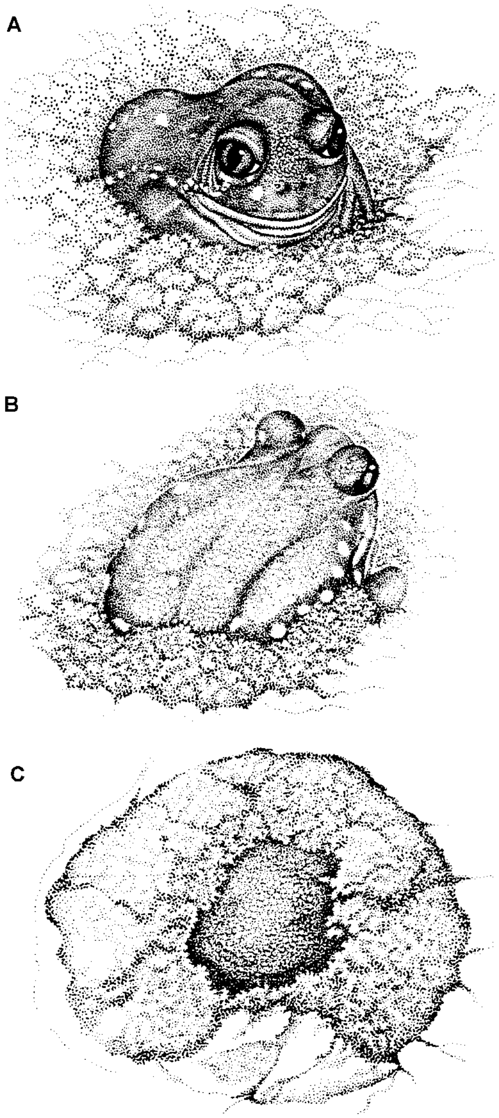

Fig. 1.24. Feet-first burrowing of the Australian myobatrachid frog *Heleioporus albopunctatus*. The frog rotates in a circle as it descends into the soil. Drawing by T. Wright from Littlejohn et al. (1993).

1976; Taigen, Emerson, and Pough 1982; Taigen and Pough 1985; Pough et al. 1992).

An alternative mode of burrowing is headfirst burrowing, but this is much less common, being found in only about 5% of fossorial anurans (Emerson 1976). These include the so-called shovel-nosed frogs of southern Africa (*Hemisus;* Hemisotidae), which not only use burrows as retreats, but lay eggs in them as well. When these frogs burrow, they bend the head downward, while keeping the vertebral column straight. The snout is inserted into the soil, and the animal pushes forward with breaststroke motions of the front legs, using the hind limbs to position itself (fig. 1.25). *Hemisus* exhibits several morphological features related to headfirst burrowing, including a pectoral girdle in which individual bones are fused, forming a single strong unit; a more forward location of the scapula (shoulder blade), which overlaps the margins of the skull; an increase in the size of the muscles involved in flexing the head; an increase in the size of muscles involved in retracting the front legs; and a fusion of the first two presacral vertebrae, which may prevent the vertebral column from buckling as the frog pushes forward through the soil (Emerson 1976). Similar morphological adaptations of the head and neck region are found in two monotypic genera of Neotropical microhylids, *Dasypops* and *Myersiella,* but the burrowing behavior of these frogs has not been described in detail (Emerson 1976).

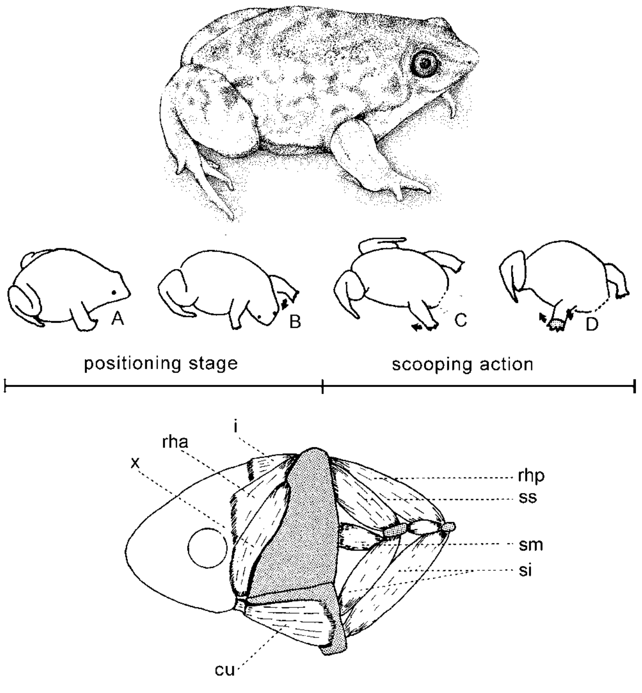

Fig. 1.25. *Hemisus marmoratus,* a headfirst burrower from southern African. The line drawings in the center show the first stages of burrowing. This frog is unique among anurans in being able to flex the head at an acute angle while not bending the vertebral column. Diagram at the bottom shows the anatomy of the head, with suprascapula (shaded) overlapping the back of the skull. Note the well-developed muscles that are used to bend the head. Abbreviations: cu = cucullaris muscle, i = intertransversarius muscle, rha = rhomboideus anterior muscle, rhp = rhomboideus posterior muscle, si = serratus inferior muscle, sm = serratus medius muscle, ss = serratus superior muscle, x = accessory muscle of the rhomboideus anterior. Drawing of frog by Mary Jane Spring from a photograph in Passmore and Carruthers (1995). Diagrams after Emerson (1976).

Several genera of microhylids in the two subfamilies found in New Guinea, the Asterophryinae and the Genyophryinae, include species that live most of their lives below the surface of the forest floor in a tangled mat of roots, rotting vegetation, and stones. These frogs not only burrow head first into the ground, but also move around and feed under the surface (Menzies and Tyler 1977). This mode of life makes backward burrowing impractical, and both Emerson (1976) and Menzies and Tyler (1977) suggested that headfirst burrowing is most likely to evolve in species that do at least part of their feeding underground. All of these species have relatively pointed snouts, and they exhibit a number of skull modifications related to burrowing. In *Copiula* and *Choerophryne,* several bones in the front of the skull are elongated, providing reinforcement for the elongated snout (fig. 1.22 C), and the whole front part of the skull is reinforced with bone. In *Xenobatrachus,* the maxillae (upper jaw bones) are fused in front, providing a stronger skull than the separated condition found in many frogs. In *Barygenys,* the mandibles (lower jaw bones) are massive and fused in front. In addition, all of these frogs exhibit varying degrees of thickening and keratinization of the skin on the snout, which presumably protects the skin from abrasion during burrowing (Menzies and Tyler 1977). Pointed snouts with cornified skin also are found in some *Eleutherodactylus* suspected of being headfirst burrowers, but the burrowing of these frogs has not been observed (Hedges and Thomas 1987).

One of the most peculiar of all burrowing frogs is the so-called turtle frog of western Australia (*Myobatrachus gouldii;* fig. 1.19 C). This frog is highly modified for subterranean life, with a small head and reduced eyes and a broad body with short, muscular legs. The front legs, which almost appear to arise from the side of the head, have greatly reduced toes and powerful muscles that are used for headfirst burrowing. It spends nearly all of its life underground, where it feeds on termites (Calaby 1956). Males either call from underground or partially or completely exposed on the surface. Once a female has been attracted, both the male and female burrow into the ground, where eggs are laid about a meter below the surface. These then develop without an aquatic tadpole stage (Roberts 1981).

Arboreal Frogs

Frogs in many different families have evolved adaptations for living in trees or other types of vegetation. These include families in which most species are tree frogs (Hylidae, Centrolenidae, Hyperoliidae, Rhacophoridae), as well as others in which some species are arboreal, but others are not (Leptodactylidae, Ranidae, Microhylidae, Dendrobatidae, Mantellidae). The most specialized arboreal frogs have a body morphology that is nearly the opposite of that seen in burrowing species, with relatively slender bodies, large heads, prominent eyes, narrow waists, long legs, and long toes equipped with enlarged digital pads (e.g., figs. 1.14 A, C, D; 1.15 B, C, E; 1.16 B, D; 1.17 F; 1.20 C, D). Not surprisingly, relatively few tree frog lineages include true burrowing species, although there are a few exceptions, such as *Pternohyla fodiens,* a burrowing Neotropical hylid that has lost many of the typical morphological features of hylid treefrogs (Trueb 1970). Some other hylids are facultative burrowers, including members of the Neotropical genus *Smilisca,* the North American barking tree frog (*Hyla gratiosa*) (Neill 1952), and two chorus frogs, *Pseudacris ornata* and *P. streckeri* (L. E. Brown, Jackson, and Brown 1972; L. E. Brown and Means 1984).

Most arboreal frogs use a combination of several modes of locomotion, including jumping, horizontal walking along branches, and vertical climbing, but the relative importance of each mode varies considerably. Very slender-bodied species, such as the North American green treefrog (*Hyla cinerea*), are powerful jumpers, and often launch themselves for considerable distances between branches or cattail stems. Others, such as the Neotropical phyllomedusine tree frogs, move mainly by walking and seldom make long jumps. Members of the genus *Phyllomedusa* have opposable digits that allow them to grasp branches with a monkeylike grip (fig. 1.15 C).

The ability of arboreal frogs to climb on vertical tree trunks, branches, and leaves is enhanced by expanded toe pads at the tips of their toes (fig. 1.26 A). These pads have a similar structure in different families, even though they undoubtedly evolved independently many times in various lineages. Typically the epidermis is divided into distinct columnar cells separated by canallike spaces filled with mucus produced by glands emptying into the canals. The individual cells have a rough surface formed by peglike projections or folds (fig. 1.26 B). When a treefrog is climbing on a rough surface, such as a tree trunk, its toes adhere mainly by interlocking of the rough toe surface with the substrate. On smooth surfaces, such as leaves, the sticky mucous secretions provide the adhesion (for detailed studies of toe-pad structure and function, see V. Ernst 1973; Welsch, Storch, and Fuchs 1974; Richards et al. 1977; D. M. Green 1979, 1981; Emerson and Diehl 1980; Linnenbach 1985; D. M. Green and Simon 1986; D. M. Green and Carson 1988; Hanna and Barnes 1991; Herrmann 1991; Hertwig and Sinsch 1995; Ba-Omar, Downie, and Barnes 2000).

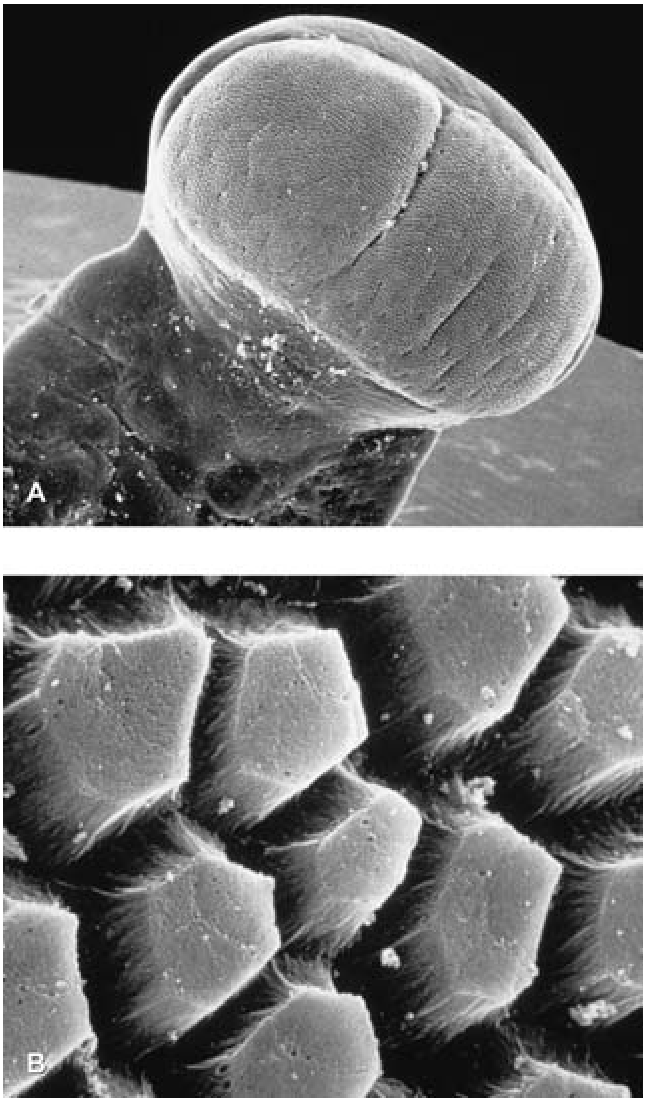

Fig. 1.26. (A) Scanning electron microscope photograph of the toe pad of an Australian treefrog, *Litoria rubella.* (B) Close-up showing peg-like projections on toe pad surface. Photos by Sharon Emerson.

In lineages of frogs that include both terrestrial and arboreal species, toe pads tend to be larger and more fully developed in the arboreal species. For example, in South American marsupial frogs of the genus *Gastrotheca,* the ancestral condition appears to be the presence of large, rounded toe pads, which is characteristic of fully arboreal species, such as *G. riobambae.* However, a few species that live in paramo habitats at very high altitudes, where trees are scarce, have become secondarily adapted to terrestrial life and have degenerate toe pads (e.g., *G. peruana;* Hertwig and Sinsch 1995). Similarly, terrestrial microhylids from New Guinea in the genus *Cophixalus* have smaller toe pads than do arboreal species in the same genus, or lack them altogether (D. M. Green and Simon 1986). Although arboreal members of this genus generally are assumed to have evolved from terrestrial ancestors, there has not been a thorough phylogenetic analysis of the group, so the direction of toe-pad evolution is unclear.

Arboreal frogs move about in a complex, three-dimensional environment, often by leaping from one narrow branch to another. This may require sensory and neural capacities not found in frogs that live in a more two-dimensional environment, such as a pond shore. Most tree frogs tend to have very large eyes relative to their body size, but this may relate as much to their largely nocturnal habits as to the complexity of their environment. G. M. Taylor, Nol, and Boire (1995) reported a tendency for arboreal frogs to have relatively larger brains for their body size than terrestrial or aquatic frogs, as well as a slightly larger cerebellum, the region of the brain involved in motor coordination. Unfortunately, they examined only two species of arboreal frogs from two families and compared them with terrestrial, fossorial, or aquatic frogs from several unrelated families. They also did not take into account the dramatic effect of variation in genome size and cell size on brain organization, patterns that appear not to be correlated with ecology (Roth, Blanke, and Wake 1994). Additional work on a larger number of species in a more rigorous phylogenetic context is needed before their hypothesis can be accepted.

Gliding Frogs

After returning from his travels in the Malay Archipelago, the English naturalist Alfred Russel Wallace described his encounter with a most unusual frog:

> One of the most curious and interesting reptiles which I met with in Borneo was a large treefrog, which was brought to me by one of the Chinese workmen. He assured me that he had seen it come down, in a slanting direction, from a high tree, as if it flew. On examining it, I found the toes very long, and fully webbed to their very extremity, so that when expanded they offered a surface much larger than the body. . . . This is, I believe, the first instance known of a "flying frog," and it is very interesting to Darwinians, as showing that the variability of the toes, which has been already modified for purposes of swimming and adhesive climbing, have been taken advantage of to enable an allied species to pass through the air like the flying lizard. It would appear to be a new species of the genus *Rhacophorus.* (A. R. Wallace, 1869, 49)

This frog is now called Wallace's flying frog (*Rhacophorus nigropalmatus;* fig. 1.27), one of several species in the genus from India, Southeast Asia, Malaysia, and Indonesia capable of gliding from one arboreal perch to another (Siedlecki 1909; Ayyangar 1915; Oliver 1951; Savile 1962; Inger 1966; Inger and Stuebing 1989; Emerson and Koehl 1990; Emerson, Travis, and Koehl 1990). Several New World frogs have similar abilities, including *Hyla miliaria* and its close relatives from Central America (Duellman 1970) and *Trachycephalus* (= *Phrynohyas*) *venulosus* from Central and South America (Cott 1926). A range of gliding abilities have been reported in Central American phyllomedusines of the genus *Agalychnis,* with some species such as *A. calcarifer* being specialized gliders (Scott and Starrett 1974; W. E. Roberts 1994; McCay 2003). All of these gliding frogs are unusually large relative to other species in the same family or genus. They apparently spend most of their lives high in the canopy, but descend to sites near the ground to breed. Several gliding species, including *Trachycephalus venulosus, Agalychnis spurrelli,* and *A. saltator,* form explosive breeding aggregations triggered by heavy rains (Roberts 1994). This may be the best way for frogs to synchronize their breeding activities and ensure that mates will be found when they live dispersed in the canopy, but depend on standing water to breed. The explosive nature of the breeding period also would favor rapid descent to breeding sites. Gliding frogs typically have very large toe pads and extensive webbing on both the front and hind feet, and some have skin flaps on the sides of the body and legs. The frogs spread their toes and hold their limbs bent to the sides of the body while gliding.

Gliding behavior has been studied in detail only in *Rhacophorus.* These frogs can maneuver during their descent by banking from side to side, whereas nongliding frogs in the

Fig. 1.27. An early depiction of *Rhacophorus nigropalmatus,* one of several gliding ("flying") frogs from Borneo. From Alfred Russel Wallace, *The Malay Archipelago* (1869).

same family cannot do this and usually drop vertically rather than gliding at an angle (Emerson and Koehl 1990). By placing models of flying frogs in various postures in a wind tunnel, Emerson and Koehl found that enlarged hands and feet are the most important morphological features that improve gliding performance by reducing the speed needed to maintain a glide and increasing maneuverability, whereas skin flaps and body form had relatively little effect. The position of the limbs was important as well, with the bent-limb position normally adopted by gliding frogs providing the best maneuverability and lowest minimum glide speed. This posture also improved parachuting performance (when the frog was dropping vertically rather than gliding horizontally). However, in nongliding rhacophorids, the bent-limb posture provided the worst gliding and parachuting performance. This suggests that behavioral evolution has accompanied morphological changes related to gliding, but the precise sequence of evolutionary changes is hard to determine.

Most of the gliding frogs also are capable of parachuting, and this behavior has been observed in other arboreal frogs that lack obvious morphological adaptations to slow their descent, such as enlarged feet and toe webbing. One example is *Eleutherodactylus coqui* from Puerto Rico, which, like other members of the genus, lacks webbing on the toes. These frogs climb into the canopy at night, apparently because food is more abundant than it is near the ground. At dawn, the frogs descend from as high as 15 m, landing on vegetation or the ground and then moving to diurnal retreat sites (Stewart 1985). Parachuting also has been observed in *Agalychnis saltator* and *A. callidryas* (fig. 1.1 A), two relatively small species with moderate amounts of toe webbing (Pyburn 1964; W. E. Roberts 1994), and in *Scinax boulengeri* (Scott and Starrett 1974). Kluge (1981) observed *Hyla rosenbergi* males descending rapidly to their nighttime calling sites by dropping several meters at a time from the surrounding vegetation. Probably this sort of rapid descent from arboreal perches is relatively common in tree frogs, especially those that forage high in the canopy, but use breeding sites at ground level.

Functional Morphology of Feeding

Diets of Anurans

Nearly all frogs are either insectivorous or carnivorous as adults. There are only two reports of anurans deliberately eating plant material. A Neotropical treefrog, *Hyla truncata,* is reported to feed on small fruits of shrubs. Among individuals with stomachs that contained food, more than 40% contained only fruits or both fruits and insects (da Silva, de Britto-Pereira, and Caramaschi 1989). An even more unusual example of herbivory has been reported for a ranid from India, *Euphlyctis hexadactylus.* Although recently transformed juveniles were entirely insectivorous, adults ate a mixture of plant and animal foods, with nearly 80% of their stomach contents (by volume) being composed of filamentous algae and leaves of various aquatic macrophytes (Das and Coe 1994; Das 1996a). Large numbers of adult frogs were examined, and the prevalence of plant material in the stomachs was much greater than could be accounted for by accidental ingestion. The conical teeth of this species appeared to be effective for snipping plant material, but whether this is an adaptation for herbivory or simply a characteristic of this particular lineage of ranid frogs is unknown. This species also has a relatively large stomach capacity (Das 1995), but it is not known whether it has special physiological adaptations for digesting plant material.

Most frogs are generalist feeders on a variety of insects, other invertebrates, or small vertebrates, with the precise taxonomic composition of the prey depending mainly on body size and microhabitat (Toft 1980a, 1981, 1985; Nishikawa 2000; see chapter 15 for a more detailed discussion). However, some frogs specialize on particular types of prey. Very small anurans and those with narrow heads, including some dendrobatid frogs, *Sooglossus gardineri* (Sooglossidae), small bufonids, and many microhylids, often specialize on tiny prey items, including mites, collembolans, ants, and termites (S. L. Mitchell and Altig 1983; Simon and Toft 1991; Channing 1993; Das and Coe 1994; Toft 1995). Many burrowing frogs also eat a lot of ants and termites (Emerson 1976; Poynton and Pritchard 1976; Dimmitt and Ruibal 1980), whereas other anurans may avoid these insects altogether (Toft 1980a). Large-bodied anurans sometimes feed on small vertebrates, including other anurans (see chapter 14), but most of these appear to eat any prey of appropriate size rather than specializing on particular types of prey (e.g., *Ceratophrys cornuta,* Duellman and Lizana 1994; see also N. Scott and Aquino 2005).

Some relatively large frogs are opportunistic predators on fish, and one African ranid, *Aubria subsigillata,* appears to specialize on fish, which are caught as they leap above the water's surface (Knoepffler 1976). The crab-eating frog (*Fejervarya cancrivora*) of Southeast Asia is best known for its habit of feeding on crabs and other invertebrates on salty mudflats at low tide, but it also feeds on a wide variety of invertebrates in rice fields and other freshwater habitats (Premo and Atmowidjojo 1987) and therefore is not a strict dietary specialist. Drewes and Roth (1981) reported an unusual feeding specialization in two hyperoliid frogs of the genus *Tornierella* from the highlands of Kenya. These frogs feed mainly on terrestrial snails, which are swallowed whole. Although the frogs have not been observed feeding, extensive modifications of the skull bones and jaw musculature to increase the gape and strengthen the bite suggest that these frogs are capable of pulling snails off of surfaces to which they are stuck. One species, *T. kouniensis,* also feeds on slugs. It has unusually long, recurved teeth that may be useful in grasping these slippery animals and may also be used to penetrate snail shells.

Correlates of Diet with Head Size and Shape

In frogs with generalized diets, prey size usually is positively correlated with body size and head width, and large frogs usually eat a wider range of prey sizes than small frogs (see chapter 15). Presumably this is because larger frogs can open their mouths wider than small frogs and therefore can accommodate larger prey, but they can still eat small prey as well (Emerson, Greene, and Charnov 1994). This sometimes results in a size-related shift in prey type, with larger individuals or larger species eating categories of prey not available to smaller frogs. For example, the Southeast Asian frog *Limnonectes blythii* eats two general categories of prey: long, thin prey and short, fat prey. Small individuals eat long, thin prey such as millipedes and other elongate invertebrates, but larger individuals also eat long, thin lizards. Beetles constitute the major short, fat prey of small frogs, but larger individuals also eat other frogs, while continuing to eat somewhat larger beetles (Emerson, Greene, and Charnov 1994). In two close relatives of this species, *Limnonectes ingeri* and *L. ibanorum,* males have wider heads and more robust jaw muscles than do females, probably a result of sexual selection (Emerson and Voris 1992; Emerson and Berrigan 1993). Juveniles eat small invertebrates, but never eat crabs, which are too large and too hard-shelled for them to handle. Adult males and females both eat crabs, but the larger heads and more powerful jaw musculature of males allow them to do so at a smaller body size (Emerson and Bramble 1993).

Interspecific comparisons of skull and jaw size and shape have revealed general correlations between diet and morphology in a wide range of anuran species. For example, large-bodied frogs that eat relatively large, slow-moving prey, such as other frogs, typically have relatively wider heads and longer jaws than related species that feed on smaller prey (Scott and Aquino 2005). These are features predicted to increase total gape and the force of jaw closing (Emerson 1985). In contrast, frogs that feed on small, slow-moving prey such as ants tend to have relatively narrow heads, small gapes, and jaws that are shorter than the head, features that facilitate rapid jaw opening and short feeding cycles (the time required to ingest prey).

Mechanisms of Tongue Protraction

The functional morphology of the tongue and associated musculature and the kinematics of feeding have been studied extensively in frogs, and we now have enough information to place the evolution of feeding behavior in a phylogenetic framework (Nishikawa et al. 1992; Nishikawa 1999, 2000; Deban, O'Reilly, and Nishikawa 2001). Frog tongues all have the same basic morphological structure, but vary in anatomical detail and the degree to which they can be protruded. The ancestral condition, which is found in frogs such as *Ascaphus, Leiopelma, Discoglossus, Bombina,* and most pelobatoid frogs, is a short, disclike tongue broadly attached to the floor of the mouth, with little capacity for projection. This condition also is retained in some neobatrachian groups, including *Telmatobius, Leptodactylus, Lepidobatrachus* (Leptodactylidae), *Limnodynastes* (Myobatrachidae), centrolenids, and all subfamilies of Hylidae except the Phyllomedusinae (fig. 1.28 A). The mechanism of tongue protraction in frogs with this type of tongue is referred to as mechanical pulling. It requires the frog to lunge forward and seize the prey with the tongue and pull it into the mouth (Nishikawa 1999, 2000).

Most of the derived frog lineages have a muscular tongue that is attached in front, with a free posterior flap that can be projected by flipping it forward out of the mouth (fig. 1.28 B; Regal and Gans 1976; Horton 1982; Trueb and Cannatella 1982; Trueb and Gans 1983; Cannatella and Trueb 1988a; Nishikawa et al. 1992; Nishikawa 1999, 2000; Deban, O'Reilly, and Nishikawa 2001). This mode of tongue protraction is called inertial elongation. It allows a frog to capture prey at some distance in front of the mouth without actually lunging toward the prey. Inertial elongation appears to have evolved independently a number of times because it occurs in lineages that are not closely related to one another, including some megophryids (*Megophrys, Leptobrachium*), some leptodacytlids (*Pleurodema, Physalaemus, Eleutherodactylus*), bufonids, phyllomedusine hylids, dendrobatids, and all ranoid frogs except hemisotids and microhylids.

A third mode of tongue protraction is found in the African burrowing frogs in the genus *Hemisus* and many, if not all, microhylid frogs (fig. 1.28 C). These frogs have tongues that are protruded hydrostatically rather than being flipped out of the mouth (Ritter and Nishikawa 1995; Nishikawa, Kier, and Smith 1999; Meyers et al. 2004). As the tongue muscles contract, the thickness of the tongue decreases, while the length increases. This mechanism allows the tongue to be protracted far beyond the tips of the jaws. Although protrusion of the tongue is relatively slow in hydrostatic elongators, this mechanism allows for more precise aiming of the tongue than in species with the other modes of tongue protraction. Precise aiming enhances the ability of these frogs to feed on very small prey, such as mites and termites. The tongue of *Hemisus* is unique in being prehensile, capturing a prey animal by grasping it rather than by adhesion of sticky mucus secretions alone. Contractile properties of the tongue muscles are not dramatically different in species with the three types of tongue protraction

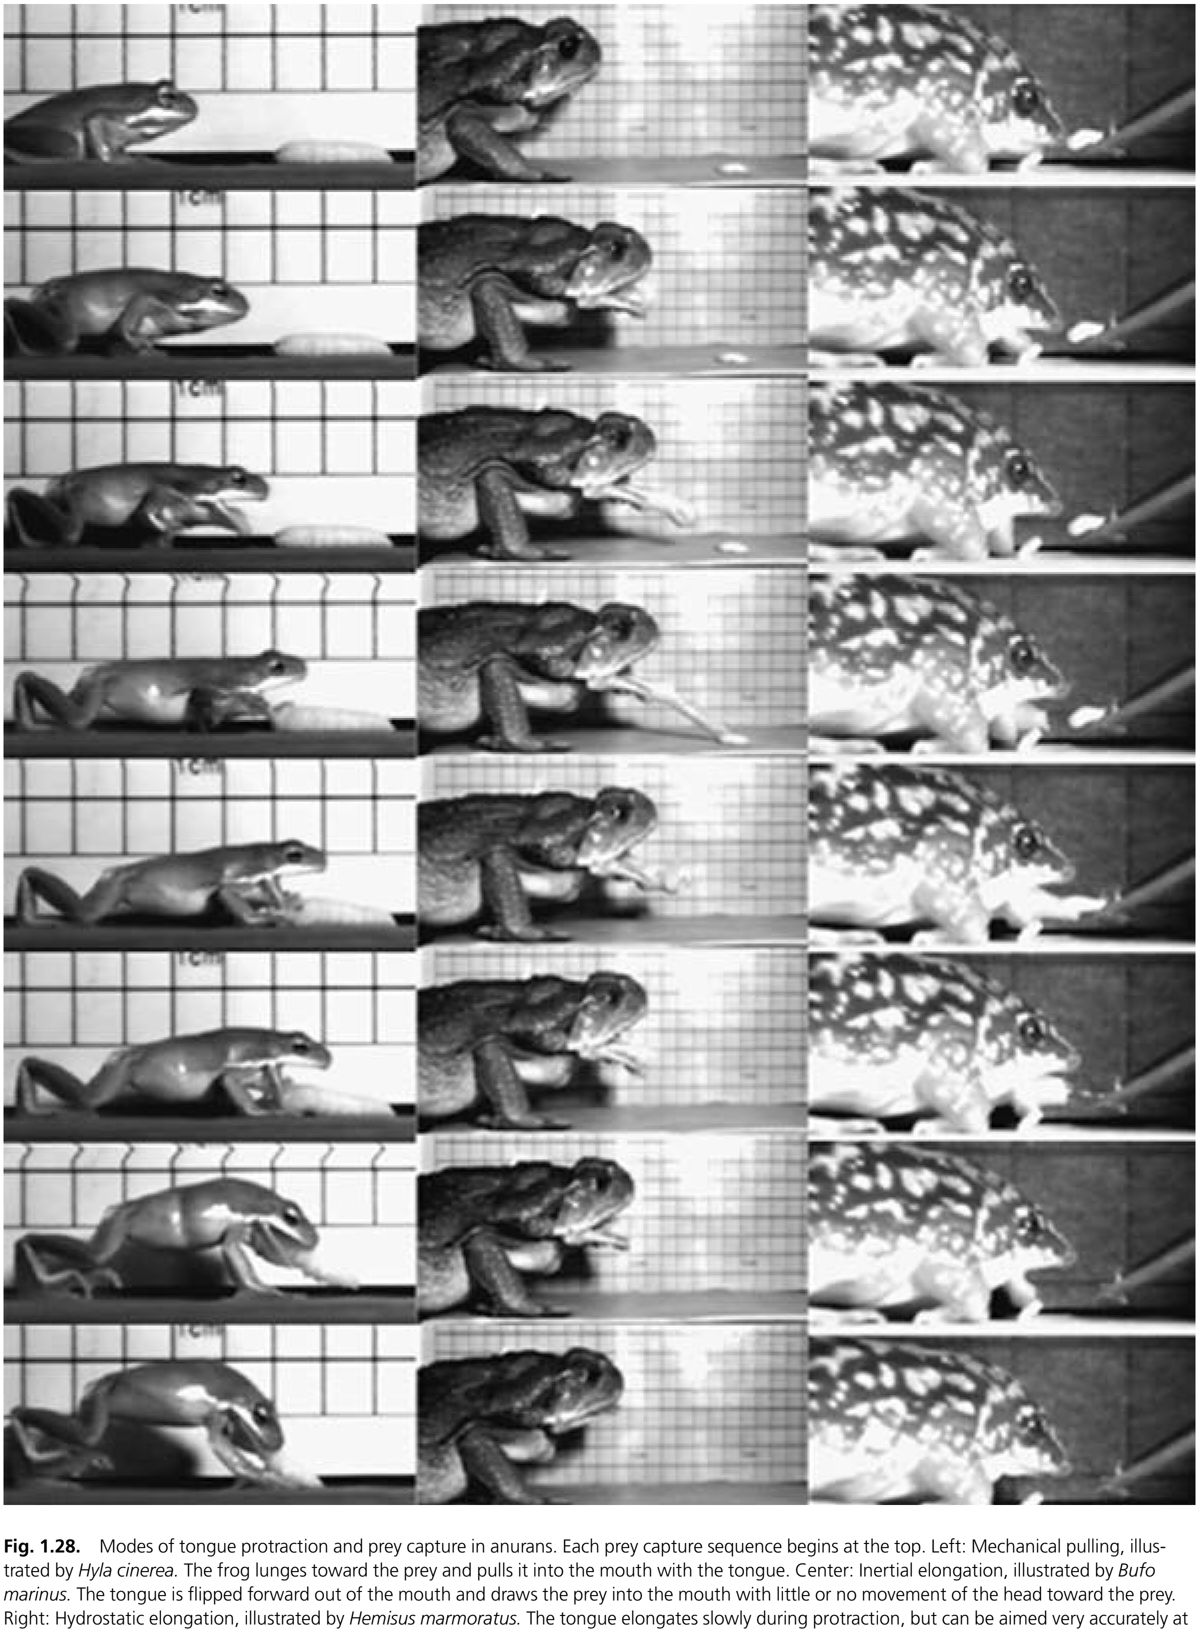

Fig. 1.28. Modes of tongue protraction and prey capture in anurans. Each prey capture sequence begins at the top. Left: Mechanical pulling, illustrated by *Hyla cinerea.* The frog lunges toward the prey and pulls it into the mouth with the tongue. Center: Inertial elongation, illustrated by *Bufo marinus.* The tongue is flipped forward out of the mouth and draws the prey into the mouth with little or no movement of the head toward the prey. Right: Hydrostatic elongation, illustrated by *Hemisus marmoratus.* The tongue elongates slowly during protraction, but can be aimed very accurately at small prey animals. Photos from high-speed videos by Kiisa Nishikawa.

mechanisms (Peters and Nishikawa 1999). The tongues do differ in the amount of connective tissue present, with mechanical pullers having the most connective tissue and hydrostatic elongators the least; inertial elongators are intermediate (Nishikawa 2000). The Mexican burrowing frog, *Rhinophrynus dorsalis,* has a tongue that is not attached at the front that can be protruded well beyond the tips of the jaws, but the mechanism of tongue projection has not been investigated in detail. It may represent functional convergence with the tongues of hemisotids and microhylids, but not necessarily convergence in the precise mechanism of tongue elongation (Nishiskawa 2000).

Pipids are unique among anurans in lacking a tongue altogether, but vestiges of the tongue muscles indicate that they evolved from ancestors with functional tongues. The loss of the tongue is related to their aquatic habits. Most pipids feed by using the front feet to shove prey into the mouth and grabbing the prey in the jaws. Members of the African pipid genus *Hymenochirus* are suction feeders both as adults and as tadpoles. Some other frogs have secondarily evolved aquatic feeding as adults, but the lack of suction feeding in the larval stage apparently limits their ability to suction feed as adults. These frogs generally use their jaws to capture prey underwater, because a protrusible tongue would be of little benefit in aquatic feeding (O'Reilly, Deban, and Nishikawa 002).

Differences in tongue protraction mechanisms are correlated with other differences in feeding behavior, but morphological and behavioral traits do not always evolve together in different lineages, and frogs with a derived morphology may retain elements of ancestral feeding behavior. A phylogenetic analysis of the evolution of feeding behavior (fig. 1.29) indicates that frogs with the ancestral tongue morphology typically feed by opening their mouths and bending the jaw downward, lunging forward with the entire body to contact the prey with the short tongue. The head is then bent downward, with the tongue and jaws being used to capture the prey (Nishikawa and Cannatella 1991; Nishikawa and Roth 1991; Nishikawa et al. 1992; Nishikawa 1999, 2000). Because the distance to which the tongue can be protracted is very short (only about 3 mm beyond the tips of the jaws), these frogs must lunge forward with the whole body, and they probably are restricted to feeding on relatively large, slow-moving prey at close range. Indeed, frogs that feed in this manner apparently do not specialize in fast-moving prey, such as flying insects, or very small prey, such as ants, termites, and mites. Instead, they appear to feed mainly on slow-moving prey such as caterpillars, beetles, aquatic insect larvae, spiders, earthworms, ostracods, and snails (Sharell 1966; Nussbaum, Brodie, Jr., and Storm 1983; Nöllert 1984; Herrmann et al. 1987; Nishikawa 2000).

Fig. 1.29. Cladogram illustrating the evolution of tongue-protraction mechanisms in anurans. This cladogram also shows relationships among genera within the large family Leptodactylidae and several other families. This analysis suggests that mechanical pulling is the ancestral condition that is found in most primitive frogs and is retained in many neobatrachian clades. Inertial elongation appears to have evolved independently in several different lineages of frogs, whereas hydrostatic elongation apparently evolved only once from an ancestor with inertial elongation. After Nishikawa (1999).

Among more derived frogs, the independent evolution of inertial elongation in several different lineages has enabled the frogs to use the tongue to capture prey without the use of their jaws. Most derived frogs with highly protrusible tongues do not lunge at the prey, but instead project the tongue toward the prey and then pull the prey back into the mouth with the tongue. The tongue can be projected at least 70% the length of the jaw at maximum extension (up to 300% in *Hemisus*). The ability to project the tongue allows for rapid prey capture and probably allows for the evolution of feeding specialization on fast-moving prey and very small prey items. Hydrostatic elongation appears to be derived from inertial elongation. While less suited to capturing rapidly moving prey, it does enable frogs to be more successful in capturing prey on each attempt (Nishikawa 2000).

There is considerable variation in the details of feeding behavior among different lineages. In *Bufo,* for example, there is relatively little forward movement of the head and body (fig. 1.28 B); the toad shoots the tongue forward and then draws the prey into the mouth (Gans and Gorniak 1982a, b). In contrast, phyllomedusine frogs often lunge toward the prey, as in other hylids, but also project the tongue. Sometimes the prey is pinned to the substrate with the tongue and then captured in the jaws when the forward lunge is completed, but small prey may be captured by the tongue and pulled back into the mouth without a lunge (Gray and Nishikawa 1995). The highly protrusible tongue of phyllomedusines may facilitate rapid capture of fast-moving prey such as orthopterans that are common in their rainforest habitats. Spadefoot toads (*Spea*) have relatively long tongues that can be protracted well beyond the tips of the jaws, but they retain the ancestral feeding behavior of lunging forward toward the prey (O'Reilly and Nishikawa 1995).

Some derived frogs exhibit shifts in feeding mode, depending on the type of prey being eaten. For example, when leopard frogs (*Rana pipiens*) are feeding on small, slow-moving prey, they capture the prey by projecting the tongue, with little movement of the body and head. However, when capturing larger prey, they revert to the ancestral pattern of lunging forward and seizing the prey in their jaws (C. W. Anderson 1993; Anderson and Nishikawa 1996). The Australian frog *Cyclorana novaehollandiae* also modulates its mode of prey capture, depending on the size and speed of movement of the prey. Visual assessment of prey characteristics appears to be more important than biomechanical feedback in determining the mode of prey capture employed (Valdez and Nishikawa 1997).

The evolution of tongue morphology and changes in feeding behavior have been accompanied by changes in neural pathways involved in the control of prey capture. In derived anurans, such as *Bufo* and *Rana,* feedback from the hypoglossal nerve running through the tongue is required to trigger proper opening of the mouth, especially when the frogs are feeding on small prey (Nishikawa and Gans 1992; Nishikawa 1999, 2000). Presumably, feeding on small prey captured by the tongue requires tight coordination of mouth opening and tongue projection. However, when *Rana* feeds on large prey by lunging forward, hypoglossal feedback is not required (C. W. Anderson and Nishikawa 1993). The absence of hypoglossal feedback appears to be the ancestral condition for anurans, because it is absent in most species examined so far. It is present in some derived lineages, including most ranoid frogs, but appears to have been secondarily lost in hydrostatic tongue elongators (*Hemisus* and microhylids). In most anurans, withdrawal of the tongue back into the mouth is controlled by another feedback system involving the glossopharyngeal nerve, which allows the frog to determine when the tongue has contacted the prey. Failure to contact the prey often results in a delayed withdrawal of the tongue (Matsushima, Satou, and Ueda 1986, 1987, 1988, 1989; Nishikawa et al. 1992). The presence of glossopharyngeal feedback appears to be the ancestral condition for anurans, but has been secondarily lost in a few anurans and is not present in salamanders.

In addition to use of the tongue and jaws to capture prey, many anurans also use their front feet to capture prey and push it into the mouth, a behavior not seen in urodeles. L. A. Gray, O'Reilly, and Nishikawa (1997) studied the use of forelimbs in feeding in more than 100 species of anurans representing 16 families. They identified several distinct behavior patterns. Two of these, scooping prey into the mouth with the back of the front foot and wiping the prey with the palm of the hand, appear to be ancestral traits that have been retained in many lineages. Other behavior patterns are found only in certain groups. For example, grasping the prey with the fingers is a behavior found only in arboreal species (hylids, hyperoliids, and rhacophorids) that have evolved grasping hands for locomotion in trees. Frogs in several lineages hold prey animals on the substrate with the front feet while pulling the prey into the mouth with the jaws. This behavior appears to have evolved independently in at least a half dozen unrelated clades.

Phylogeny and Classification of the Urodela

Most recent classifications of the Urodela (also called Caudata; Frost 2004; Frost et al. 2006) recognize 10 families, with about 60 genera and more than 400 species. The family-level classification of salamanders has remained relatively stable, but phylogenetic relationships among the families have been uncertain. One hypothesized phylogeny is shown in fig.1.30. One problem with assessing the relationships of many urodele families is the frequency with which larval characters are retained in reproductive adults (Wiens, Bonett, and Chippindale 2005). In addition, phylogenies based entirely on morphological characters often are not consistent with those based on molecular characters (Mueller et al. 2004; Weisrock, Kozak, and Larson 2005). Some of these problems have been accommodated in recent phylogenetic analyses that combine morphological and molecular data (Larson and Dimmick 1993; Larson, Weisrock, and Kozak 2003).

Many authors place the Sirenidae in a basal position as the sister taxon to all other caudate families. However, the phylogeny presented by Trueb (1993), which was based on an unpublished morphological data set, placed the Sirenidae as the most derived family of salamanders, an arrange-

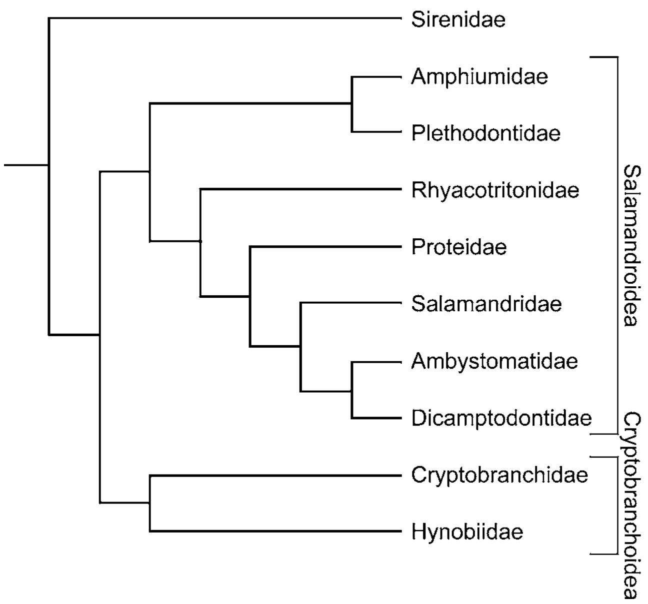

Fig. 1.30. Phylogenetic relationships of the urodeles, based on combined molecular and morphological data. Some other recent phylogenies differ in the placement of the family Sirenidae, which may or may not be basal to all other salamander families. There also is some debate over whether Salamandroidea is a monophyletic clade. After Pough et al. (2004), based on A. Larson and Dimmick (1993).

ment that most workers consider unlikely, in part because it would require the secondary loss of internal fertilization in this group (if fertilization actually is external in sirenids). A combined molecular and morphological analysis by Gao and Shubin (2001), which included fossil taxa, did not place sirenids in a basal position, but as the sister group to the Proteidae. Other recent phylogenetic studies based on molecular or combined molecular and morphological data also did not place sirenids in a basal position, but the issue has yet to be fully resolved (Weisrock, Harmon, and Larson 2005; Wiens, Bonett, and Chippindale 2005; Frost et al. 2006).

The remaining families of urodeles usually are placed in two distinct clades, the Cryptobranchoidea (Cryptobranchidae and Hynobiidae) and the Salamandroidea (all remaining families). If Sirenidae is considered a basal group, then this arrangement suggests that internal fertilization probably arose only once in salamander evolution (all salamandroids have internal fertilization, whereas sirenids, cryptobranchids, and hynobiids do not; Weisrock, Harmon, and Larson 2005). Relationships among the salamandroid families are the subject of some debate. In particular, the relationship of the amphiumas to other families is unclear. Most recent phylogenies suggest they are closely related to the plethodontids, as shown in fig. 1.30 (Larson and Dimmick 1993; Larson, Weisrock, and Kozak 2003; Weisrock, Harmon, and Larson 2005; Wiens, Bonett, and Chippindale 2005). The phylogeny presented by Trueb (1993) placed them as the sister group to the Proteidae, an unlikely arrangement that almost certainly results from similar paedomorphic characters (Wiens, Bonett, and Chippindale 2005). There also is conflicting evidence about the position of the plethodontids, the largest and most diverse family of salamanders. Analyses based on morphological characters have identified them as a highly derived group, whereas some molecular phylogenies place them in a position basal to other families (Larson, Weisrock, and Kozak 2003; Weisrock, Harmon, and Larson 2005).

Synopsis of Families of Urodela

The following accounts summarize the classification, distribution, and natural history of the 10 currently recognized families of urodeles. The classification scheme and numbers of genera and species follow Larson, Weisrock, and Kozak (2003). The family-level classification of the Urodela has been more stable in recent years than that of anurans. The only major change from the classification presented in Duellman and Trueb (1986) is the recognition of the Rhyacotritonidae as a separate family. The genus *Rhyacotriton* was previously included in the family Dicamptodontidae, but it is now clear that *Rhyacotriton* and *Dicamptodon* are not closely related (Good and Wake 1992; Larson and Dimmick, 1993; Larson, Weisrock, and Kozak 2003; Weisrock, Harmon, and Larson 2005; Wiens, Bonett, and Chippindale 2005). *Dicamptodon* appears to be most closely related to the ambystomatids, and with *Rhyacotriton* now removed from the Dicamptodontidae, the dicamptodontids and ambystomatids could be placed in the same family (fig. 1.30). The number of new species of salamanders described each year is much lower than the number of new anuran species, but only slightly lower in proportion to the total number in the two groups (about a 10% increase in caudate species from 1985 to 1992, compared to 14% for anurans; Duellman, 1993a). The difference is due mainly to the low diversity of salamanders in much of South America and their absence from the Old World tropics, the regions where most new frog species have been discovered. It is therefore particularly surprising that a new plethodontid salamander was recently described from Korea, a well-studied region of a continent on which plethodontid salamanders have never been found before (Min et al. 2005).

Information on the general natural history of salamanders is taken from literature cited elsewhere in this book and from standard reference sources, including Bishop (1941b, 1947), Liu (1950), Stebbins (1954a, 1985), Steward (1969), E. N. Arnold and Burton (1978), Duellman and Trueb (1986), Pfingsten and Downs (1989), Conant and Collins (1991), Griffiths (1996), Petranka (1998), Bruce et al. (2000), and Pough et al. (2004).

Family Ambystomatidae

Distribution: North America from Alaska to the eastern United States and the Mexican Plateau.

Content: One genus, *Ambystoma,* 31 species (fig. 1.31 A). Four stream-dwelling species from Mexico formerly were placed in a separate genus *Rhyacosiredon,* but a phylogenetic analysis of electrophoretic data showed *Rhyacosiredon* nested within the genus *Ambystoma* (Shaffer 1984a). Nearly all of the morphological characters thought to distinguish *Rhyacosiredon* from *Ambystoma* are the result of incomplete metamorphosis, a trend that is common in this family. Therefore, *Rhyacosiredon* is now considered a synonym of *Ambystoma* (Reilly and Brandon 1994). Species in the *A. tigrinum* complex show significant genetic divergence with little morphological differentiation (Shaffer 1993; Shaffer and McKnight 1996; Irschick and Shaffer 1997). Several members of this complex traditionally have been treated as subspecies of *A. tigrinum* (*A. t. tigrinum, A. t. diaboli, A. t. mavortium, A. t. melanostictum, A. t. nebulosum, A. t. stebbinsi;* Petranka, 1998). Irschick and Shaffer (1997) recommended that *A. t. tigrinum* and two closely related species, *A. californiense* and *A. velasci,* be recognized

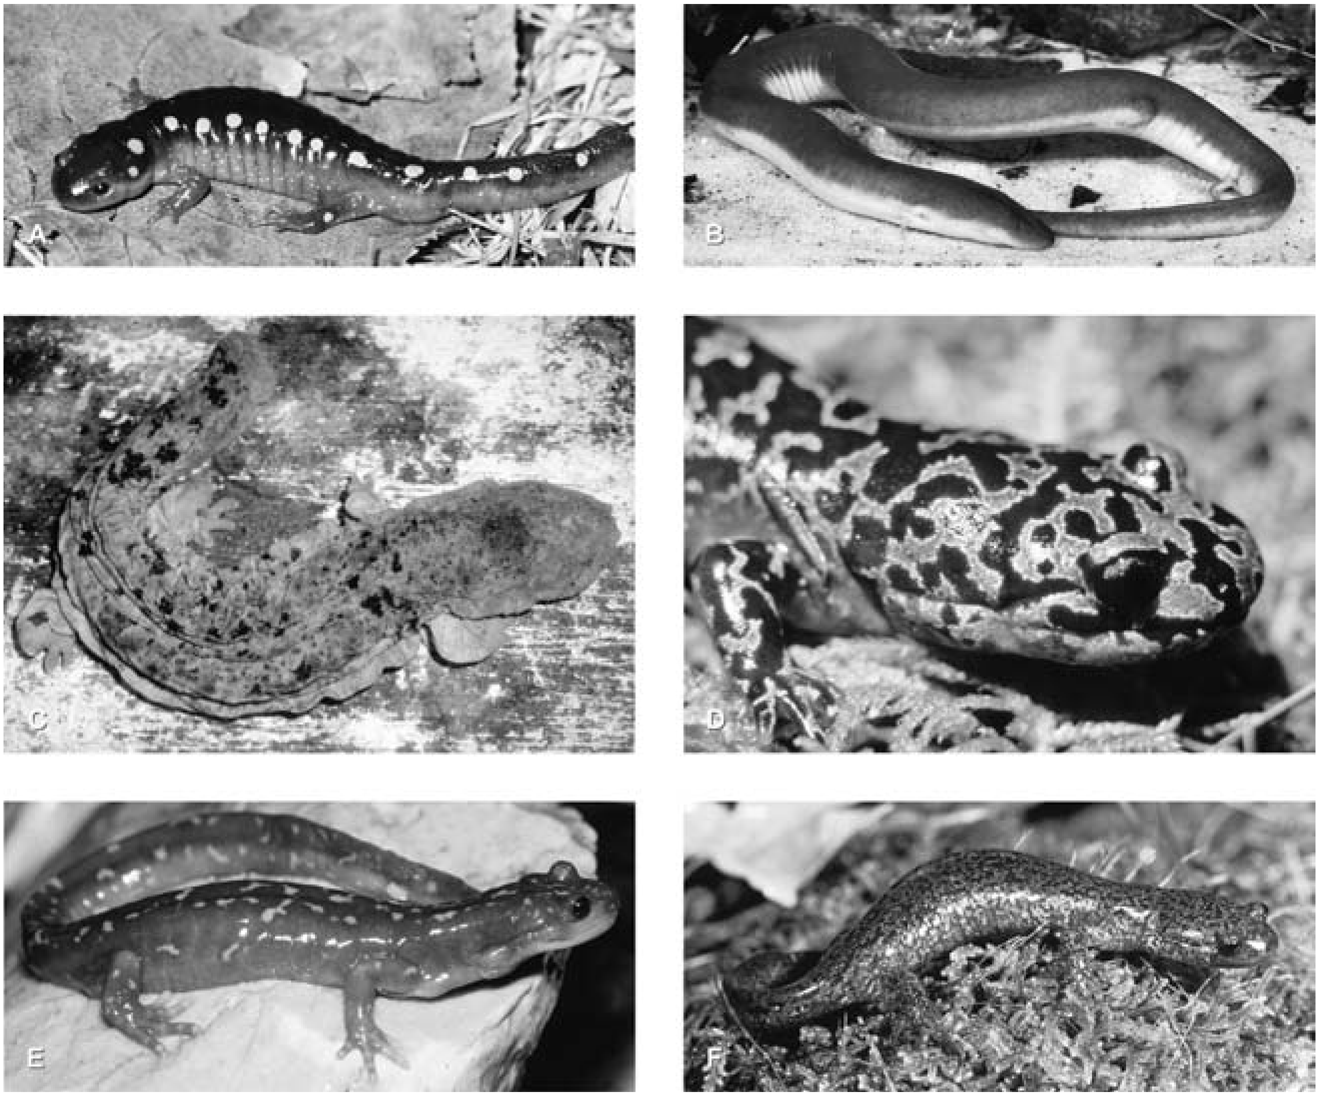

Fig. 1.31. Diversity of urodeles (Ambystomatidae to Hynobiidae). (A) *Ambystoma maculatum* (Ambystomatidae) from Connecticut. (B) *Amphiuma tridactylum* (Amphiumidae) from the southern United States. (C) *Cryptobranchus alleganiensis* (Cryptobranchidae) from the Ozark Mountains. (D) *Dicamptodon ensatus* (Dicamptodontidae) from California. (E) Batrachuperus persicus (Hynobiidae) from Iran. (F) *Hynobius* sp. (Hynobiidae) from Asia. Photos by Kentwood D. Wells (A), Wayne Van Devender (B, C, E, F), and William P. Leonard (D). For additional photos of these families, see fig. 1.1 B, 11.2 B, 14.30 F, 16.8 B, 16.9 (*Ambystoma*) and 11.12 A (*Amphiuma*).

as distinct species. The remaining taxa are almost indistinguishable morphologically, but their taxonomy was left unresolved. Frost (2004) and Larson, Weisrock, and Kozak (2003) placed all of these populations in a separate species, *A. mavortium.* Most of the published literature on the ecology of these groups treats them as subspecies of *A. tigrinum.*

Natural History: Most ambystomatids are moderately large terrestrial salamanders with lungs. Although commonly called mole salamanders, members of this family have limited burrowing ability and use tunnels constructed by other animals or root channels as retreats outside of the breeding season. Most species are winter or early spring breeders that lay eggs in ponds, either in gelatinous clumps, individually attached to plants, or scattered on the pond bottom (e.g., *A. maculatum, A. tigrinum, A. texanum*). Several Mexican species, including *A. rosaceum, A. ordinarium,* and those formerly placed in *Rhyacosiredon,* are stream breeders that lay eggs in clusters underneath flat stones. The only species in the United States with these breeding habits is *A. barbouri,* a close relative of the pond-breeding species *A. texanum.* Two species, *A. opacum* and *A. cingulatum,* lay eggs on land in depressions that are flooded by winter rains. Females sometimes remain with their eggs in *A. opacum,* but not in *A. cingulatum.* In all species, fertilization is internal by means of spermatophores deposited singly or in groups. Many ambystomatids are paedomorphic and perrenibranchiate, retaining external gills and other larval characters after reaching sexual maturity. In some cases, such as the Mexican axolotl (*A. mexicanum*), the capacity for metamorphosis has been lost, but in others, such as *A. talpoideum,* a paedomorphic life history is facultative. This type of life history is especially common at high altitudes or arid regions where the environment surrounding the breeding ponds is inhospitable to terrestrial life (see chapter 13 for a more detailed discussion of this type of life history). Also common is the production of hybrid, polyploid, all female "species" that depend on sperm from a parental species to initiate egg development (gynogenesis). The best known are populations resulting from hybridization between *A. jeffersonianum* and *A. laterale* in the northeastern United States and Canada, but polyploid hybrids that incorporate genomes of *A. texanum* and *A. tigrinum* also occur (Bogart 2003).

Family Amphiumidae

Distribution: Southeastern United States.

Content: A single genus, *Amphiuma,* with three species (fig. 1.31 B).

Natural History: These are largely aquatic salamanders that have elongate bodies and greatly reduced limbs. They inhabit swamps and ponds that often are poorly supplied with oxygen and therefore depend mainly on their lungs for respiration (see chapter 4). Not much is known about their mating behavior, but fertilization is internal by means of spermatophores. Eggs are laid in burrows constructed at the edges of ponds, under logs, or in the nest mounds of alligators, and are attended by females for several months during dry periods (Fontenot 1999). The larvae hatch at an advanced stage of development and undergo relatively minor morphological change during metamorphosis. The gills are lost in adults, but the gill slits remain open.

Family Cryptobranchidae

Distribution: Eastern Asia and eastern North America.

Content: Two genera, the Chinese and Japanese giant salamanders, *Andrias* (two species) and the North American hellbender, *Cryptobranchus alleganiensis* (fig. 1.31 C). These are generally considered to be among the most primitive of living salamanders and are most closely related to hynobiids.

Natural History: The three species in this family are the three largest living salamanders. All live in relatively large, well-oxygenated streams and rivers and are completely aquatic. They have flattened bodies with many folds of loose skin that serve as the principal respiratory organ. Male hellbenders are territorial in the breeding season and defend nest sites under rocks, where several females deposit their eggs. In contrast to most salamanders, male cryptobranchids fertilize eggs externally by releasing sperm as they are laid. Males of the Japanese giant salamander (*Andrias japonicus*) build nests in tunnels in riverbanks and defend them as territories, but more than one male sometimes manages to fertilize the eggs of a female in a nest (Kawamichi and Ueda 1998).

Family Dicamptodontidae

Distribution: Pacific Northwest region of the United States and adjacent Canada.

Content: A single genus, *Dicamptodon,* with four species (fig. 1.31 D). These salamanders were formerly placed in the family Ambystomatidae and most phylogenetic analyses place them as the sister group to that family. There is considerable genetic differentiation among the four species, but little morphological difference.

Natural History: These salamanders are terrestrial as adults, and may even climb a meter or more into vegetation (Stebbins 1954a; Nussbaum, Brodie, and Storm 1983). They usually live near cold, well-oxygenated streams, where eggs are laid in well-hidden locations. Fertilization is internal by means of spermatophores. The larval period is prolonged, sometimes lasting for several years, and some populations exhibit facultative paedomorphosis, retaining larval traits such as external gills as adults (see chapter 13). *D. copei* is permanently paedomorphic.

Family Hynobiidae

Distribution: Eastern Asia, including Siberia, northern China, Korea, and Japan. Disjunct populations in Central Asia.

Content: Seven to nine genera, 49 species. This small family comprises some of the most basal of living salamanders and is the sister-group to the cryptobranchids. About two-thirds of the species are in the genus *Hynobius* (fig. 1.31 F). The only other genus with more than two described species is *Batrachuperus* (nine species; fig. 1.31 E). Usually five species are placed in the genus *Ranodon,* but some classifications restrict this genus to the single species *R. sibiricus,* placing the other species in the genera *Liua* (one species) and *Pseudohynobius* (three species).

Natural History: Most are terrestrial as adults, but all breed in water, usually in the winter or early spring. *Onychodactylus* is semiaquatic and lives among the rocks of cold mountain streams. It lacks lungs and depends primarily on the skin for respiration. Lungs are reduced in *Ranodon,* another stream-dwelling genus. Hynobiids lay eggs in paired sacs that sometimes resemble the egg clutches of ambystomatids. Eggs are fertilized externally when the male clasps an egg sac after it has been deposited. In one genus, *Ranodon,* the male deposits a large sperm mass, and the female then places her eggs on top of it to achieve fertilization.

Family Plethodontidae

Distribution: North, Central, and South America, with one genus (*Hydromantes*) having a disjunct distribution in northwestern North America and southern Europe. A single species, *Karsenia koreana,* occurs in Korea, the only plethodontid known from Asia (Min et al. 2005).

Content: 27 genera, more than 375 species. With more than 70% of all living species, this is the largest and most diverse family of salamanders. Two subfamilies have long been recognized, the Desmognathinae, with two genera (fig. 1.32 A, B), and the Plethodontinae, with all of the rest (fig. 1.32 C–F). The monophyly of the Desmognathinae is strongly supported in most phylogenetic analyses, but several recent studies have shown that this group is derived from within the Plethodontinae, which therefore is not a monophyletic group (Chippindale et al. 2004; Mueller et al. 2004). Frost et al. (2006) recommended eliminating the subfamily name and placed the desmognathine genera in the subfamily Plethodontinae. An analysis based on complete mitochondrial genomes did not support the monophyly of any of the three major clades traditionally recognized within the Plethodontinae (the tribes Plethodontini, Hemidactyliini, and Bolitoglossini; Mueller et al. 2004).

Several of the largest genera of plethodontids, including *Bolitoglossa* (fig. 1.32 C), *Pseudoeurycea, Oedipina* (fig. 1.35 A), and *Nototriton* (fig. 1.35 C), *Chiropterotriton,* are restricted to the Neotropics and are most abundant in montane regions of Mexico and Central America. All of these genera belong to a single clade that is presumed to have invaded the area from North America. Plethodontid salamanders in Central America exhibit a high degree of genetic differentiation among local populations, both within and among species, as well as restricted ranges and sharp elevational limits to their distributions (García-París et al. 2000). This means that there probably are many more species in the region than are currently recognized, and new species are described every year. The only other genera of plethodontids with more than 10 species all are found in North America: *Plethodon* (more than 50 species), *Eurycea* (26 species; fig. 1.32 E), *Desmognathus* (at least 19 species; fig. 1.32 A), and *Batrachoseps* (20 species; fig. 1.35 B).

Plethodontid systematics is somewhat confusing because genetic differentiation and morphological differentiation often have proceeded at different rates. Some genera, including the large genus *Plethodon* and the genus *Aneides,* do not appear to be monophyletic clades as presently constituted (Mahoney 2001). Within genera, there are many cryptic species that are well differentiated genetically, but very similar morphologically. Especially problematic groups are the *Plethodon jordani-P. glutinosus* complex (see fig. 15.11 in chapter 15) of large forest-floor species (Highton 1970, 1990, 1995; Highton and Henry 1970; Highton and Larson 1979; Highton, Maha, and Maxson 1989; Highton and Peabody 2000) and members of the *Desmognathus ochrophaeus* complex of streamside salamanders (see fig. 15.16 in chapter 15; Tilley and Mahoney 1996; Tilley 1997). In these groups, there are many geographic isolates that are morphologically similar, and there are morphologically distinct populations that hybridize to varying degrees where their ranges overlap. There also are cases, as in *Desmognathus imitator,* where extensive variation in color pattern does not correspond to a similar degree of genetic differentiation (Tilley 2000). This has led to disagreement among different authors over how many distinct species should be recognized and what names should be assigned to those species. Similar problems arise in determining species boundaries in other plethodontid genera, including populations of *Eurycea* in Central Texas (Chippindale 2000; Chippindale et al. 2000; Wiens, Chippindale, and Hillis 2003) and populations of *Batrachoseps* (D. Wake and Jockusch 2000) and *Ensatina* on the West Coast of the United States (Jackman and Wake 1994; D. Wake 1997; Highton 1998; D. Wake and Schneider 1998; D. Wake and Jockusch 2000).

(D) *Eurycea cirrigera* from North Carolina, with elongated cirri on the male's snout. (E) *Gyrinophilus porphyriticus* from North Carolina. (F) *Hydromantes platycephalus* from California. Photos by Wayne Van Devender (A, B, D–F) and Walter Hödl (C). For additional photos of plethodontid salamanders, see fig. 1.35 A (*Oedipina*); 1.35 B (*Batrachoseps*); 1.35 C (*Nototriton*); 1.42 (*Hydromantes*); 9.13, 14.33 B, 15.16 (*Desmognathus*); 9.19, 14.33 A, 15.11, 16.5 A, B (*Plethodon*); 9.27, 14.25 D (*Aneides*); 11.12 (*Hemidactylium*); 13.24 A (*Gyrinophilus*); 13.24 B, D–F, 14.20 D (*Eurycea*); and 13.24 C (*Haideotriton*).

The complexity of plethodontid systematics reflects a tendency toward morphological conservatism in the group and a history of population interactions at various stages of isolation and speciation (S. J. Arnold 2000). A practical consequence is that different names sometimes have been used in studies of the same or adjacent populations, or names have changed as studies have been conducted. I have attempted to use the currently accepted names for species when discussing studies of ecology and behavior in this book. In some cases, however, this is made more difficult by the lack of agreement on what names should be used. For example, Highton and Peabody (2000), Frost (2004), and Larson, Weisrock, and Kozak (2003) use the name *Plethodon teyahalee* for populations in the *P. glutinosus* complex that were called *P. oconaluftee* by Hairston (1993) and Petranka (1998).

Natural History: Plethodontids are lungless salamanders, which depend primarily on the skin for respiration. They generally are small to medium-sized salamanders that are terrestrial, arboreal, or semiaquatic as adults. The desmognathines have wedge-shaped heads (fig. 1.32 A) that may be an adaptation to burrowing under rocks and other cover objects (Dunn 1926c; D. Wake 1966; Schwenk and Wake 1993). One member of this subfamily, *Phaeognathus* *hubrichti* (fig. 1.32 B), is highly fossorial and lays terrestrial eggs that probably undergo direct development (Brandon 1965a). Most other members of this subfamily are associated with streams. The two largest species, *Desmognathus quadramaculatus* (see fig. 15.16 A in chapter 15) and *Desmognathus marmoratus* (fig. 1.32 A), are the most aquatic. Others live along the margins of streams, where eggs are deposited under partially submerged rocks or wet seepage areas and hatch into aquatic larvae (*D. monticola, D. fuscus, D. ochrophaeus, D. ocoee, D. orestes,* and other species; see fig. 15.16 in chapter 15). Two very small species, *D. aeneus* and *D. wrighti,* lay terrestrial eggs that hatch into nonfeeding larvae or undergo direct development. The genus *Desmognathus* thus exhibits a gradient in body size from large aquatic species to very small terrestrial ones. Traditionally this gradient has been viewed as reflecting an ancestral life history of aquatic eggs and larvae, with the smaller and more terrestrial species being more derived (e.g., Dunn 1926c). A molecular phylogenetic study by Titus and Larson (1996) questioned this interpretation. They found that the most terrestrial species represent relatively basal lineages, with some of the more aquatic species being more derived. If this is correct, then it suggests the possible reacquisition of aquatic development in most members of this genus from an ancestor with direct development (Larson, Weisrock, and Kozak 2003; Chippindale et al. 2004). Indeed, within the plethodontids as a whole, the reevolution of an aquatic larval stage from a direct-developing ancestor may have occurred a number of times (Mueller et al. 2004; see fig. 10.14 in chapter 10).

Until recently, nondesmongnathine plethodontids that lay eggs in or near water and have aquatic larvae were considered to be members of a monophyletic clade, the Tribe Hemidactyliini, but a recent analysis indicated that *Hemidactylium* is not closely related to other members of this group (Mueller et al. 2004). Aquatic-breeding plethodontids use a variety of habitats, including springs, streams, and seepage areas (*Pseudotriton, Gyrinophilus,* and most *Eurycea;* fig. 1.32 D, E), as well as ponds, swamps, and ditches (*Stereochilus marginatus, Eurycea quadridigitata,* and *Hemidactylium scutatum*). Many species have become adapted to life in caves. These include some species of *Eurycea* and *Gyrinophilus,* as well as the highly specialized cave salamanders (*Typhlotriton* and *Haideotriton;* cave salamanders previously placed in the genus *Typhlomolge* are now considered synonymous with *Eurycea*). Cave salamanders often have reduced pigment, or lack it altogether, and the eyes often are reduced or absent as well. The most specialized cave-adapted salamanders spend nearly all of their lives in underground streams and pools, and some retain gills throughout life (see further discussion in chapter 13, and fig. 13.24).

Most plethodontids lay nonaquatic eggs that undergo direct development. In North America, most species are terrestrial inhabitants of the forest floor, where they shelter under rocks and logs, or move underground through root channels and tunnels constructed by other animals. Members of the genus *Aneides* have enlarged toe pads for climbing and are arboreal or live in rock crevices. Members of the genus *Hydromantes* (fig. 1.32 F), found in both western North America and southern Europe, live on rock outcrops, cliffs, and in caves (some authors place the European species in the genus *Speleomantes*). Some Neotropical plethodontids also are found under rocks and logs on the ground, but others live in specialized habitats, such as bromeliads or mats of moss and other vegetation on the branches of trees in cloud forests. Within the largest genus *Bolitoglossa,* there are seven well-defined clades, of which only one has made its way into South America from Central America (Parra-Olea, García-París, and Wake 2004).

Family Proteidae

Distribution: Southern Europe and eastern North America.

Content: Two genera, *Necturus* from North America (five species; fig. 1.33 A) and *Proteus* from Europe (one species; fig. 1.33 B). Most phylogenetic analyses unite these two genera in a single family, although the analysis of Weisrock, Harmon, and Larson (2005) did not support the monophyly of this group.

Natural History: The mudpuppies (*Necturus*) are fully aquatic salamanders with prominent external gills and small eyes. They usually live in relatively large rivers and lakes, but can be found in smaller streams as well, where they prey on invertebrates and small vertebrates. Eggs are laid in clusters under flat stones. *Proteus anguinus,* the European olm, is a blind, cave-dwelling species. Most populations lack skin pigment, but one fully pigmented population has been reported. The natural history in the field is poorly studied, but in captivity, males defend territories centered around rock crevices that are used as oviposition sites by females. All proteids have internal fertilization by means of spermatophores.

Family Rhyacotritonidae

Distribution: Pacific Northwest region of the United States.

Content: One genus, *Rhyacotriton,* with four species (fig. 1.33 C). These small salamanders once were all classified as one species, *R. olympicus,* and were placed in the family Dicamptodontidae. The work of Good and Wake (1992) revealed hidden taxonomic diversity in the genus.

Natural History: These salamanders live in or near cold, fast running streams. Their lungs are reduced and nonfunc-

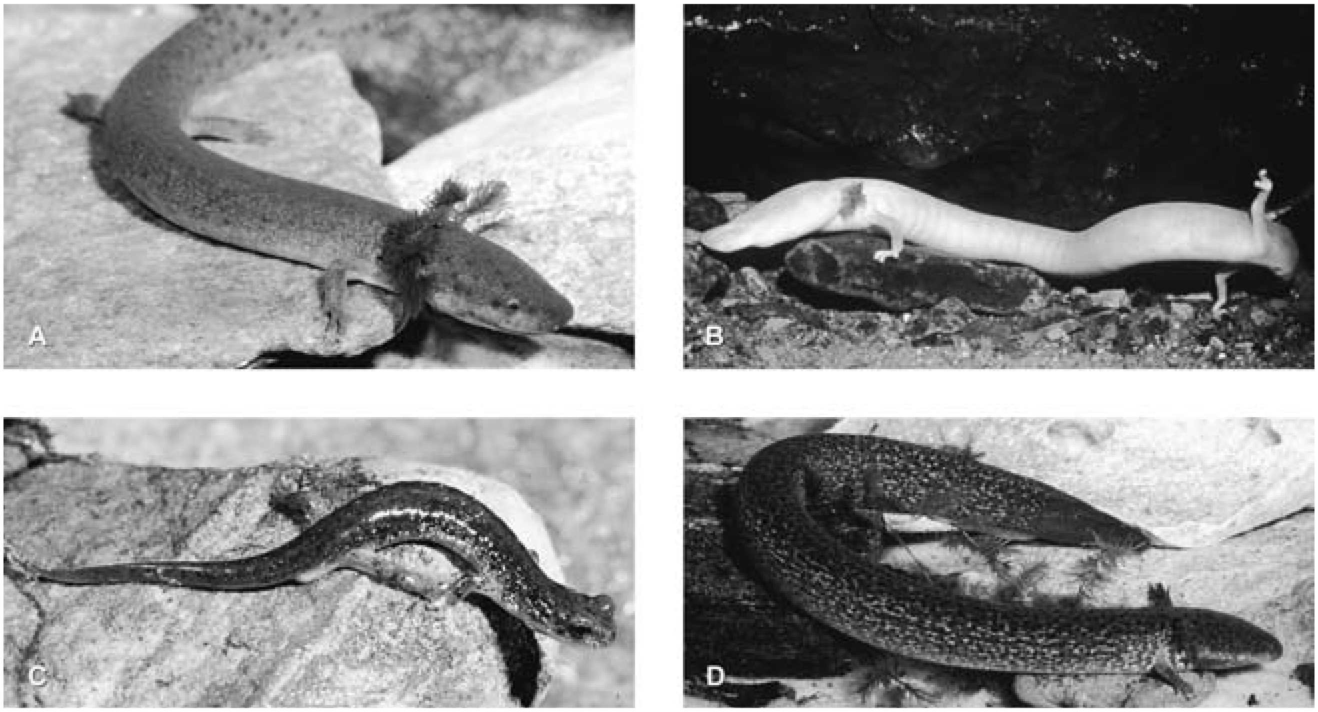

Fig. 1.33. Diversity of urodeles (Proteidae to Sirenidae). (A) *Necturus punctatus* (Proteidae) from the Coastal Plain of the southeastern United States. Photos by Wayne Van Devender (A, C, D) and Walter Hödl (B).

tional for respiration. Their natural history is poorly known, but eggs are laid in well-hidden locations under rocks and in underground springs feeding into the streams where the larvae complete their development. Fertilization is internal by means of spermatophores.

Family Salamandridae

Distribution: Europe, Asia, extreme northern Africa, North America.

Content: 15–20 genera, about 70 species (fig. 1.34). Most classifications recognize 15 genera, but new names have been proposed for some species within the genus *Triturus* (*Lissotriton, Mesotriton, Ommatotriton*) and *Salamandra* (*Lyciasalamandra;* see Frost et al. 2006, and Amphibia Web at http://elib.cs.berkeley.edu/aw/lists/Salamandridae.shtml), but I have used the traditional genus names throughout this book. The largest genera are *Triturus* (including the new names listed above [14 species;] fig. 1.34 C), *Salamandra* (up to 13 species, including *Lyciasalamandra*), and *Tylototriton, Cynops* and *Paramesotriton* (seven species each). No other genus has more than four species. Only two genera occur in North America, *Notophthalmus* (fig. 1.34 A) and *Taricha* (fig. 1.34 B), each with three species. Several phylogenetic analyses of the family based on mitochondrial DNA provide strong support for a monophyletic clade composed of *Salamandra, Mertensiella* (fig. 1.34 F), and *Chioglossa* being the sister group to the newts (all remaining genera in the family; Titus and Larson 1995; Weisrock et al. 2001; Larson, Weisrock, and Kozak 2003). Within this group, the two previously recognized species of *Mertensiella* do not appear to form a monophyletic group, and *M. luschani* has been placed in the genus *Salamandra* (or *Lyciasalamandra*) by most recent authors (Weisrock et al. 2001; Larson, Weisrock, and Kozak 2003). Numerous color morphs, described as subspecies of *S. luschani,* may or may not be distinct species. The phylogenetic position of *Salamandrina terdigitata* is uncertain. Its tongue morphology is similar to that of *Salamandra* and *Chioglossa,* both of which feed on land as adults (Özeti and Wake 1969), but it groups with the more aquatic newt clade in mDNA analyses (Titus and Larson 1995). Within the newt clade, the genus *Triturus* appears not to be monophyletic (hence the proliferation of new genus names for members of this group). In addition, the genus *Euproctus* appears to be polyphyletic. Two species, *E. montanus* and *E. platycephalus,* which are found on the islands of Corsica and Sardinia, respectively, are closely related. The Pyrrenean newt (*Euproctus asper*) is more closely related to a clade that includes *Neurergus* and several species of *Triturus* that occur in the Iberian Peninsula and southern Europe. This species has been placed in the genus *Calotriton,* along with a newly de-

(F) *Mertensiella caucasica* from northeastern Turkey and western Georgia in the Caucasus Mountains. Photos by Kentwood D. Wells (A), William P. Leonard (B), and Wayne Van Devender (C–F). For additional photos of salamandrids, see fig. 14.30 A (*Taricha*), 14.30 B (*Paramesotriton*), 14.30 C (*Triturus*); 14.30 E (*Echinotriton*); 14.32 E (*Salamandra*); and 14.32 F (*Tylototriton*).

scribed speceis, *C. arnoldi,* which occurs in an isolated population in Spain (Carranza and Amat 2005). The two North American genera, *Taricha* and *Notophthalmus,* form a monophyletic clade that is closely related to one clade of Old World newts.

Natural History: Most salamandrids are newts, semiaquatic salamanders that breed in water, but usually live at least part of their lives on land. *Notophthalmus, Triturus, Cynops, Paramesotriton, Pleurodeles, Tylototriton,* and one species of *Taricha* breed mostly in ponds and attach eggs individually to submerged plants or scatter them individually or in clumps on the pond bottom. After metamorphosis, adults of most species leave the breeding ponds to live on land, although in some populations, adults remain in the water permanently. In most populations of *Notophthalmus,* larvae metamorphose into a terrestrial eft stage (fig. 1.34 A) that lasts up to seven years before adults return to the water to breed. In some populations, some individuals do not lose their gills upon reaching adult body size, but eventually all individuals metamorphose completely. *Chioglossa, Calotriton, Euproctus, Salamandrina,* and two species of *Taricha* are stream-breeders that deposit eggs in hidden locations under rocks. *Euproctus, Calotrion* (fig. 1.34 E), and *Salamandrina* live permanently in or near cold, well-oxygenated streams and have greatly reduced lungs, whereas *Chioglossa* and *Taricha* are more terrestrial as adults. *Salamandra* and *Mertensiella* are fully terrestrial salamanders as adults. Some species lack an aquatic larval stage and give birth to young that develop inside the female's reproductive tract. Most salamandrids are protected by distasteful, and in some cases, highly toxic skin secretions, and they often are aposematically colored. They exhibit a wide range of defensive postures that display their warning colors or direct poison glands toward predators.

Family Sirenidae

Distribution: Southeastern and central United States and northeastern Mexico.

Content: Two genera, *Siren* (two species; fig. 1.33 D) and *Pseudobranchus* (two species). Until recently, the genus *Pseudobranchus* was considered to be monotypic, with five recognized subspecies within *P. striatus.* Studies of chromosomes revealed that populations in peninsular Florida belong to a separate species, *P. axanthus* (Moler and Kezer 1993).

Natural History: These are fully aquatic salamanders with external gills. They have elongate bodies that lack hind legs. The front limbs are reduced in both genera, and *Pseudobranchus* has only three toes on each front foot. Sirens live mainly in weed-choked ponds, swamps, and ditches, often in habitats with very little oxygen in the water. They utilize gills, skin, and lungs for respiration, but depend mostly on their lungs when oxygen levels are low. They are thought to have external fertilization, because females lack sperm storage organs (spermathecae) characteristic of salamanders with internal fertilization, but mating has not been observed. Eggs are attached to submerged plants.

Morphological Evolution and Ecology in Salamanders

The salamanders are less diverse morphologically than the anurans. Most species retain the ancestral tetrapod morphology of a relatively small head, elongate body, four limbs of more or less equal size, and a tail. They lack the specialized modes of locomotion seen in anurans, utilizing instead two ancestral modes of locomotion, lateral undulation and walking. Lateral undulation involves bending the body by contracting the trunk and vertebral musculature and is the principal mode of locomotion in water. It also is used when salamanders are slithering across a wet substrate, such as a muddy stream bank. Walking involves alternating movements of the limbs on opposite sides of the body, which are held out from the body in a sprawling gait, along with contractions of the trunk musculature. Despite the general lack of specialization in urodeles compared to anurans, the group does exhibit some morphological variation related to exploitation of different microhabitats. Important themes in salamander evolution include the evolution of very small body size, paedomorphosis, and the evolution of lunglessness.

Habitat Associations of Adult Salamanders

Four families of salamanders, the Amphiumidae, Cryptobranchidae, Proteidae, and Sirenidae, are largely or strictly aquatic. All are relatively large salamanders that retain some larval features as adults. Some ambystomatids and hynobiids are permanently aquatic as well. Most species in these families are terrestrial as adults, but return to the water to breed. Pond breeding is most common in both families, but some species are stream-breeders. The salamandrids are somewhat more diverse in their habitat associations. The large newts of the genus *Pachytriton* from Asia are permanently aquatic stream-dwellers. Most of the other genera of newts are terrestrial for at least part of their lives, but return to ponds or streams to breed. *Euproctus, Salamandrina,* and *Chioglossa* all breed in streams, but adult *Chioglossa* are more terrestrial than adults of the other two genera. Two genera, *Salamandra* and *Mertensiella,* are fully terrestrial.

The family Plethodontidae is by far the largest lineage of salamanders and also the most diverse. Even within the relatively small subfamily Desmognathinae, there are species with aquatic, riparian, terrestrial, and fossorial habits. In the subfamily Plethodontinae, aquatic, riparian, terrestrial, fossorial, and arboreal habits are represented. All of the species closely associated with water occur in the tribe Hemidactyliini (with *Hemidactylium* removed from this group). These include species mostly associated with streams, a few that are associated with ponds, bogs, and swamps, and a number of cave-dwelling species (see earlier summary under Plethodontidae). All species traditionally placed in the tribe Plethodontini are terrestrial, fossorial, or arboreal, having been freed from dependence on water by the evolution of direct development of terrestrial eggs.

The most diverse plethodontids are the Neotropical bolitoglossines, which include terrestrial, fossorial, and arboreal species. Most species are tropical or subtropical inhabitants of Mexico, Central America, and northern South America. They are particularly diverse in montane cloud forests, where they occupy several unusual microhabitats, including bromeliads and moss mats on trees or on the ground (D. Wake 1987). Some arboreal species have unusual morphological characteristics, including prehensile tails and feet adapted for clinging to vegetation (see the following). This clade also includes the largely terrestrial and fossorial genus *Batrachoseps* from the west coast of North America, and *Hydromantes,* a rock- and cave-dwelling genus from California and Europe (D. Wake 1966) (some authors place European *Hydromantes* in the genus *Speleomantes*).

The bolitoglossines are characterized by a high degree of convergent evolution, with repeated evolution of similar lifestyles in rather distantly related lineages (Parra-Olea and Wake 2001). This has made it extremely difficult to unravel the phylogenetic relationships of the group as a whole. One example of such convergence is the evolution of elongate body form and reduced limbs in fossorial species, including *Batrachoseps* and two Central American genera, *Oedipina* and *Lineatriton* (fig. 1.35 A, B). This morphology also is seen to a lesser degree in some *Plethodon* that live under rocks, logs, and other surface cover. *Oedipina* and *Lineatriton* exhibit the most extreme elongation and are so similar in appearance that they were once placed in the same genus. However, *Oedipina* has evolved an elongate body form by increasing the number of trunk vertebrae, while *Lineatriton* has done so by increasing the length of each individual vertebra (D. Wake 1991; Parra-Olea and Wake 2001).

Another example of convergent evolution in bolitoglossines is found among species adapted for climbing on vegetation or on the walls of caves. Species in a number of different lineages have independently evolved webbed feet, a morphology that greatly increases the surface area that contacts a smooth, wet substrate such as a plant leaf or a cave wall. However, the way in which this morphology has evolved differs, even among members of the same genus. In the genus *Bolitoglossa,* most lowland tropical forest species are arboreal. Larger species have enlarged feet with webbing formed by growth of skin between the toes (fig. 1.36, bottom). These are equipped with muscles that allow the salamander to pull the center of the foot upward, thus creating a suction force that adheres to the leaf (Alberch 1981).

Some small *Bolitoglossa,* many of which live in the leaf axils of *Heliconia* and banana plants, have superficially similar webbed feet, but these are the result of an entirely different evolutionary process. In these species, the feet are not fully developed, but retain the padlike structure that all plethodontid feet have early in development before the toes are fully grown (fig. 1.36, top). These paedomorphic feet cannot generate suction by muscular action, but depend instead on surface adhesion to the leaf (Alberch 1981). This morphology is largely a consequence of reduction in body size through paedomorphosis, not selection for living in a specific habitat; some small species with similar foot morphology are terrestrial rather than arboreal. This sort of convergent evolution in foot morphology apparently has

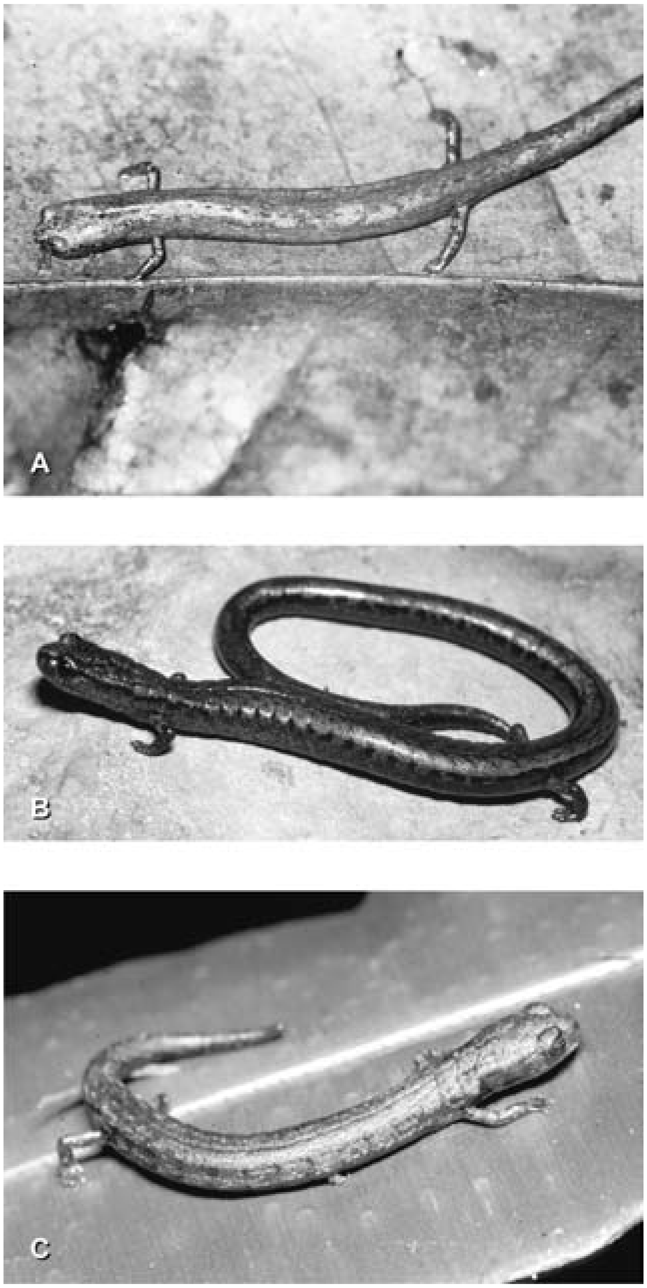

Fig. 1.35. Reduction of body size, elongation of the trunk and tail, and reduction of limbs and feet are common themes in the evolution of plethodontid salamanders. Fig. 1.36. Convergent evolution of webbed feet in tropical bolitoglossine salamanders. *Bolitoglossa rufescens* (top) is a small species with padlike feet that are paedomorphic, but without true cutaneous webbing. *Chiropterotriton magnipes* (middle) is a cave-dwelling salamander from northern Mexico with enlarged feet with cutaneous webbing that has grown between the toes. An unrelated species from Guatemala, *Bolitoglossa salvinii* (bottom), also has enlarged feet with cutaneous webbing that has grown between the toes. After D. Wake (1991).

occurred repeatedly in the genus *Bolitoglossa* in different parts of Central America. Some species in other genera, such as *Chiropterotriton,* which also are adapted for climbing, have independently evolved a foot morphology very similar to that of the large *Bolitoglossa,* even though they live in caves, not on vegetation (fig. 1.36, middle; Wake and Brame 1969; D. Wake and Lynch 1976; D. Wake 1987, 1991).

Body Size and Ecology

As mentioned in the discussion of habitat associations, most of the largest species of salamanders are fully aquatic, while the smallest species tend to be terrestrial or arboreal. This pattern is evident in salamanders as a group, and in particular lineages, such as the desmognathines. There are, however, some exceptions. Members of the genus *Salamandra* are larger than most other salamandrids, yet they are the most terrestrial in the family. Some terrestrial species of *Plethodon* are considerably larger than more aquatic plethodontids such as *Eurycea* or *Stereochilus,* although in this case, the terrestrial and riparian species are in different clades. In general, as terrestrial and arboreal salamanders become smaller, they tend to utilize more cryptic microhabitats that provide protection from desiccation, such as bromeliads, leaf axils, or spaces under bark on fallen logs, whereas larger species are more likely to be seen out and about in the leaf litter, at least on rainy or humid nights.

A trend toward the evolution of very small body size is at least as apparent in salamanders as it is in anurans, and the phenomenon of miniaturization has been studied in considerabe detail in this group (Hanken and Wake 1993). In anurans, miniaturization has occurred in many unrelated lineages, but in salamanders, the evolution of very small body size is limited entirely to plethodontids and occurs most commonly in a single clade, the bolitoglossines. D. Wake (1991, 1992) defined miniaturized salamanders to be those in which at least one sex becomes sexually mature at a body length of less than 30 mm. These include *Desmognathus aeneus* and *D. wrighti, Hemidactylium scutatum, Eurycea quadridigitata, Plethodon websteri, Batrachoseps attenuatus,* a number of species in the Neotropical genera *Bolitoglossa* and *Chiropterotriton,* and all members of the Neotropical genera *Dendrotriton, Nototriton* (fig. 1.35 C), *Parvimolge,* and *Thorius.*

The genus *Thorius* exhibits the most extreme miniaturization, with some species having adult body lengths of less than 20 mm, making them the smallest terrestrial tailed vertebrates (Hanken and Wake 1998). These tiny salamanders typically live in spaces under bark on logs and may even shelter in channels made by insects. They exhibit many features that are paedomorphic relative to more generalized plethodontids. For example, the limbs are greatly reduced, as are the size of the feet and the number of bones in the digits. However, the limb bones and some foot bones exhibit greater ossification than in more typical plethodontids. This had been interpreted by some authors as compensation for a reduction in size by strengthening the bones (D. Wake 1966). However, Hanken (1982, 1993) suggested that this actually is part of a mechanism that restricts bone growth after the salamanders reach sexual maturity (bones cannot increase in length once they are completely ossified). He also found that smaller species in the genus reached this stage of ossification earlier than in larger species, suggesting that differences in adult body size are largely a product of differences in the timing of development.

The most dramatic effects of miniaturization in *Thorius* are seen in the skull, the brain, and the sense organs of the head. The skull is highly paedomorphic, with many features that normally appear late in development being reduced or absent. In fact, even the skull roof is incomplete, with much of the brain being covered with connective tissue rather than bone (fig. 1.37), a most unusual situation in vertebrates. Many other bones of the skull are not fused together, but lie

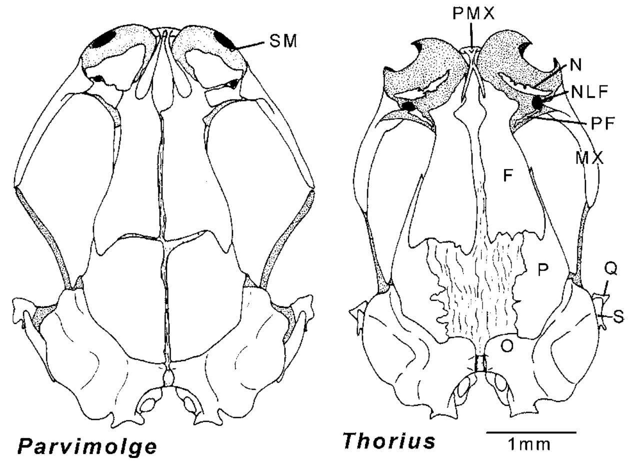

Fig. 1.37. Dorsal views of the skulls of two miniaturized species of Neotropical bolitoglossine salamanders. Left: *Parvimolge townsendi* from Veracruz, Mexico. Right: a species of *Thorius* from Mexico. The skulls of both species are somewhat retarded (paedomorphic) in their development. This is especially evident in *Thorius,* in which the braincase is not fully closed and the brain is covered by fibrous connective tissue (wavy lines). Stippled areas represent cartilage. Abbreviations: F = frontal, MX = maxillary, N = nasal, NLF = nasolacrimal foramen, O = otic-occipital, P = parietal, PF = prefrontal, PMX = premaxillary, Q = quadrate, S = squamosal, SM = septomaxillary. After D. Wake (1991).

in a sheet of cartilage (Hanken 1984). The brain and sense organs, especially the eyes, appear enormous in proportion to the size of the skull, although in absolute size, they may be approaching the lower size limit for proper functioning in vertebrates. This results from negative allometry of these organs with body size (that is, relative brain and sense organ size increase among species with decreasing body size). This negative allometry also is evident within the genus *Thorius:* the smallest species have the smallest absolute eye and brain sizes and the largest relative sizes of these organs (Roth, Blanke, and Ohle 1995). Not surprisingly, these relatively large organs impinge on each other. The huge eyes have changed the configuration of the brain, which has been forced downward and backward in the skull, while the large otic capsules that house the inner ear have resulted in major changes in the articulation of the jaw (Hanken 1983).

All of this rearrangement might be expected to have major effects on the functioning of the brain and nervous system. The situation is complicated by the relatively enormous genome of *Thorius,* and of bolitoglossines in general. The main functional consequence of a large genome is large cell size. Thus, as body size becomes smaller, the large cells that make up the brain and sense organs must be packed into smaller and smaller spaces. The inevitable result is a reduction in number of cells. For example, one of the smallest species, *T. narisovalis,* has the smallest number of visual cells in the brain, because its cells are relatively large. However, another small species, *T. pennatulus,* has evolved some evolutionary compensation for small size. It has smaller cells that are more densely packed than in other small species, and consequently has more visual cells than are found in some much larger species. *Thorius* eyes, while large relatively to body size, are still small relative to other amphibian eyes, with only about 6% of the number of photoreceptors found in a ranid frog eye. On the other hand, the number of retinal ganglion cells is approximately equal to the number of photoreceptors, which has the effect of making the entire retina equivalent to the fovea of a frog eye, the region of maximal visual acuity. Thus, while miniaturization has had a major impact on the structure of the eye and brain in these tiny salamanders, they still appear to have the same high visual acuity found in larger plethodontids, a necessity since they use vision to capture prey (Linke, Roth, and Rottluff 1985; D. Wake 1991; Roth, Nishikawa, and Wake 1997).

Paedomorphosis

The evolution of webbed feet and changes in skull morphology in very small bolitoglossines are part of the broader phenomenon of paedomorphosis that is a dominant theme in the morphological evolution of salamanders (Hanken 1989; D. Wake 1992). Indeed, many morphological features of amphibians in general, and salamanders in particular, are considered highly simplified or paedomorphic relative to ancestral tetrapods (Roth, Dicke, and Nishikawa 1992). In addition to relatively obvious changes in limb and skull morphology discussed previously, paedomorphic simplification can occur in organ systems such as the brain and sense organs. A phylogenetic analysis of the visual, auditory, olfactory, and lateral line systems and several features of the brains of salamanders revealed that most characters exhibit secondary simplification relative to other tetrapod vertebrates, including hagfishes, lampreys, sharks and rays, bony fishes, coelacanths, lungfishes, frogs, and amniotes. Among the salamanders, the greatest degree of simplification is found in the bolitoglossines, considered the most derived lineage in the group (Roth et al. 1993; Roth, Nishikawa, and Wake 1997).

This extensive paedomorphic simplification of the nervous system is correlated with large genome and cell size and slow rates of cell proliferation and differentiation (Roth et al. 1993; Roth, Nishikawa, and Wake 1997). Among salamanders, the large, permanently aquatic families have the largest genomes and cell sizes, while bolitoglossines have the largest genomes and cell sizes among the more terrestrial lineages (Sessions and Larson 1987). In contrast, anurans have smaller genomes than salamanders and exhibit less dramatic examples of paedomorphosis; caecilians are intermediate. If paedomorphosis and simplification of morphological structure, particularly in the nervous system, are a result of slower development and differentiation rates in species with larger genomes and cells, then these morphological patterns may not be adaptive consequences of selection for simplification, but rather constraints placed on morphological evolution by basic characteristics of the salamander lineage. In fact, in some of the very small bolitoglossines with the most simplified nervous systems, there is evidence for the evolution of new structural features that compensate for the overall morphological simplification. Hence, these are among the most specialized of all salamanders in their visual systems and feeding behavior (see the following), in spite of, but not because of, their paedomorphic morphology (Roth and Wake 1985a, b; D. Wake and Roth 1989; Roth et al. 1993).

The Evolution of Lunglessness

The plethodontids, by far the most successful salamander clade, are unusual among terrestrial vertebrates in having completely lost their lungs, relying entirely on the skin and the lining of the mouth and throat (the buccopharyngeal region) for gas exchange (see chapter 4). Since there are no close relatives of living plethodontids that exhibit an intermediate condition (reduced lungs), it has been difficult to understand exactly what selective pressure led to the initial evolution of lunglessness in this group. Most authors have dismissed the possibility that loss of lungs could be a specific adaptation for terrestrial life, since the switch to cutaneous respiration limits the types of microhabitats in which these animals can live to relatively cool, moist environments (Feder 1983b). The traditional explanation, first proposed by Wilder, Whipple, and Dunn (1920) and elaborated by Dunn (1926c), is that the ancestral plethodontids were highly aquatic, stream-dwelling salamanders from the southern Appalachians, with a lifestyle similar to that of *Desmognathus quadramaculatus* or *D. marmoratus*. The ostensible benefit of lunglessness is to reduce buoyancy, thereby enabling the salamanders to maintain their position in a swift current. Presumably the high oxygen content of cool mountain streams would allow for this because most of the animal's oxygen requirements could be accommodated through cutaneous respiration. Several stream-dwelling salamanders in other families also exhibit moderate to complete loss of lungs, including *Onychodactylus* and *Ranodon* (Hynobiidae), *Rhyacotriton* (Rhyacotritonidae), and *Salamandrina, Euproctus,* and *Chioglossa* (Salamandridae).

Ruben and Boucout (1989) challenged this traditional scenario for the evolution of lunglessness in plethodontids, largely on the grounds that the topography and climate of the southern Appalachian region was not the same as it is today when the plethodontids first appeared. Instead, they believed the geological evidence points to a lowland environment with a warmer, perhaps subtropical climate. In this type of habitat, low oxygen concentration in the water would make lungs essential for fully aquatic salamanders, because they would not be able to take up sufficient oxygen through the skin, and indeed, might lose oxygen to hypoxic water (see chapter 4). They suggested instead that ancestral plethodontids were riparian or terrestrial. Most salamanders in these habitats have narrower heads than more fully aquatic species, and reduction in head width results in reduced capacity to fill the lungs because of a reduction in the throat musculature used to pump air into the lungs. Ruben and Boucout proposed that a reduction in relative head width occurred first, perhaps because of advantages in acquiring terrestrial prey or utilizing cryptic microhabitats under rocks and logs. The reduced ability to use the lungs would then result in increased reliance on cutaneous respiration, a shift that would be easiest in small species with relatively large surface to volume ratios. Reagan and Verrell (1991) speculated that a shift to courtship and mating on land, where oxygen availability is much greater than in the water, might have facilitated the loss of lungs in plethodontids.

Ruben and Boucout's alternative scenario for the evolution of lunglessness was criticized by Beachy and Bruce (1992), who maintained that there were sufficient upland habitats available in the late Mezozoic to allow for the evolution of plethodontids in cool, upland habitats. They also argued that most salamanders, except those that live in hypoxic environments, rely mainly on the skin for respiration, even if they have lungs, and that lungs may have evolved mainly as hydrostatic organs that are used only secondarily as respiratory organs. They stated that desmognathines and hemidactyliines that are closely associated with streamside habitats typically have prolonged larval periods, in some cases lasting for several years (see chapter 13). This suggests that loss of lungs is primarily an advantage for plethodontid larvae in reducing buoyancy in stream habitats. Experiments in which larvae of *Ambystoma maculatum* were raised with and without access to air supported this hypothesis. Those raised without access to air developed smaller and more solidified lungs than did those raised with access to air, and the result was reduced buoyancy and less tendency to be displaced by a current (Bruce et al. 1994).

There clearly is no consensus concerning the origins of lunglessness in the plethodontids. Ruben et al. (1993) challenged the geological data presented by Beachy and Bruce, as well as their assumption that the unusually long larval periods of stream-dwelling plethodontids represent the ancestral condition for plethodontids as a whole. They suggest that the much shorter larval periods characteristic of most ambystomatids and other salamander families are more likely to resemble those of ancestral plethodontids, with the long larval periods of stream-dwelling forms being secondarily derived, or perhaps a proximate result of cold environmental temperatures. They also point out that the larvae of many lunged salamanders live in flowing water and are perfectly capable of walking on the bottom of a stream and reduce buoyancy by releasing air from the lungs. Unfortunately, it may be difficult to resolve this argument definitively. There is considerable disagreement among systematists as to which family is the most likely sister-group to the plethodontids, so it is difficult to infer ancestral larval characteristics from a phylogenetic analysis. Furthermore, the length of the larval period is a notoriously plastic trait in amphibians that tends to be greatly influenced by local environmental conditions (see chapter 13), so the patterns we see in living species may not have been characteristic of their ancestors. Finally, a major morphological change such as the loss of lungs may result from multiple selective pressures and may not be explainable by a simple adaptive advantage such as a reduction in buoyancy or a shift to terrestrial courtship.

Functional Morphology of Feeding

All salamanders are carnivorous, both as larvae and as adults, although there is evidence that sirens can derive some nutrition from plant material (Pryor, German, and Bjorndal 2006). The mode of prey capture varies among different clades and is affected by habitat, mode of life history, and the presence or absence of lungs (Lombard and Wake 1977, 1986; D. Wake 1982, 1991; D. Wake and Larson 1987; Deban and Wake 2000; D. Wake and Deban 2000; Deban and Marks 2002; O'Reilly, Deban, and Nishikawa 2002). Aquatic salamander larvae have tongues that are little more than thickened pads on the floor of the mouth, a condition that is retained in aquatic salamanders such as *Cryptobranchus* and *Necturus* (fig. 1.39 A). The tongue is not involved in prey capture in salamander larvae or aquatic adults. Instead, they capture prey by suction feeding, an ancestral feeding mode for aquatic vertebrates (Lauder and Shaffer 1993; Deban and Wake 2000; Deban and Marks 2002; O'Reilly, Deban, and Nishikawa 2002). Because lunging toward prey in water tends to displace it away from the salamander's mouth, it is more efficient to capture prey by suddenly opening the mouth and depressing the floor of the buccal cavity, causing the prey to be sucked in (see chapter 12). The hyobranchial apparatus in the floor of the buccal cavity and its associated musculature provide the main force for suction feeding in all aquatic vertebrates. When this apparatus is pulled backward there is a rapid expansion of the buccal cavity. Patterns of muscle activity involved in suction feeding are highly conserved across widely diverse taxa, including fishes and salamanders (Lauder and Shaffer 1985, 1986, 1993; Wainwright et al. 1989). When salamander larvae metamorphose and move onto land, they undergo major morphological changes that affect their feeding behavior. In most species, adults acquire a moveable tongue pad that is supported by a modified hyobranchial apparatus (now the hyolingual apparatus; fig. 1.38). The branchial musculature is modified in such a way that the hyolingual apparatus is protracted, rather than being retracted as it is in suction feeding (Bramble and Wake 1985).

The hyolingual apparatus of adult terrestrial salamanders has a very different structure from that of aquatic larvae. Many skeletal elements, especially those associated with support of the gills, are lost. The ceratohyals, which

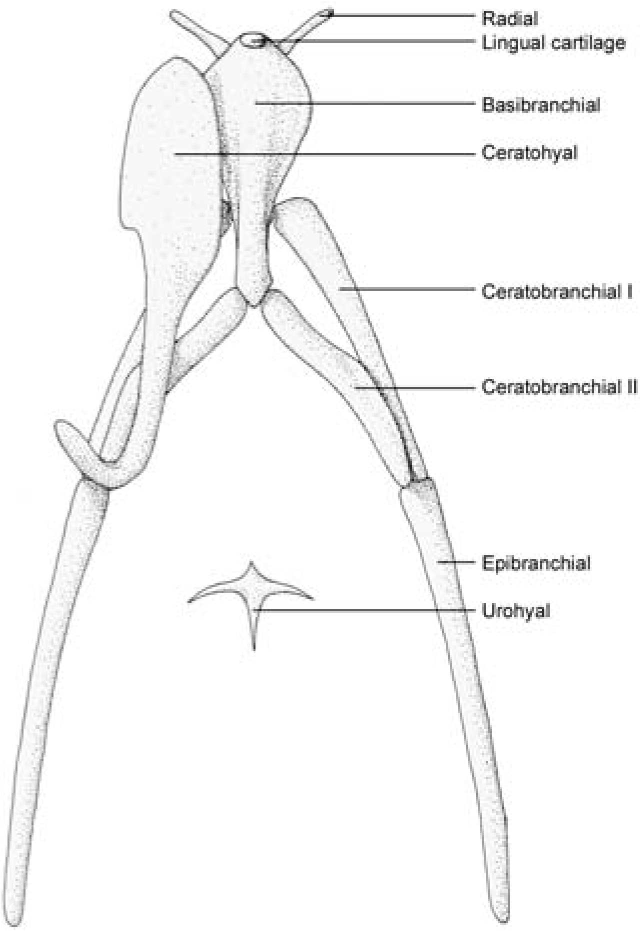

Fig. 1.38. Structure of the hyolingual apparatus of an adult plethodontid salamander, *Eurycea bislineata.* The ceratohyals are anchored in the floor of the mouth, while the tongue is supported by the lingual cartilage. During tongue protraction, the whole apparatus slides forward on the ceratohyals. The ceratobranchials are derived from the larval branchial arches that supported the gills. In adult salamanders with lungs, the ceratobranchials are relatively large and are involved in moving the floor of the mouth to fill the lungs with air. In the lungless plethodontids, the ceratobranchials are reduced, but the single pair of epibranchials becomes elongated and the whole hyolingual apparatus becomes specialized for tongue projection. The highest degree of specialization of the hyolingual apparatus is found in plethodontids that undergo direct development, because they are freed from the constraints imposed by larval morphology adapted for suction feeding in water. After Lombard and Wake (1976).

anchor the whole apparatus, become somewhat detached from the other elements that support the tongue pad. This allows those elements to slide forward during tongue protraction. In adult terrestrial salamanders, only two pairs of branchial arches remain from the original three or four present in larval salamanders, represented by the two pairs of ceratobranchials (fig. 1.38). In all families of terrestrial salamanders except hynobiids, these articulate with only a single pair of epibranchials. In salamanders with lungs, the hyolingual apparatus provides the main force to fill the lungs with air by positive-pressure pumping of the throat. In particular, the ceratobranchials are important in depressing the mouth during respiration, as well as during suction feeding in larvae, and they become enlarged early in development. In the lungless plethodontids, the ceratobranchials are reduced, but the epibranchials often become highly elongated (fig. 1.38), and this allows the hyolingual apparatus to become more specialized for tongue projection (D. Wake 1982; Roth and Wake 1989; Deban and Marks 2002).

The hynobiids, ambystomatids, and dicamptodontids, most of which have well-developed lungs, have the most generalized tongue morphology, which is considered to be the ancestral condition for terrestrial salamanders. The tongue is relatively broad and padlike, tightly attached to the floor of the mouth, with only part of the margin of the tongue free (fig. 1.39 B). Consequently, the capacity for tongue projection is limited, with little projection beyond the tip of the snout (Larsen and Guthrie 1975; D. Wake and Deban 2000). Nevertheless, the slight projection of the tongue and the use of the tongue to seize the prey is the principal difference in feeding behavior of terrestrial adults and aquatic larvae. Most other aspects of the kinematics of feeding are remarkably similar (Shaffer and Lauder 1988; Lauder and Reilly 1990; Gillis and Lauder 1994). Although the tongue is used to seize the prey, these salamanders cannot capture prey at long distances, nor are they well adapted to feeding on very small or fast-moving prey (Reilly and Lauder 1989).

Salamandrids generally have a somewhat greater ability to project the tongue than do ambystomatids or dicamptodontids, and there is considerable variation within the family (Özeti and Wake 1969; D. Wake 1982). In *Salamandra salamandra,* eggs are retained in the female's reproductive tract, and larvae are born at a relatively large size and advanced stage of development (see chapter 10). The aquatic larvae use the typical suction feeding seen in other aquatic vertebrates. Motor patterns are very similar to those seen in other aquatic salamander larvae, although larvae of this species capture prey more rapidly than most other species (Reilly 1995). Metamorphosed adults are entirely terrestrial and have a land-tongue morphology similar to that of other terrestrial salamanders. Although their ability to protract the tongue is limited, it can be projected beyond the mouth and is used for prey capture (Özeti and Wake 1969; D. Wake 1982). Two other terrestrial genera, *Salamandrina* and *Chioglossa,* have a much greater ability to project the tongue (up to 20% of snout-vent length in *Salamandrina*). In this respect, they are convergent with plethodontids that have highly protrusible tongues (see the following), although the mechanism of tongue projection is different (Özeti and Wake 1969; Findeis and Bemis 1990). It is undoubtedly significant that these genera, like the plethodontids, lack lungs and therefore do not use the hyolingual apparatus for breathing, so it is freed for use in tongue protrusion (D. Wake 1982).

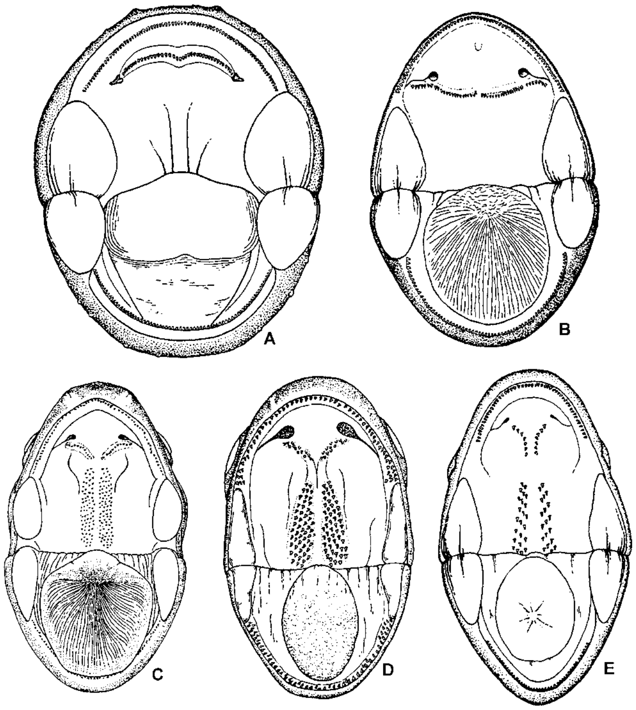

Fig. 1.39. Representative salamander tongues. (A) The tongue of the aquatic salamander *Cryptobranchus alleganiensis* is little more than a thickened pad on the floor of the mouth. (B) The tongue of a terrestrial adult of *Ambystoma maculatum* is a padlike structure with only part of the tongue margin detached from the floor of the mouth. (C) *Plethodon glutinosus* has a generalized tongue morphology similar to the ancestral condition for the family Plethodontidae. (D) *Hemidactylium scutatum* has a smaller tongue that is attached in front, but capable of some forward projection. (E) *Eurycea bislineata* has a tongue that is not attached to the tips of the jaws, which allows for greater projection of the tongue to capture prey. After Bishop (1941).

Most of the newts that are largely aquatic as adults have a water tongue morphology with a poorly developed tongue pad and very limited ability to project the tongue (Özeti and Wake 1969; D. Wake 1982). Those that remain in the water for most of their lives, such as the Asian genus *Pachytriton,* retain the labial lobes that aid in suction feeding, but they are lost in species that spend most of their lives on land (they may regrow during the aquatic breeding season). Some newts that are largely terrestrial except during the breeding season have moderately protrusible tongues. One example is *Taricha torosa,* which captures prey on land with a forward lunge coupled with tongue projection; the prey is drawn into the mouth with the sticky tongue. This species also suction feeds in the water, and the need for a hyolingual apparatus that can depress the floor of the mouth for suction feeding and for breathing has apparently limited the evolution of tongue protrusion. In addition, the details of tongue protrusion and the anatomy of the hyolingual apparatus are different from those of plethodontids, clearly indicating an independent evolution of a protrusible tongue (Findeis and Bemis 1990).

All plethodontids have been freed from the morphological constraint of having to use the hyolingual apparatus to fill the lungs with air, although they still pump air into the mouth for buccopharyngeal respiration. This has allowed the hyobranchial apparatus to become specialized for tongue projection. In those species that have aquatic larvae, morphological constraints associated with larval suction feeding remain, and in general, plethodontids with aquatic larvae (the desmognathines and hemidactyliines) have less protrusible tongues than do those that have lost the larval stage altogether. However, even within these groups, there is considerable variation, and it is clear that protrusible tongues have evolved in different ways independently many times in plethodontids (Lombard and Wake 1977, 1986; D. Wake 1982; D. Wake and Larson 1987; D. Wake and Deban 2000; Deban and Marks 2002).

Based on the relationships among plethodontids as they were understood in the 1980s, Wake and Larson (1987) presented a phylogeny of tongue evolution in the family. Recent thinking about phylogenetic relationships within the family have since changed, so some revision of their scenario will be required, particularly regarding the number and direction of evolutionary transitions between different tongue morphologies (Mueller et al. 2004). Because a thorough analysis of tongue evolution based on new ideas of plethodontid phylogeny has yet to be published, I discuss the original ideas of Wake and Larson (1987) here. They argued that the ancestral condition for the family was to have the front of the tongue attached to the jaw by a short, stout genioglossus muscle (fig. 1.41). In species with this type of tongue morphology (the desmognathines, *Plethodon,* and *Aneides*), the tongue is projected by flipping forward a posterior flap of the tongue (fig. 1.40 A, B). This is referred to as an attached protrusible tongue and still would be the ancestral condition under the revised phylogeny of the family (Mueller et al. 2004). Species with this morphology have a limited ability to project the tongue, so they cannot capture prey at long distances (Schwenk and Wake 1993). Several

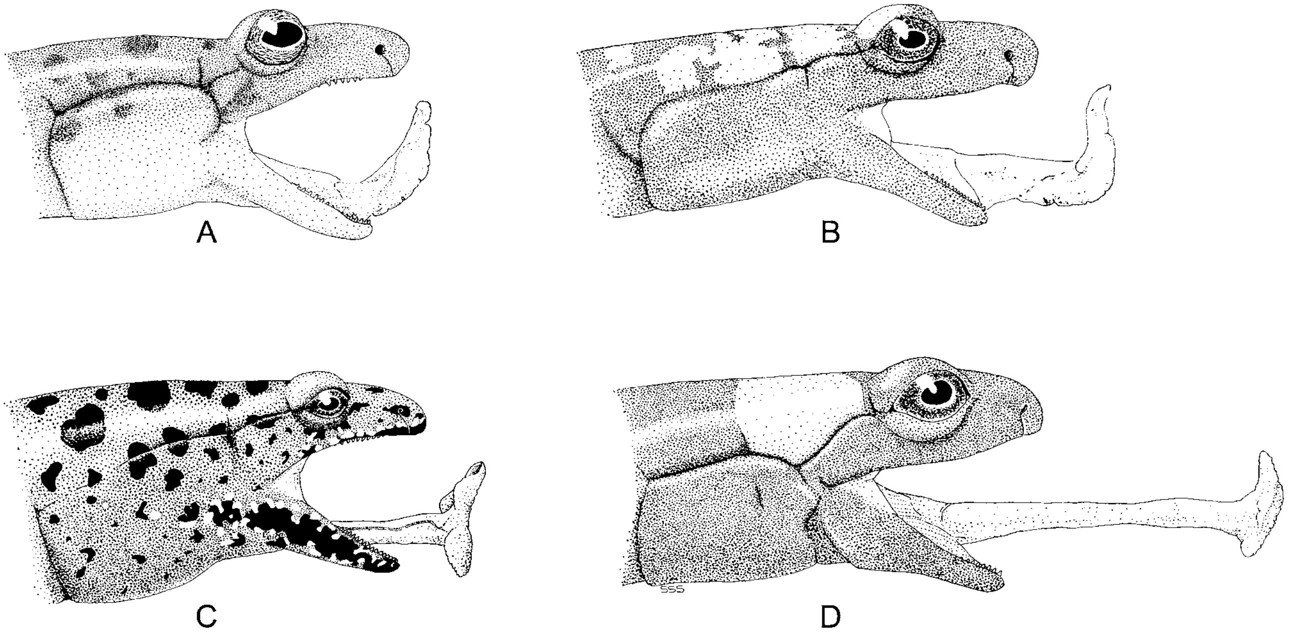

Fig. 1.40. Tongue protrusion in plethodontid salamanders. (A) *Desmognathus monticola* exhibits what is thought to be the ancestral condition (attached protrusible tongue), with the tongue attached to the front of the jaw with a short genioglossus muscle. This allows for only limited tongue protraction as the tongue is flipped forward out of the mouth. (B) *Ensatina eschscholtzii* retains the genioglossal connection, but the muscle has become elongated, allowing for greater forward projection of the tongue (attached projectile tongue). (C) *Pseudotriton ruber* has lost the genioglossus muscle, and the tongue pad is detached from the jaw, allowing for much greater forward projection of the tongue (free projectile tongue). (D) A similar tongue morphology has evolved independently in bolitoglossine salamanders, represented here by *Pseudoeurycea bellii,* but these salamanders are capable of even greater projection of the tongue beyond the tips of the jaws. From Lombard and Wake (1977).

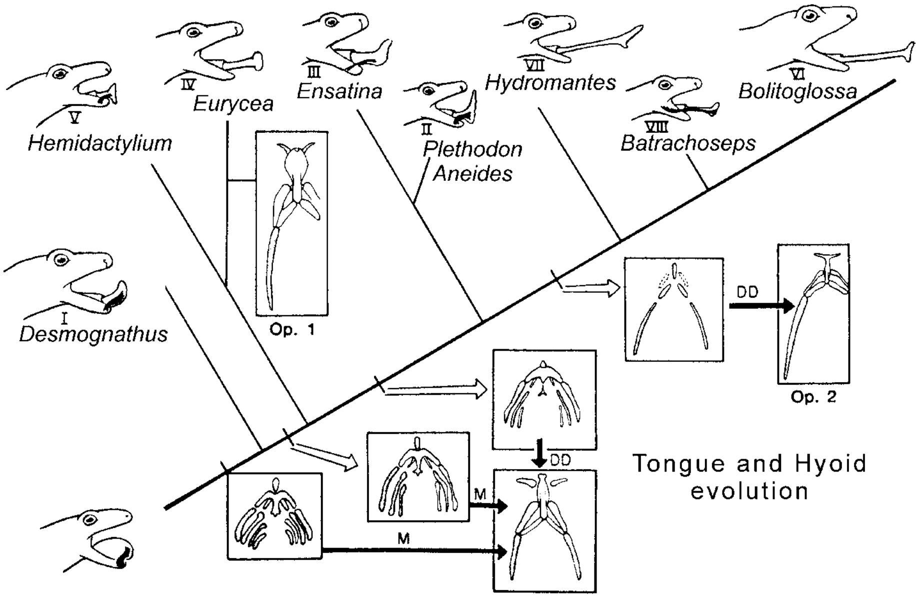

Fig. 1.41. Phylogeny of tongue evolution in plethodontid salamanders. Roman numerals refer to eight different modes of tongue projection. In the ancestral condition and in modes I (desmognathines) and II (*Plethodon* and *Aneides*), the tongue is attached to the front of the jaw with a short, stout genioglossus muscle that limits forward tongue projection. In modes III (*Ensatina*), V (*Hemidactylium*), and VIII (*Batrachoseps*), the genioglossal connection is retained, but elongation of the muscle allows for greater tongue projection (attached projectile tongues). This condition appears to have evolved at least three times independently from the ancestral condition. In modes IV (*Eurycea*), VI (bolitoglossines), and VII (*Hydromantes*), the genioglossal connection has been lost, allowing for much greater forward projection of the tongue (free projectile tongues). Tongue projection also is affected by the structure of the hyobranchial apparatus (boxes), which is constrained by larval morphology. Larval desmognathines have four pairs of epibranchials, whereas larval plethodontines have three. In both clades, these are transformed during metamorphosis into a single adult epibranchial on each side. In those species that undergo direct development (tribes Plethodontini and Bolitoglossini), there also is a transformation to a single pair of adult epibranchials. The most derived condition is found in the bolitoglossines, in which the larval epibranchials never form, and only the adult morphology is present. Op. 1 (*Eurycea*) and 2 (bolitoglossines) represent two different options for the evolution of free projectile tongues involving different developmental pathways and different biomechanical properties. After D. Wake and Larson (1987).

lineages that have retained the genioglossal attachment have secondarily achieved a greater degree of tongue protrusion through elongation of the genioglossus muscle. This condition, attached projectile tongues, has evolved independently in *Hemidactylium,* Ensatina, and *Batrachoseps* (fig. 1.41). Of these, only *Hemidactylium* has aquatic larvae, and it has the least protrusible tongue of these genera, while *Batrachoseps,* a genus with direct development, has the most protrusible tongue and probably the greatest ability to feed on small prey at long distances.

In three lineages of plethodontids, the genioglossus muscle has been lost, and the tongue is completely free (fig. 1.41). This condition is found in *Eurycea, Pseudotriton, Hydromantes,* and all of the Neotropical bolitoglossines (fig. 1.40 D). The last two groups, both of which lack aquatic larvae, have the most specialized projectile tongues, capable of extending up to 20–40% of snout-vent length (fig. 1.42). Among the Neotropical bolitoglossines, the most specialized tongues are found in the miniaturized genus *Thorius.* In this group, the different elements of the hyolingual apparatus become disarticulated, allowing them to collapse into a compact linear bundle when the tongue is projected. This results in a highly efficient biomechanical system that probably allows them to capture small, relatively fast-moving prey. The morphological and behavioral specializations of the bolitoglossines are possible because this group is freed from both major morphological constraints on tongue evolution, the use of the hyobranchial apparatus for suction feeding in larvae and its use for breathing in adults. In addition, since these salamanders do not undergo metamorphosis, there is the possibility of novel developmental patterns evolving, and indeed, the structure of the hyobranchial apparatus is different in these species than in other salamanders with projectile tongues (fig. 1.41). However, the fact that lungless salamanders with direct development have not all evolved such specialized tongues indicates that other selective pressures are at work as well (Lombard and Wake 1976, 1977; Roth 1976; D. Wake 1982; D. Wake and Larsen 1987; D. Wake and Deban 2000; Deban and Marks 2002).

Phylogeny and Classification of the Gymnophiona

The caecilians are elongate, legless amphibians adapted to fossorial or aquatic life. Many species are rarely encountered and have not been studied in great detail. In addition, the highly derived morphology of these animals makes it difficult to determine the phylogenetic relationships of caecilians based entirely on morphological characters (Nussbaum and Wilkinson 1989). Some recent phylogenetic work has been based on molecular data, but the results are not always consistent with the results of morphological studies (Hass, Nussbaum, and Maxson 1993; Hedges, Nussbaum, and Maxson 1993). Even different types of morphological data do not always yield congruent results (M. Wilkinson 1997). There is general agreement that the family Rhinatrematidae is the most primitive group of living caecilians, and the families Ichthyophiidae and Uraeotyphlidae are relatively basal lineages as well and may be closely related to each other (Wilkinson, Drewes, and Tatum 2002; San Mauro et al. 2004; Frost et al. 2006, placed *Uraeotyphlus* within the family Ichthyophiidae). All of these families have free-living aquatic larvae, presumed to be the ancestral condition for caecilians. Some caeciliids also have aquatic larvae, but many caeciliids lay eggs that undergo direct development or are viviparous. The relationships among the more derived families are not yet resolved, but the typhlonectids appear to be closely related to, and possibly derived from, members of the family Caeciliidae, which may not be a monophyletic group (fig. 1.43). Indeed, the major systematists working on caecilians have alternated between treating the typhlonectids as a separate family or as a subfamily of Caeciliidae (Hedges, Nussbaum, and Maxson 1993; M. Wilkinson and Nussbaum 1999).

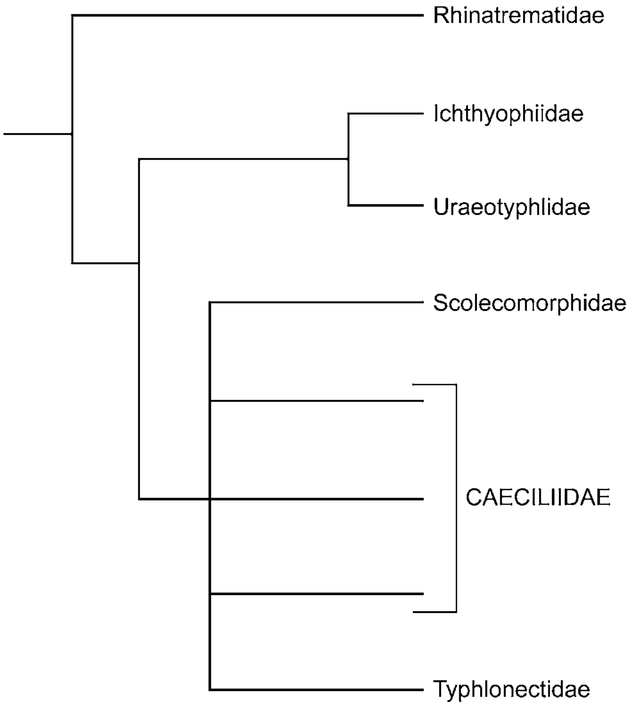

Fig. 1.43. Phylogenetic relationships of caecilians, derived from a combination of morphological and molecular data. The family Caeciliidae probably is not a monophyletic group as currently constituted and is shown as several distinct lineages. Some classifications place the typhlonectids in the family Caeciliidae. After Pough et al. (2004), based on Wilkinson and Nussbaum (1999).

Synopsis of Families of Gymnophiona

The family-level classification of caecilians has remained essentially unchanged since the late 1980s, although Frost et al. (2006) proposed collapsing the five generally recognized families into three. Although there have been some minor taxonomic rearrangements at the genus and species level, Duellman (1993a) did not record any net change in the number of described caecilian species between 1985 and 1992. Very little is known about the natural lives of caecilians, so the following summaries of natural history are necessarily brief. The major monograph on the caecilians of the world (E. H. Taylor 1968) contains almost no information on their ecology or natural history. Probably the best-known aspect of their biology is reproduction (M. Wake 1977b, 1992), but only a few species have been studied in detail, almost exclusively in captivity. Sensory systems and locomotion also have been studied in some detail (see the following references cited). Himstedt (1996) provides the best overview of caecilian biology.

Family Caeciliidae

Distribution: Tropical South and Central America, tropical Africa, the Seychelles Islands, the Indian subcontinent.

Fig. 1.44. Diversity of caecilians (Gymnophiona). (A) *Oscaecilia ochrocephala* (Caeciliidae) from Panama. (B) *Geotrypetes seraphini* (Caeciliidae) from the Ivory Coast. (C) *Grandisonia alternans* (Caeciliidae) from the Seychelles Islands. (D) *Ichthyophis bannanicus* (Ichthyophiidae) from Vietnam. The tentacle, a sensory organ unique to caecilians, is clearly visible in B and D. Photos by Kentwood D. Wells (A), Mark Oliver Rödel (B), and Wayne Van Devender (C, D). For additional photos of caecilians, see fig. 1.1 C and 11.13 (*Siphonops*).

Content: 21 genera, about 100 species (fig. 1.44 A–C). With about 55% of the described species, this is by far the largest family of caecilians and also is the most widely distributed. Most genera have only one to five described species. The largest genus is *Caecilia* (33 species) of northern South America and Panama. Molecular systematic work suggests that this family is paraphyletic, with the genus *Typhlonectes,* often placed in a separate family, being closely related to *Caecilia.* M. Wilkinson and Nussbaum (1999) recommended retaining the Typhlonectidae as a separate family until higher order relationships are further resolved, but Frost (2004) and Frost et al. (2006) treated typhonectids as a subfamily of Caeciliidae. The species found in the Seychelles Islands (*Grandisonia, Hypogeophis, Praslinia;* fig. 1.44 C) appear to form a monophyletic clade that is most closely related to the Indian genus *Gegeneophis* (Hass, Nussbaum, and Maxson 1993; M. Wilkinson et al. 2002).

Natural History: The caeciliids are elongate, terrestrial burrowers with blunt heads and no tails. However, they also are capable of living in water, and one species from the Seychelles Islands, *Hypogeophis rostratus,* is commonly found in streams and even engages in aquatic courtship (Nussbaum 1984). As in all caecilians, the eyes are reduced and covered with skin, and specialized tactile and chemosensory organs, the tentacles, are present on the head. Species range in size from less than 100 mm to an impressive 1.5 m. Like all caecilians, they have internal fertilization, which is achieved by use of a special copulatory organ, the phallodeum. Although the reproductive biology of most species is unknown, the family includes species with free-living aquatic larvae (fig. 1.45), species that lay eggs that undergo direct development, and some that give birth to live young (viviparity). Ecological information has been collected on only a handful of species. Densities of some populations can be surprisingly high, even in disturbed habitats such as agricultural land (Oommen et al. 2000; Measey and DiBernardo 2003; Measey et al. 2003a, b; Gower et al. 2004; Measey 2004). The few available studies of diets indicate that these animals are generalist predators on soil invertebrates, including earthworms, termites, and other insects (Gaborieau and Measey 2004; Measey et al. 2004).

Family Ichthyophiidae

Distribution: Southeast Asia, the Indian subcontinent, Sri Lanka, Borneo, Sumatra, the Philippines.

Fig. 1.45. Eggs of *Grandisonia alternans* from the Seychelles Islands, a caecilian with aquatic larvae. The eggs normally would be placed in moist areas near water. Photo by Wayne Van Devender.

Content: Two genera, *Ichthyophis* (34 species; fig. 1.44 D) and *Caudacaecilia* (five species).

Natural History: These are elongate, burrowing animals with longer tails than caeciliids. Eggs are deposited in muddy burrows near water, where they may be attended by the female. Larvae are aquatic and live in both ponds and streams, and adults are perfectly capable of swimming as well (Crapon de Caprona and Himstedt 1985). Recent molecular phylogenetic work suggests that the ichthyophiids of Southeast Asia form a monophyletic clade derived from ancestors that originated on a landmass that included India, Sri Lanka, and the Seychelles, and dispersed into mainland Asia after India became connected to that continent (Gower et al. 2002; M. Wilkinson et al. 2002). This pattern of dispersal out of India also has been reported for some clades of frogs (Bossuyt and Milinkovitch 2001).

Family Rhinatrematidae

Distribution: Tropical South America.

Content: Two genera, *Epicrionops* (eight species) and *Rhinatrema* (one species).

Natural History: Relatively small, burrowing animals, with short tails. The eyes of these caecilians are less reduced than in more derived families. They lay eggs that hatch into aquatic larvae.

Family Scolecomorphidae

Distribution: Disjunct distribution in tropical West and East Africa.

Content: Two genera, *Scolecomorphus* (three species) and *Crotaphatrema* (three species). These two genera together are treated as a subfamily of Caeciliidae by Frost et al. (2006).

Natural History: These are moderately large, elongate burrowers with vestigial eyes and no orbits. *Scolecomorphus* probably is viviparous, whereas *Crotaphatrema* may be oviparous (Nussbaum and Wilkinson 1989).

Family Typhlonectidae

Distribution: Disjunct distribution in northern South America and southern Brazil and northern Argentina.

Content: Five genera, *Chthonerpeton* (eight species), *Typhlonectes* (two species), *Nectocaecilia* (one species), *Potomotyphylus* (one species), and *Atretochoana* (one species). The genus *Typhlonectes* appears to be closely related to *Caecilia,* based on molecular data, and typhlonectids sometimes are treated as a subfamily of Caeciliidae (Frost 2004; Frost et al. 2006).

Natural History: Although often described as strictly aquatic, some typhlonectids exhibit few morphological adaptations for swimming and apparently live in moist soil (e.g., members of the genus *Chthonerpeton;* Nussbaum 1986). The genus *Typhlonectes* is the most aquatic. Although it lacks a true tail, the posterior part of the body is laterally compressed into a fin for swimming. These animals spend the daylight hours in flooded burrows along the margins of streams and rivers. At night, they form large foraging groups in the water (Moodie 1978). All species in this family are assumed to be viviparous. One species of typhlonectid, *Atretochoana eiselti,* was described from a single specimen collected somewhere in South America in the nineteenth century. It was previously placed in the genus *Typhlonectes,* but a reexamination of the specimen revealed that it is completely lungless. It is the only lungless caecilian, and with a length of 725 mm, is the largest known lungless vertebrate (Nussbaum and Wilkinson 1995). After the discovery of a second specimen, the anatomy and systematic relationships of this unusual caecilian were studied in considerable detail (M. Wilkinson and Nussbaum 1997, 1999). It appears to be most closely related to the monotypic genus *Potomotyphylus,* which is fully aquatic. The ecology of *Aretochoana* is completely unknown, but the presence of a fin and laterally compressed body are consistent with an aquatic lifestyle.

Family Uraeotyphlidae

Distribution: Southern India.

Content: A single genus, *Uraeotyphlus* (five species).

Natural History: These are relatively small caecilians that look similar to ichthyophiids, with a true tail, and appear to be the sister group to that family (M. Wilkinson and

Nussbaum 1996; M. Wilkinson et al. 2002) or part of that family (Frost et al. 2006). They are presumed to be oviparous, and at least one species has aquatic larvae (M. Wilkinson 1992).

Morphological Evolution and Ecology of Caecilians

All caecilians are elongate animals with large numbers of vertebrae (95–285). They lack any trace of limbs or pelvic and pectoral girdles, and in all but the basal groups, the tail is absent as well (Duellman and Trueb 1986; Himstedt 1996). This morphology presumably is a derived condition related to their fossorial habits. The discovery of well-preserved fossil caecilians from the early Jurassic has shown that the ancestors of modern caecilians probably had well-developed legs and tails (Jenkins and Walsh 1993). The elongation of the body has led to many internal organs, such as the testes and lungs, being elongated as well, a condition also seen in snakes. The left lung is dramatically reduced relative to the right lung, or is lost altogether. This is the same pattern seen in derived families of snakes, which also lack the left lung.

Most caecilians are medium-size to large animals (the largest is *Caecilia thompsoni* at about 1.5 m). However, the miniaturization that has occurred repeatedly in the evolution of anurans and salamanders is evident in caecilians as well. Two of the smallest species, *Idiocranium russeli* of West Africa and *Grandisonia brevis* of the Seychelles Islands, are only slightly more than 100 mm in length (Nussbaum 1984; M. Wake 1986a). *Idiocranium* exhibits a number of paedomorphic features in addition to reduced body size, including retention of some cartilage in the skull and vertebrae and the loss of certain bony elements in the skull that appear in other caecilians relatively late in development (M. Wake 1986a). Unfortunately, nothing is known about the ecology of these tiny caecilians, so functional correlates of reduced body size are unknown.

Modes of Locomotion

Caecilians are unusual in that the trunk musculature forms a thick band that is closely attached to the skin and relatively unattached to the vertebral muscles. This allows the vertebral column to move independently of the skin and trunk muscles (Naylor and Nussbaum 1980; Nussbaum and Naylor 1982). Caecilians move either by lateral undulation, an ancestral mode for all tetrapods, or by a modified form of concertina locomotion in which the body is thrown into curves to form an anchor to push the front of the body forward. The latter is used when moving inside burrows. Many burrowing caecilians do not bend the entire trunk, but instead bend the vertebral column into curves without bending the trunk musculature, a form of internal concertina locomotion that is unique to caecilians and a few snakes. This type of movement is possible only if there is a loose connection between the trunk and vertebral muscles. Forward movement is enhanced by hydrostatic pressure generated by vertical muscles in the body wall and a helical array of tendons that surrounds the body wall (O'Reilly, Ritter, and Carrier 1997; O'Reilly, Summers, and Ritter 2000). This condition has been lost in the highly derived aquatic typhlonectids, which have a tighter connection between these muscle groups and move mainly by lateral undulation (Gaymer 1971; Gans 1974; Summers and O'Reilly 1997).

Burrowing

Caecilians burrow by inserting the snout into the ground at an angle, bracing the loosely curved body against the substrate, and elevating the head to push the soil aside. Once the burrow is started, it is enlarged by pushing and compacting the soil with the head, while pushing forward with contractions of the trunk and vertebral muscles (M. Wake 1993b). There are differences in burrowing ability among families of caecilians. Rhinatrematids, which are considered relatively primitive caecilians, spend at least part of their lives on the surface moving through leaf litter and are not as well adapted for burrowing as more derived families. The same is true of ichthyophiids. Ducey et al. (1993) compared the burrowing ability of one ichthyophiid species (*Ichthyophis kohtaoensis*) with several species in the more derived family Caeciliidae. All of the species tested easily burrowed into loosely compacted soil, but had difficulty penetrating more heavily compacted substrates. *Dermophis mexicanus,* a caeciliid, was the only species that could burrow into tightly compacted soil, and only a few individuals succeeded in doing so. When placed on slightly or moderately compacted soil, *Ichthyophis* and one caeciliid (*Schistometopum*) used preexisting artificial tunnels in preference to constructing their own burrows. *Dermophis* did so as well, but was more likely to construct its own burrows. Limited observations in the field indicate that this genus is found in a wider range of soil types than other caecilians.

The skulls of caecilians are highly derived relative to ancestral amphibians, and very different in structure from those of anurans and urodeles. The head is flattened and wedge-shaped, with the mouth underneath a relatively pointed snout. In most species, the whole skull is heavily covered in dermal bone, and the snout region is strengthened (fig. 1.46). The completely roofed skull is similar to that of some elongate fossil tetrapods, especially the microsaurs, leading some authors to conclude that it represents an ancestral condition for caecilians and that this

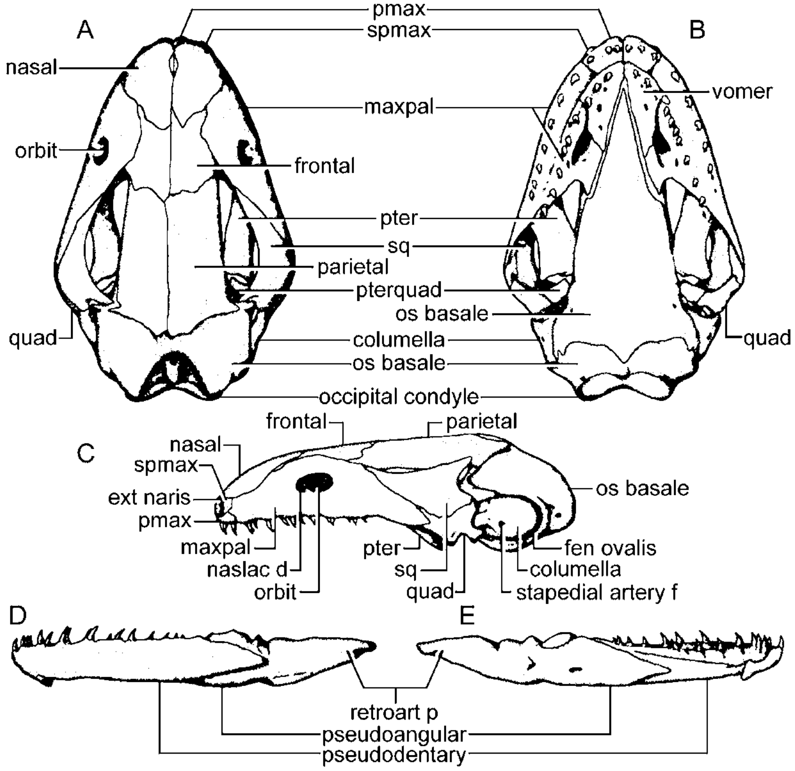

Fig. 1.46. Skull of a primitive caecilian, *Epicrionops petersi* (Rhinatrematidae). (A) Dorsal view. (B) Ventral view. (C) Lateral view. (D) Lateral view of mandible. (E) Medial view of mandible. Heavy dermal bone covers the entire skull and snout region. Note the very small size of the orbit. After Trueb (1993).

group is derived from a different clade than anurans and urodeles (Carroll and Currie 1975; see Trueb and Cloutier 1991b for a review of controversies over amphibian evolution). It is more likely a secondary derivation related to fossorial life (M. Wake and Hanken 1982; M. Wake 1986b; Trueb 1993). The skin of the snout and jaw are co-ossified (tightly bound) to the underlying bone, and the skin of the snout is thickly padded (M. Wake and Hanken 1982; Straub 1984; Duellman and Trueb 1986; Trueb 1993; M. Wake 1993b). The skulls of caeciliids appear to be more derived and more specialized for burrowing than those of rhinatrematids and ichthyophiids. The muscles of the head region are modified for burrowing, with powerful muscles that bend the head upward or downward.

Feeding

Caecilians feed on several types of subterranean prey, including termites, ants, beetles, earthworms, and even an occasional lizard or snake (M. Wake 1986b; O'Reilly 2000; Presswell et al. 2002; Gaborieau and Measey 2004; Measey et al. 2004; the diets of most species are unknown). Until recently, detailed observations of feeding behavior were available only for *Dermophis mexicanus* feeding on earthworms (Bemis, Schwenk, and Wake 1983). These animals seize the prey in their jaws, which are equipped with sharp, recurved teeth. When the mouth is closed, the row of teeth on the lower jaw fit into a space between rows of teeth on the upper jaw (fig. 1.47). This provides an interlocking mechanism that enhances the ability of the animal to hold onto prey. Caecilians lack the protrusible tongue found in most anurans and urodeles, so prey is captured with the jaws. Caecilians have evolved a jaw-closing mechanism that is unique among vertebrates. The skulls of most terrestrial caecilians are heavily roofed with bone, so there are no large openings for expansion of the jaw closing muscles (the temporal fossae) seen in many other tetrapods. Instead, the posterior interhyoideus muscle, which serves a completely different function in other amphibians, runs from the ventral and lateral body walls and inserts on the underside of a vertical process of the jaw (fig. 1.47 A). When this muscle contracts, in conjunction with jaw-closing muscles running from the jaws to the side of the head, the jaw rotates around the quadrate joint (fig. 1.47 C), resulting in rapid closure of the mouth (Bemis, Schwenk, and Wake 1983; Nussbaum 1983).

O'Reilly (2000) studied the kinematics of feeding in sev-

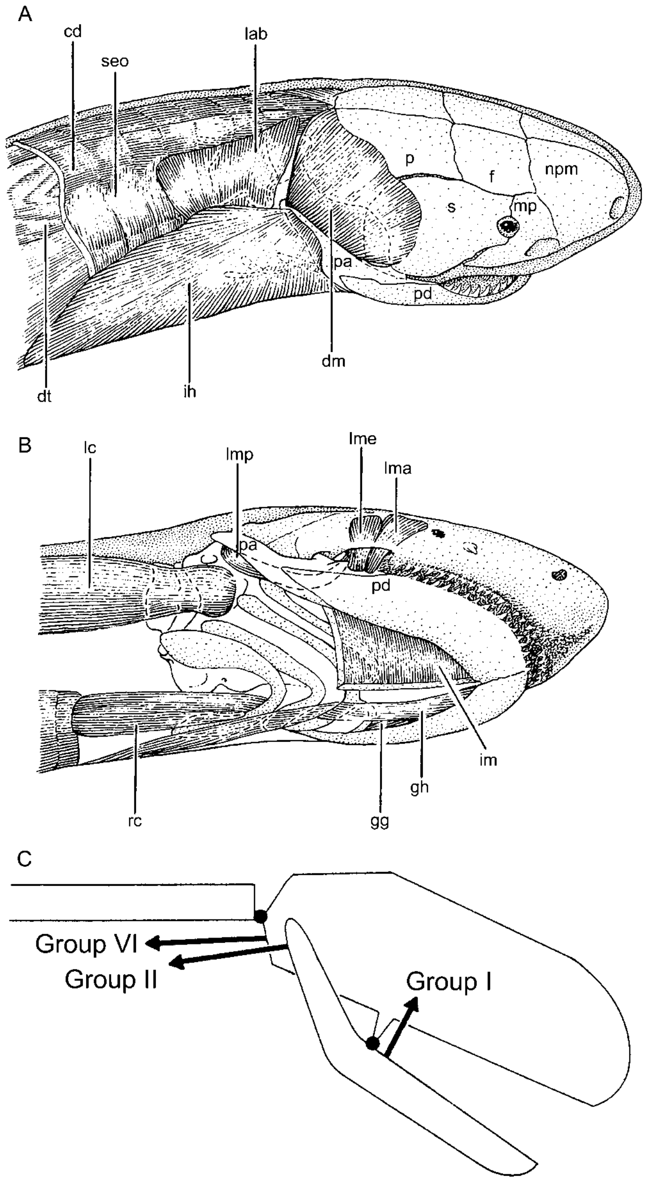

Fig. 1.47. Head and jaw muscles of the caecilian *Dermophis mexicanus*. (A) Dorsolateral view, showing superficial muscles. (B) Ventrolateral view with superficial muscles removed. (C) Schematic diagram illustrating mechanism of jaw closing. Group I muscles are the internal adductors (M. levator mandibulae anterior, M. levator mandibulae externus). Group II is the lateral adductor (M. interhyoideus). Group VI is the ventral trunk musculature (M. longus capitis et colli). Arrows indicate direction of movement when these muscles contract. Abbreviations for muscles: dm = depressor mandibulae, dt = dorsalis truncae, gg = genioglossus, gh = geniohyoideus, ih = interhyoideus, im = intermandibularis, lab = levator arcus branchiales, lc = longus capitus, lma = levator mandibulae anterior, lme = levator mandibulae externus, lmp = levator mandibulae posterior, rc = rectus cervicus, rl = rectus lateralis, seo = superficial external oblique. Abbreviations for skull bones: f = frontal, mp = maxillopalatine, npm = nasopremaxilla, p = parietal, s = squamosal. Abbreviations for jaw bones: pa = pseudoangular, pd = pseudodentary. After Bemis, Schwenk, and Wake (1983).

eral families of caecilians. He found that most features of caecilian feeding are relatively conservative in that they do not differ greatly among families. Prey capture in ichthyophiids, which are considered relatively primitive caecilians, is nearly indistinguishable from that of the more derived caeciliids. Typhlonectids differ from these families mainly in being able to close their jaws more rapidly. This may be related to the structure of the skull, which has a temporal opening to accommodate jaw-closing muscles, a feature not seen in most caecilians. This allows for a larger, more powerful muscle that can close the jaw more rapidly. All caecilians open their jaws more slowly than do frogs or salamanders, most of which protrude the tongue to capture prey. O'Reilly (2000) suggested that slow opening of the jaw is necessary in caecilians because they are blind. They must assess the size and activity of their prey with their jaws, whereas frogs and salamanders do so visually before initiating a prey strike. Although some adult caecilians, such as *Hypogeophis* and *Typhlonectes*, are capable of feeding in water, they all capture prey with the jaws rather than employing suction feeding, as seen in many other aquatic vertebrates (O'Reilly, Deban, and Nishikawa 2002).

Sensory Systems

The sense organs of caecilians have been highly modified for fossorial life. Adult caecilians have reduced eyes, a typical condition for fossorial animals, although many species probably retain some photoreceptive ability, even if they cannot form visual images. Early embryonic development of the eyes proceeds as in other amphibians, but development of various structures is retarded at different stages. Reduction of these parts does not proceed completely in parallel; that is, a species may have a greatly reduced lens or eye musculature, but retain a fully functional retina or optic nerve. However, general evolutionary trends in eye reduction include covering of the eye with skin or both skin and bone, reduction or loss of muscles that control eye movement, reduction in the number of retinal cells, reduction in the optic nerve, reduction or loss of the lens, reduction or loss of the vitreous body of the eyeball, and increased attachment of the lens to the cornea and retina. In general, the least reduced eyes are found in the most primitive families (Rhinatrematidae and Ichthyophiidae), which appear to be adapted to subsurface life under rocks, logs, or leaf litter. The most reduced eyes are found in the more derived families (Caeciliidae and Scolecomorphidae) that are more fully adapted to subterranean life. However, eyes also are somewhat reduced in aquatic typhlonectids, which are thought to have evolved from fossorial caeciliids (M. Wake 1985).

Caecilians have one sense organ that is unique among vertebrates, the tentacle (Fox 1985). This appears to be primarily a chemosensory organ that projects from the side of the head (fig. 1.44 C, D) and has a hollow chamber that connects with the Jacobson's organs, part of the vomeronasal system. The tentacle can be moved and extended or retracted with muscles that originally served to move the eye, but have been taken over for an entirely new function. These muscles are innervated by branches of the oculomotor nerve, which controls eye movements in other amphibians. It also is lubricated with secretions of the Harderian gland, which normally lubricates the eye (M. Wake 1985, 1986b; Billo and Wake 1987). The tentacle is closely associated with the vomeronasal system and may serve to conduct chemicals from the substrate to the vomeronasal organ (Schmidt and Wake 1990). Presumably the tentacle is used to detect prey, perhaps by trailing prey animals in burrows. It also may function in the location and recognition of mates. The only experimental study of tentacle function revealed that blocking the tentacles of *Ichthyophis kohtaoensis* did not impair the animal's ability to locate prey, whereas blocking the nares did interfere with prey location (Himstedt and Simon 1995).

Summary and Conclusions

The living amphibians are representatives of the first vertebrates to move onto land about 400 million years ago. As such, they must be considered a remarkably successful clade if one measures success in terms of phylogenetic persistence. Amphibians as a group not only survived and prospered through major geological upheavals and rearrangements of the continent landmasses and major changes in climate, but they also survived several major mass extinction events, including the one that wiped out the dinosaurs at the end of the Cretaceous. They also have managed to occupy most of the world's major terrestrial habitats, from the driest deserts to wet tropical rainforests.

Modern amphibians bear only a superficial resemblance to the first tetrapods that emerged onto land, and many morphological features of early tetrapods suggest that they had not yet acquired the distinctive physiological traits of modern amphibians. All living amphibians have a highly permeable integument that is susceptible to desiccation, intolerant of submersion in seawater, and an essential avenue of gas exchange. In contrast, many of the earliest tetrapods were covered with heavy dermal armor, and some evidentially lived in marine environments. By the Carboniferous, a diverse array of tetrapod clades had become the dominant land vertebrates, many of which reached quite large sizes. This contrasts with modern amphibians, most of which are among the smallest of all land vertebrates. Indeed, an evolutionary reduction in body size is a theme that has been repeated many times in the history of amphibians and may account for their success in modern ecosystems, where they often occupy niches not available to larger vertebrates, especially birds and mammals.

The origin of the living groups of amphibians, the frogs, salamanders, and caecilians, is obscure because of a limited fossil record. Nevertheless, by the Jurassic, these three lineages were well differentiated from one another and probably found throughout the world. Animals that we would recognize as modern frogs, salamanders, and caecilians were present by the early Cretaceous, living literally under the feet of the large dinosaurs that dominated terrestrial ecosystems at that time. Indeed, one can speculate that some frogs might have used the water-filled footprints of some of the largest dinosaurs as breeding pools, much as some tropical frogs use the tracks of tapirs and other animals as breeding sites today.

In addition to a general reduction in body size, living amphibians have several general characteristics that have profoundly affected their ecology and behavior. One is a tendency toward paedomorphosis and a simplification of many organ systems. Many living amphibians, for example, have highly simplified sense organs compared to other vertebrates, including fishes. In addition, amphibians have unusually large genomes and large cell size, which in turn affects physiological traits such as metabolism, growth rates, and rates of development. Relatively slow rates of development in turn affect the evolution of parental care, the biology of amphibian larvae, and the timing of metamorphosis.

With about 5,300 of the more than 6,000 species of living amphibians, anurans are by far the most diverse clade of modern amphibians, and this diversity undoubtedly results in part from their highly derived morphology. Frogs in general are morphologically specialized for jumping, which in turn has allowed these animals to radiate into a wide range of aquatic, terrestrial, fossorial, and arboreal habitats. One consequence of this tendency to occupy many different habitats is widespread convergent evolution in morphology. There are, for example, burrowing frogs with very similar morphology in at least a half dozen major anuran families, and there has been repeated evolution of morphologically similar arboreal, semiaquatic, and terrestrial species as well. This tendency toward morphological convergence has made it difficult to resolve the taxonomy and phylogenetic relationships of the major clades of frogs. Some of the largest families of anurans, such as the Ranidae and Leptodactylidae, probably are not monophyletic groups as currently constituted, and relationships among subclades within these families are unclear. The relationships within the large derived ranoid clade (the family Ranidae and its close relatives) are especially problematic, with major conflicts between morphological and molecular data that have resulted in large groups (subfamilies and genera) being placed in different families by different investigators. Recent debates over the relationships of the frogs of Madagascar and the phylogenetic position of the Neotropical dendrobatid frogs are just two examples of the difficulties encountered by systematists in resolving the higher-order relationships of frogs.

In contrast, the urodeles are far less diverse, with about 550 species, and exhibit a tendency toward morphological conservatism. Consequently, the family-level taxonomy of this group has remained relatively stable for many years, although there are continuing debates over the precise relationships among families. The relatively conservative nature of morphological evolution in salamanders has led to different sorts of problems, however. For example, there is a tendency in several groups for genetic differentiation among populations to be much greater than morphological differentiation, and this has resulted in the recognition of many cryptic species and a realization that species-level diversity of some families is greater than previously thought. This is evident to a limited extent in small families such as the Sirenidae, Rhyacotritonidae, and Dicamptodontidae, but is especially characteristic of the family Plethodontidae, which includes more than 70% of all salamander species. This tendency toward a high degree of local genetic differentiation is related to the low vagility of most salamander populations and the very limited geographic ranges of many species, especially those found in mountainous regions that are topographically complex.

With only about 170 described species, the caecilians are the least diverse of the living amphibians, and they also are the most specialized. All caecilians are limited to the wet tropics, and all are either specialized for burrowing or are derived from burrowing ancestors. Their highly derived morphology, which includes a loss of limbs, reduction or loss of the eyes, and major modifications of the skull, has made it difficult to determine the relationships of caecilians to other amphibians. It also has complicated attempts to determine phylogenetic relationships among major clades of caecilians, with morphological data often in conflict with molecular data. The highly derived morphology of caecilians undoubtedly affects nearly every aspect of their ecology and behavior, from modes of locomotion to feeding ecology, physiological ecology, and reproduction. Yet we currently know less about the ecology and behavior of these animals than that of any other amphibians, and indeed, most other vertebrates.

Chapter 2 Water Relations

The amphibians are a defeated group. They were the first vertebrates to emerge from the waters onto the lands, but they were not destined to complete the conquest, and, at first abundant, they have shrunken into insignificance among four-footed vertebrates. . . . The typical amphibian is still chained to the water. In the water it is born; to the water it must periodically return. We have noted various devices among living amphibians which have enabled them to circumvent this difficulty to some extent. But these makeshifts have not been particularly successful. The amphibian is . . . in many respects, little more than a peculiar type of fish which is capable of walking on land.
—Alfred Sherwood Romer, *The Vertebrate Story* (1959)

For centuries, people have associated amphibians with the margins of the land, viewing them as somewhat loathsome denizens of rivers, swamps, marshes, and ponds. The ancient Egyptians believed that frogs were born of river slime, generated from the coupling of land and water during the annual flooding of the Nile. Frogs were so closely associated with the life-giving properties of water that they became symbols of new life, fertility, and rebirth. The goddess Heqet, who served as a kind of divine midwife, was depicted with the head of a frog and the body of a woman (Keller 1913; Egger 1931; Budge 1969; M. Weber 1972). In other cultures, frogs have been widely associated with rain and fertility of the land. In various parts of India and Nepal, frogs have been hung from trees or presented with offerings of rice and milk to help bring on the rains (Briffault 1927). To the Maya of Central America, frogs were attendants of the thunder gods, and served as musicians who announced the coming of the rains (Wassen 1934; Hamblin 1984). Frogs were considered harbingers of rain by many other tribes in South and Central America, western North America, and the Caribbean. This belief was particularly common in regions subject to periodic drought, where frogs simply disappeared when water was scarce, only to reappear with the onset of rain (Wassen 1934).

Even today, frogs and other amphibians generally are associated in the popular imagination with water and aquatic habitats, although some amphibians are recognized as having made the first tentative steps toward colonization of land. Among biologists, amphibians have assumed the role of transitional animals in progressionist views of evolution that depict the history of vertebrates as a gradual movement from aquatic to terrestrial environments. For example, a review of amphibian endocrinology stated that “Amphibia can be conceived as spanning the phylogenetic step between purely aquatic vertebrates and their terrestrial successors. The contemporary groups contain those that are indeed purely aquatic (the urodeles) and those that are terrestrial as adults (the apodans) and those that essentially dwell in either water or on land (the anurans)” (Balment and Henderson 1987, 490). Actually, the salamanders, caecilians, and anurans all include fully aquatic, fully terrestrial, and semiaquatic species.

The notion that most amphibians remain tied to the water is all too common among biologists unfamiliar with the enormous diversity of amphibian life. Many amphibians are associated with standing water, but some of the most successful lineages are completely independent of standing water, although they do require moist microhabitats. Amphibians can be found in terrestrial habitats from tropical rainforests to some of the driest deserts on earth (Bentley 1966a; Mayhew 1968; Warburg 1972, 1997; Shoemaker 1975, 1988; Heatwole 1984). Although absent from Antarctica and high Arctic latitudes, they are found in nearly all other environments, from below sea level to altitudes above 4,500 m. In North America, one species of toad, *Bufo punctatus,* can be found from the hot floor of Death Valley to above 3,000 m in the Colorado Rockies. Amphibians cannot live in strictly marine environments, but they are found in nearly every other type of aquatic habitat, from brackish estuaries and salty pans to rivers, streams, ponds, lakes, marshes, swamps, and ditches. Some species can survive in acidic or alkaline waters. One of the most interesting aspects of amphibian biology is their ability to tolerate a wide range of environmental conditions, especially variation in the availability of water.

Biologists have known for at least two centuries that amphibians are unusual in several aspects of their water relations. In the late eighteenth century, Robert Townson conducted experiments at Göttingen University on the water relations of *Hyla arborea,* using pet tree frogs named Damon and Musidora (Townson 1794–1795, 1799). He found that his frogs lost water quickly when exposed to dry air, but they could take up water quickly as well, even when only the ventral surface of the skin was in contact with water (C. B. Jørgensen 1994a, 1997a). Subsequent work confirmed the importance of the skin in water exchange (Overton 1904; Maxwell 1913; Adolph 1925, 1932, 1933) and also showed that amphibians can tolerate unusually high levels of water loss compared to other vertebrates (Kunde 1857; Langlois and Pellegrin 1902; F. Hall 1922). C. B. Jørgensen (1997a) provided a detailed and fascinating review of the early history of research on amphibian water relations.

Modern work on water balance, osmoregulation, and nitrogen excretion in amphibians began with the classic work of August Krogh (1939) and continued in the tradition of comparative physiology that he established (Krebs 1975; Bennett 1987; C. B Jørgensen 1997a). This work emphasizes patterns of adaptation to features of the physical environment by comparing selected species with different lifestyles. Generally, certain species have been chosen to represent aquatic, terrestrial, or semiaquatic habits, with relatively little attention to phylogenetic relationships among these species. For example, *Xenopus* and *Siren* often are considered strictly aquatic, *Bufo* and *Salamandra* strictly terrestrial, and various species of *Rana* semiaquatic. Yet all of these animals can face periodic problems of desiccation on land or osmoregulatory stress in water. The "strictly aquatic" *Xenopus* and *Siren* often spend extended periods encased in drying mud, while all "terrestrial" toads (*Bufo*) must return to water to breed, and some spend much of their time in the water. Furthermore, these species differ not only in their habitat requirements, but also in evolutionary history, general morphology, and other aspects of their biology that could influence water relations. Consequently, data from such comparisons must be used cautiously in attempting to explain the evolution of physiological adaptations to the environment (Huey 1987; Bennett and Huey 1990; Harvey and Pagel 1991; Garland and Adolph 1994).

This chapter focuses on the types of problems encountered by amphibians in terrestrial and aquatic environments. I begin with a brief overview of the ecological implications of water availability for amphibians. I then review some aspects of the biology of amphibian skin, because the structure of the skin has important implications not only for problems of water balance, but also for nearly every other aspect of amphibian ecology and behavior. I then discuss adaptations to terrestrial life, since this presents the greatest challenge to the survival of most amphibians. The problems of amphibians living in water are then considered, along with some aspects of kidney function and nitrogen excretion. Although I will touch on cellular-level processes of osmoregulation, transport of water and materials across membranes, and hormonal control of water balance, the main emphasis is on the physiological ecology of whole organisms. For more detailed treatment of physiological mechanisms, readers should consult reviews by Boutilier, Stiffler, and Toews (1992), Shoemaker et al. (1992), and C. B. Jørgensen (1997a).

Ecological Implications of Water Availability

The availability of water affects nearly every aspect of the lives of amphibians. The availability of aquatic breeding sites undoubtedly is a major determinant of the geographic and local distribution of species that rely on standing water to breed (Rodríguez, Belmontes, and Hawkins 2005). The persistence of aquatic sites can have a major effect on reproductive success (e.g., Pechmann et al. 1989; Rowe and Dunson 1993, 1995; see also chapter 15). Complete reproductive failure is common among amphibians that breed in temporary ponds, especially in arid climates (e.g., Semlitsch et al. 1996; Read 1999). Even in equable climates, periodic drought often decreases the size of local amphibian populations (Dodd 1993, 1994, 1996; Jędrzejewska, Brzeziński, and W. Jędrzejewski 2003; Daszak et al. 2005). Prolonged droughts have been suggested as one of many possible causes for the decline or extinction of populations of aquatic-breeding amphibians in various parts of the world. Such declines can result from either failure of reproduction in several successive years, or drought-induced mortality of juveniles and adults (Corn and Fogleman 1984; W. Osborne

1989; Weygoldt 1989a; M. Crump, Hensley, and Clark 1992; Kagarise Sherman and Morton 1993; Pounds and Crump 1994; Grafe et al. 2004; see also chapter 16).

The availability of suitable moist microhabitats for the terrestrial life-history stages of amphibians is important as well. Some species have successfully colonized deserts and semiarid habitats, but terrestrial amphibians are most diverse and abundant in relatively moist environments, such as cool upland areas and wet tropical rainforests (Wake 1970; Kiester 1971; N. Scott 1976, 1982; D. Wake and Lynch 1976; Pefaur and Duellman 1980; Duellman and Trueb 1986). Comparisons of wetter and drier habitats on a more local scale almost invariably reveal greater diversity and abundance of terrestrial amphibians in the wetter sites (Lloyd, Inger, and King 1968; Barbault 1976a, b; D. Wake and Lynch 1976; Inger 1980; J. Lee 1980; Toft 1980b; Duellman 1988; see chapter 15). On an even smaller scale, soil moisture and the availability of moist retreat sites can be important determinants of the local distribution and abundance of species (Hairston 1949; Stebbins 1954b; Rosenthal 1957; Cunningham 1960; Taub 1961; Heatwole 1962b; Jaeger 1971b, 1980b; Spotila 1972; Pough et al. 1987; Wyman 1988; Petranka, Eldridge, and Haley 1993; Grover 1998, 2000; Vences, Galán et al. 2000).

Problems of evaporative water loss also affect seasonal and daily patterns of activity. Foraging often is limited by dry weather, and this can affect total food intake and allocation of energy to growth and reproduction (Stille 1952; Jaeger 1978, 1980a; Feder 1983b; Feder and Londos 1984; Keen 1984; Stewart 1985; Cree 1989; Duellman 1995). Variation in rainfall can affect the abundance and distribution of prey, which in turn can affect the growth and survival of amphibians (Toft 1980b; Toft, Rand, and Clark 1982; Galatti 1992; Stewart 1995). The availability of moist microhabitats also influences the size and location of individual activity ranges (Dole 1965a, b; Toft 1980a, b; Semlitsch 1981a; Carpenter and Gillingham 1987; Crump and Pounds 1989). When moist retreat sites are scarce, individual amphibians sometimes fight over choice sites (e.g., Wiewandt 1971; Wells 1980a; Keen 1982; Mathis 1989, 1990a).

Movements to and from breeding sites often are affected by rainfall (Blanchard 1930; Baldauf 1952; Packer 1960; Hurlbert 1969; Dole 1971; Fitzgerald and Bider 1974b; Gibbons and Bennett 1974; Semlitsch 1981a, 1983a, 1985a; Gittins 1983a; Griffiths 1984; Semlitsch and Pechmann 1985; Sinsch 1988c; Spieler and Linsenmair 1998; D. Marsh 2000). In both aquatic and terrestrial breeders, reproductive activities such as calling to attract mates, oviposition, and transport of tadpoles, also are affected by rainfall and water availability, especially in strongly seasonal environments (Wells 1980a; Pough et al. 1983; Aichinger 1987a, 1991; Donnelly 1989c; Praderio and Robinson 1990; Moreira and Lima 1991; Donnelly and Guyer 1994; Townsend and Stewart 1994; Moreira and Barreto 1997; Pröhl 1997a; Bertoluci 1998; Arzabe 1999; N. Mitchell 2001, 2002b; Bertoluci and Rodrigues 2002; Kupfer, Nabhitabhata, and Himstedt 2004, 2005; Prado, Uetanabaro, and Haddad 2005; Vaira 2005).

Structure and Function of Amphibian Skin

The skin of an amphibian is the interface between the animal and its surroundings. It not only provides mechanical protection, but it also serves as a major avenue for the exchange of gases, water, and other materials between the animal and the environment. The maintenance of a relatively stable internal environment (homeostasis) is critical for the proper functioning of various physiological systems and biochemical pathways. The skin is involved in many other facets of amphibian ecology and behavior as well (Heatwole and Barthalmus 1994). Glands in the skin are important for courtship, sex recognition, and other aspects of chemical communication, especially in urodeles (Houck and Sever 1994; chapter 9). Skin glands also produce toxic or distasteful substances that protect amphibians from their predators (Barthalmus 1994; Erspamer 1994; B. Clarke 1997; chapter 14). Changes in the color of the skin are important for communication (chapters 7, 8, 9), temperature regulation (chapter 3), and protection from predators (chapter 14). Structures derived from the epidermis, such as nuptial pads, spines, and claws, are used in courtship and mating (chapters 8, 9, and 10). Hence, an understanding of the basic structure and function of amphibian skin is necessary for understanding the ecology and behavior of these animals.

Epidermis

The skin of amphibians consists of two major layers, the outer epidermis and the inner dermis (fig. 2.1). The epidermis is derived embryologically from ectodermal cells. The dermis is derived mainly from mesodermal cells, which also give rise to most of the body's other tissues, including bone, muscle, and connective tissues. The pigment cells and glands in the dermis are of ectodermal origin and migrate downward into the dermis during development (Lindemann and Voulte 1976; Whitear 1977; Duellman and Trueb 1986; H. Fox 1986a, b, c, 1994).

The outermost layer of the amphibian epidermis, the *stratum corneum,* generally consists of a single layer of flattened cells. Underlying the *stratum corneum* is a layer of replacement cells known as the *stratum granulosum,* several additional cell layers known as the *stratum spinosum,* and finally the *stratum germinativum,* the site of production of replacement cells for the outer layers of the epidermis

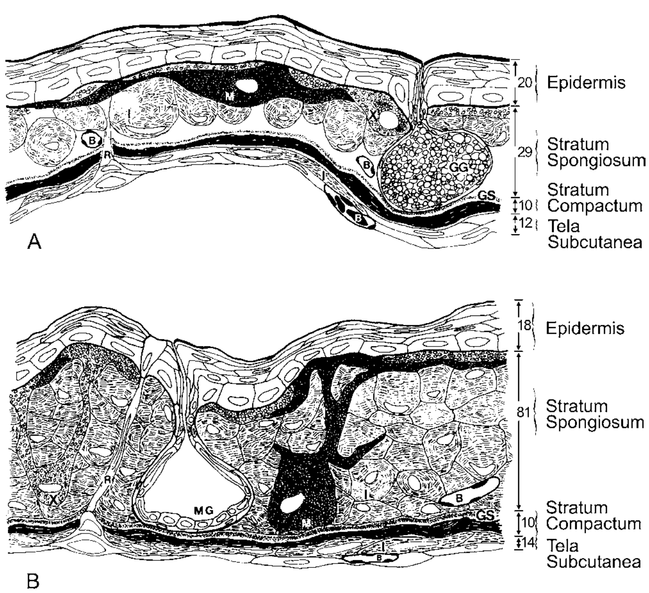

Fig. 2.1. Cross-sections of amphibian skin. (A) Dorsal skin of *Hyperolius viridiflavus* in the wet season. (B) Dorsal skin in the dry season, with the number of iridophores having increased by four to six times over the wet season condition. Numbers give thickness of each layer in µm. Abbreviations: B = blood capillary; GS = ground substance layer; GG = granular gland; I = iridophore; M = melanophore; MG = mucus gland; R = radial fiber; X = xanthophore. After Kobelt and Linsenmair (1986).

(H. Fox 1986c, 1994). In most adult amphibians, the epithelial cells forming the *stratum corneum* contain the protein keratin. The degree of keratinization is much less than in other terrestrial vertebrates, and living amphibian species never have keratinized scales on the skin (Lillywhite 2006). Larval amphibians generally do not have keratinized epidermal cells on most of the body. Keratinized cells also are absent from the skin of paedomorphic forms, such as the axolotl (*Ambystoma mexicanum*) and mudpuppies (*Necturus*), which retain some features of larval morphology as reproductive adults (Elias and Shapiro 1957; Spearman 1968; Ling 1972; Duellman and Trueb 1986; Fox 1986c; Warburg, Lewinson, and Rosenberg 1994). In many anuran larvae, cells around the mouth become highly keratinized to form a beak or jaw sheath, as well as rows of denticles or labial teeth. These are used by tadpoles for feeding (chapter 12), but are lost at metamorphosis (Luckenbill 1965; Kaung 1975; Marinelli and Vagnetti 1988; Fiorito de Lopez and Echeverria 1989). Larval amphibians also have a variety of other specialized epidermal cells involved in hatching, adhesion to the substrate, and sensory perception. Adult amphibians retain some of these specialized cells and also have various morphological specializations of the epidermis, such as adhesive toe pads and nuptial pads (see chapters 1 and 9). These specializations are not related to problems of water balance and need not be discussed in detail here (see Fox 1986c, 1994 for reviews).

All amphibians periodically shed the outer layer of the epidermis (*stratum corneum*) and replace it with a new layer of cells. Molting can occur at intervals of less than a week, but the exact timing varies among species. The process begins with increased keratinization of the *stratum corneum* and separation of these cells from the underlying cell layers. Once cornification of the new *stratum corneum* is complete, the old layer of cells is shed intact and usually is swallowed by the animal as molting progresses (Adolph and Collins 1925; Bensden 1956; Taylor and Ewer 1956; Heusser 1958b; C. B. Jørgensen and Larsen 1960, 1961; Ling 1972; H. Fox 1986c). The function of this periodic molting is not entirely clear, but presumably it relates to a need for renewal of the outer layer of skin cells, which are not well protected against injury or mechanical abrasion. Molting cycles do not appear to be directly correlated with periods of increased feeding or growth, but are affected by temperature, metabolic rate, and photoperiod, and are under hormonal control (Ling 1972; H. Fox 1986c). The ability of amphibians to detach the outer layer of cells as one piece has important implications for water balance in burrowing species that form cocoons. These cocoons often are composed of multiple layers of keratinized epidermal cells that have been detached from the underlying layers of skin, but not shed from the body (see the following discussion).

Dermis

The dermis is considerably thicker than the epidermis and consists of two major layers (fig. 2.1). The *stratum spongiosum* is composed of a network of collagen and elastic fibers, along with a variety of specialized cells, chromatophores, glands, blood vessels, and nerves. Below this is the *stratum compactum,* consisting mainly of compact layers of collagen fibers (H. Fox 1986b, 1994). In some anurans, there is a ground-substance layer between these two, consisting of a thin layer of polysaccharide and calcium granules. Elkan (1976a) noted that this layer is found almost exclusively in terrestrial species and proposed that it acts like a sponge to conserve water. Drewes et al. (1977) disputed this, pointing out that the position of the ground substance layer below the heavily vascularized *stratum spongiosum* puts it in a poor position to retard water loss through the skin. The presence of a ground substance layer in the dorsal skin of *Hyperolius viridiflavus,* and its absence in the highly permeable ventral skin, supports the idea that it plays a role in reducing water loss (Kobelt and Linsenmair 1986), but its precise function is still unclear.

The dermis of caecilians contains unique structures not found in the other groups of amphibians. These are dermal scales, flat discs composed mainly of layers of collagen fibers and minerals that are imbedded in special pockets, with the base of each scale attached to connective tissue (Zylberberg, Castanet, and de Ricqles 1980; H. Fox 1983, 1986c, 1994; Zylberberg and Wake 1990). Neither the evolutionary homology of these scales nor their function is well understood. One possible function is that they provide some structural support that aids in locomotion (Duellman and Trueb 1986). They appear to have no effect on water loss through the skin, which is very high in the few species that have been studied.

Bony osteoderms are present in a number of anuran species from several different families. In some cases, most of the animal's back is covered with this bony armor, which lies beneath the epidermis (Ruibal and Shoemaker 1984). Most of the anurans that have such osteoderms are arboreal, terrestrial, or fossorial, but they occur in a wide variety of habitats, and there is no clear ecological correlation with the presence of osteoderms. Whether osteoderms reduce evaporative water loss is not known, but in most species, the skin between the osteoderm layer and the outer surface of the epidermis is heavily vascularized, suggesting that the osteoderms would provide a poor barrier to water loss. At least one species, *Phyllomedusa bicolor,* applies lipid secretions to its skin to reduce water loss (see the following), so it seems unlikely that the osteoderms serve as a water barrier.

Dermal Glands

The skin of amphibians is highly glandular compared to that of other vertebrates (Whitear 1977; H. Fox 1986a; B. Clarke 1997). All amphibians have two major types of glands in the dermis: granular glands and mucous glands. The granular glands secrete various proteinaceous substances that serve primarily as defensive chemicals (see chapter 14). They do not play any role in water exchange or moistening of the skin. Mucous glands tend to be much more numerous than granular glands and usually are distributed over the entire surface of the skin, although their precise distribution differs among species (Le Quang Trong 1971, 1975a, b). These glands secrete watery, transparent mucus that keeps the outer surface of the skin moist. This ensures that evaporation of water takes place from the mucus layer rather than the skin itself, protecting the skin from the damaging effects of desiccation (Lillywhite and Licht 1975; Lillywhite and Maderson 1988).

The rate of mucus discharge varies considerably among species of amphibians and is related to their ecology. In anurans that bask in the sun, increased body temperature triggers synchronized release of mucus over the skin surface, thereby cooling the body through evaporation (see also chapter 3). These synchronized discharges are not seen in nocturnal, fossorial, or largely aquatic species, although some of these exhibit a gradual release of mucus over the skin surface in response to desiccation or increased temperature (Lillywhite 1971b, 1975; Lillywhite and Licht 1975). Toads (*Bufo*) generally do not secrete large quantities of mucus except when shedding their skins, giving them their characteristic dry texture, in contrast to the slimy texture of many other anurans. They keep the skin moist via direct movement of water across the skin surface, movement that is facilitated by extensive epidermal sculpturing (Lillywhite and Licht 1974, 1975; see "Water Uptake").

In addition to the two types of glands found in all amphibians, Blaylock, Ruibal, and Platt-Aloia (1976) described a new type of gland in four species of hylid frogs in the genus *Phyllomedusa* from southern South America. These are lipid glands that secrete a waxy coating that the frogs smear over the surface of the skin. This coating provides a remarkably effective barrier against evaporative water loss (see the following discussion). The species in which lipid glands have been described, *P. sauvagii, P. iherengii, P. hypochondrialis,* and *P. boliviana* (= *P. pailona*), live in semiarid regions. Many other species in this genus, including *P. trinitatis, P. lemur,* and *P. tarsius,* live in tropical rainforests, and there is no report of lipid secretion in any of these. Blaylock, Ruibal, and Platt-Aloia (1976) also examined two other species in the same subfamily, *Agalychnis annae* and *Pachymedusa dacnicolor,* and found no evidence of lipid glands. The lipid-producing glands of *Phyllomedusa* appear to be structurally related to the serous (granular) glands that secrete defensive compounds, not to the mucous glands found in all anurans (Delfino et al. 1998; Barbeau and Lillywhite 2005; Lillywhite 2006).

At least one species of rhacophorid tree frog, *Polypedates maculatus,* also produces lipid secretions that are smeared on the skin in a manner nearly identical to that of *Phyllomedusa* (Lillywhite et al. 1997a, b). This behavior undoubtedly evolved independently, because these frogs are not closely related. In contrast to the phyllomedusine frogs, *Polypedates* does not have distinct lipid glands, but secretes a mixture of mucus and lipids from glands that resemble typical mucous glands of other anurans. An Australian tree frog (*Litoria caerulea*) also wipes glandular secretions on its skin, but the structure of the glands that produce these secretions has not been described (Christian and Parry 1997). The glandular secretions of these frogs are composed mostly of protein, but contain lipids as well.

Regional Differences in Skin Structure and Osmotic Permeability

The skin of amphibians is not uniform throughout the body in either morphology or physiology. Skin in different regions of the body varies in thickness of the various cell layers, vascularization, permeability to water and ions, and in its response to hormones (for a review, see Toledo and Jared

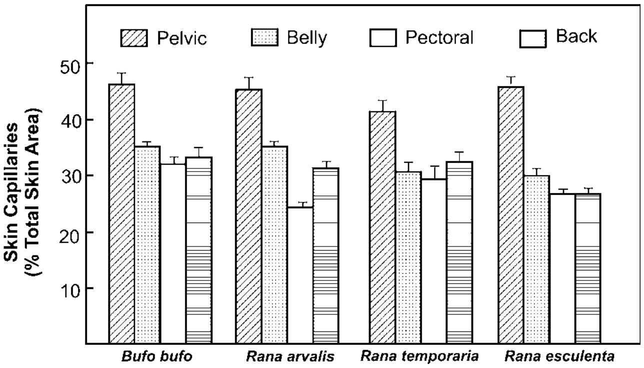

Fig. 2.2. Capillary densities of skin from different regions in four species of European anurans, shown as a percentage of total skin area + 1 SE. Pelvic skin has more capillaries than does skin from other regions in all of these species. Plotted from data in Christensen (1974).

1993). It has been known for many years that anurans can take up water from a moist surface through the ventral skin alone, and that the ventral skin is more heavily vascularized than dorsal skin (Overton 1904; Adolph 1933; J. Czopek 1965). In a quantitative study of four species of European anurans, C. Christensen (1974) found that skin from the pelvic region (the pelvic patch) consistently had higher capillary densities than skin from the belly, pectoral region, or back (fig. 2.2). J. Roth (1973) reported that various species of toads (*Bufo*) and spadefoot toads (*Scaphiopus* and *Spea*) have an extensive network of cutaneous veins draining the pelvic region and joining to form large common pelvic veins. This network is largely absent in *Rana catesbeiana* and in *Xenopus laevis,* and the latter also lacks the high density of pelvic skin capillaries found in other anurans (Christensen 1974). The pelvic patches of some toads also have an elaborate complex of cutaneous muscles that press the pelvic patch close to the ground during water absorption behavior (Winokur and Hillyard 1992; Hillyard, von Seckendorff Hoff, and Propper 1998).

Many anurans that take up water from moist substrates rather than bodies of water also have specialized roughened skin either on the entire ventral surface, or concentrated in the pelvic region (fig. 2.3). The rough, granular appearance of the skin derives from flattened polygon-shaped papillae or bumps (termed *verrucae hydrophilica* by Drewes et al. 1977) that are separated by narrow grooves or channels. These *verrucae* are highly vascularized, and along with the network of channels that surrounds them, undoubtedly facilitate rapid uptake of water. This epidermal sculpturing also serves to increase the surface area of the skin available for uptake of water. This structural specialization is common in arboreal frogs such as *Hyla, Phyllomedusa, Litoria, Chiromantis,* and *Hyperolius,* as well as many terrestrial toads (*Bufo*), but it is absent from more aquatic species such as *Rana* and *Xenopus* (Noble 1925; Elias and Shapiro 1957; Drewes et al. 1977; Duellman and Trueb 1986; Kobelt and Linsenmair 1986). Other epidermal adaptations to facilitate water uptake are described in a later section.

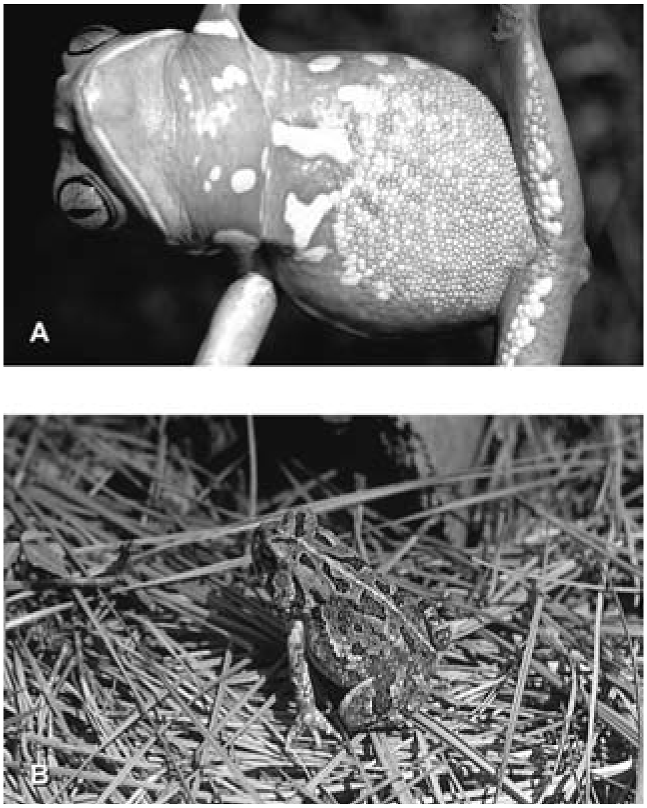

Fig. 2.3. (A) Ventral surface of the South American treefrog *Phyllomedusa sauvagii,* showing texture of the highly permeable area on the posterior part of the ventral skin. (B) A terrestrial toad, *Bufo fowleri,* showing extensive epidermal sculpturing that conducts water onto the dorsal surface of the skin. Photos by Rudolfo Ruibal (A) and Kentwood D. Wells (B).

In addition to these structural differences, skin from different parts of the body varies in its osmotic permeability, at least in anurans. Comparisons of isolated samples of skin from ranids, bufonids, hylids, myobatrachids, and leiopelmatids have shown that osmotic flux through the ventral skin generally is somewhat higher than through dorsal skin. Ventral skin from the specialized pelvic region generally exhibits greater osmotic flux than skin from the belly or pectoral area (McClanahan and Baldwin 1969; Bentley and Main 1972b; R. Baldwin 1974; Christensen 1974; Yorio and Bentley 1977; Cree 1988a). Pelvic skin also tends to be much more responsive than skin from other regions to arginine vasotocin (AVT), a hormone that increases skin permeability (fig. 2.4; Bentley and Main 1972a; R. Baldwin 1974; Yorio and Bentley 1977; Cree 1988a, b; see further discussion under "Water Uptake"). In at least one species of treefrog, *Hyla japonica,* males exhibit a greater water absorption response through the ventral skin than do females, suggesting a role for sex hormones in regulation of water

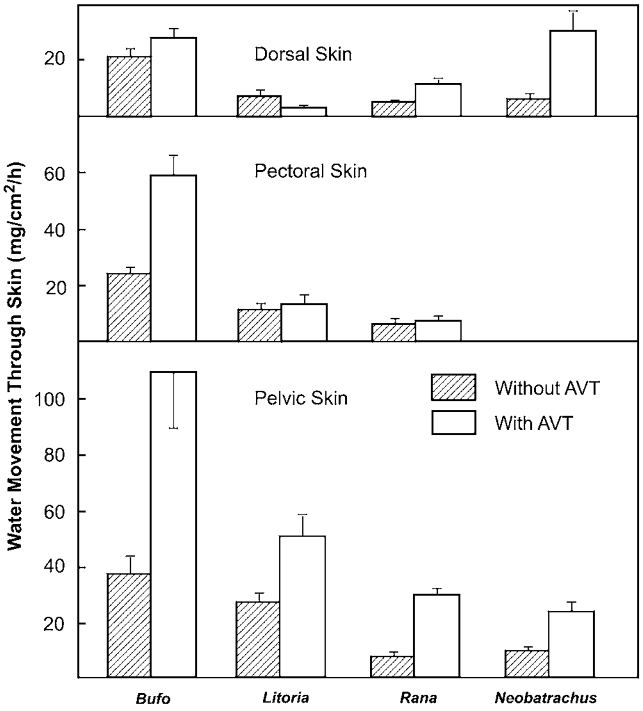

Fig. 2.4. Osmotic permeability of skin in different regions and the effects of arginine vasotocin (AVT) on skin permeability in four genera of anurans, including a terrestrial toad (*Bufo*), arboreal frog (*Litoria*), semiaquatic frog (*Rana*), and a fossorial frog (*Neobatrachus*). Pelvic skin exhibits a greater increase in skin permeability to water in response to AVT than does skin from other regions. Plotted from data in Yorio and Bentley (1977).

balance (Kohno et al. 2004). The fossorial Australian frog *Neobatrachus pelobatoides* exhibits a moderate hormonal response in both dorsal and pelvic skin (fig. 2.4). Presumably this is correlated with their habit of taking up water inside a burrow while surrounded by moist soil (Bentley and Main 1972b).

Determinants of Evaporative Water Loss

The major challenge faced by amphibians in terrestrial environments is evaporative water loss through the skin. Some amphibians have evolved morphological, physiological, or behavioral adaptations that reduce rates of water loss, but many species are limited to moist microhabitats because they have little or no ability to regulate water loss. The variables that affect rates of water exchange between amphibians and the environment have been reviewed by a number of authors (Spotila 1972; Tracy 1975, 1976; Spotila and Berman 1976; Shoemaker et al. 1992; Spotila, O'Connor, and Bakken 1992). An extensive discussion of the biophysics of the process is beyond the scope of this book, and readers should consult these references for further details. In simple terms, the rate of evaporative water loss by an amphibian is a function of the vapor density gradient between the animal and its environment, the resistance of the animal to water loss, and the surface area of the skin exposed to the air. The vapor density gradient is largely a property of the physical environment and cannot be modified by the animal unless it moves to a new microhabitat. It is the difference between the water vapor density at the animal's surface and the water vapor density of the surrounding air. Both temperature and relative humidity of the air affect the vapor density gradient. The gradient will increase as the body temperature of an amphibian increases or as the humidity of the surrounding air decreases. Thus, an amphibian exposed to direct sunlight in relatively dry air will lose water at a much faster rate than the same animal exposed to very humid air at night (Tracy 1976). Nevertheless, even when the air surrounding an amphibian is nearly saturated, as often occurs in a tropical rainforest at night, the animal will continue to lose water at low rates unless its body temperature is lower than that of the air. This is because low levels of metabolic heat production by the animal will be sufficient to raise the temperature of the skin and maintain the vapor density gradient with the environment (Spotila, O'Connor, and Bakken 1992).

The tendency for water to move through a material such as amphibian skin can be expressed in terms of a mass transfer coefficient (measured in centimeters of water movement per second). The reciprocal of this coefficient is termed the resistance to water movement (Shoemaker et al. 1992; Spotila, O'Connor, and Bakken 1992). This represents the combined effects of the inherent resistance of the skin to water movement and the resistance of the boundary layer around the animal. Skin resistance is a function of the skin's morphology and of substances secreted onto its outer surface. Therefore, it can be modified through evolutionary time by changes in the structure of the skin that either increase or decrease resistance to water movement. It also is possible for skin resistance to be modified through physiological responses to water loss (Blaylock, Ruibal, and Platt-Aloia 1976; Kobelt and Linsenmair 1986; Wygoda 1988). Morphological and physiological adaptations that increase skin resistance to water loss are discussed in more detail in a later section.

Boundary layer resistance is more complex. When an amphibian is relatively immobile, water evaporated from the skin's surface forms a thin layer around the animal that reduces the gradient between the animal and the surrounding environment, thereby reducing evaporative water loss. Movement by an animal tends to break up the boundary layer, as does air moving across the animal's surface. Hence, as an animal becomes more active or air speed increases, the resistance afforded by the boundary layer decreases and evaporative water loss increases. For animals with highly permeable skin, boundary layer resistance is a quantitatively more important determinant of water loss than skin resistance (Wygoda 1984; Shoemaker et al. 1992). This means that most amphibians will inevitably have relatively high rates of evaporative water loss when they carry out their normal activities. Boundary layer resistance increases with increasing body mass, so larger amphibians will have greater resistance to water loss than smaller species, even if all other conditions are equal (Shoemaker et al. 1992). In addition, boundary layer resistance can be modified behaviorally by avoidance of windy microhabitats and by changes in the activity of the animal (Heatwole et al. 1969; Pough et al. 1983).

The surface area of skin exposed to the air has a major effect on rates of water loss. Again, large animals are at an advantage over small animals because surface-to-volume ratios decrease as body size increases. This means that for small animals, the area through which water can be lost is increased relative to the volume of water that can be stored inside the body. This makes newly metamorphosed juveniles especially vulnerable to desiccation. Newman and Dunham (1994) found that larger metamorphs of spadefoot toads (*Scaphiopus couchii*) lost water at slower rates than small metamorphs. Because suitable moist microhabitats were patchily distributed, larger metamorphs could survive longer while moving from one moist soil patch to another.

Relative surface area also varies with the shape of an animal. Elongate forms such as plethodontid salamanders have very high surface areas for their body mass and hence are subject to severe water stress (Spotila 1972; Feder 1983b). In contrast, many anurans that inhabit arid regions tend to be globular in shape, with round bodies and relatively short legs. This shape minimizes the surface-to-volume ratio of these animals and therefore reduces rates of water loss. Amphibians also can modify the amount of skin surface exposed to the air by postural changes or by aggregating with other individuals (see "Behavioral Modification of Water Balance").

Ecological Correlates of Evaporative Water Loss

There have been many studies of evaporative water loss in amphibians, dealing either with single species or with comparisons among species from different habitats. Unfortunately, differences in experimental techniques make quantitative comparisons among studies difficult. Variation in air flow rates in experimental chambers and activity of experimental subjects have a major effect on boundary layer resistance and can lead to differences in rates of water loss that mask any correlation with habitat. Some workers have not corrected data for differences in body mass or accounted for changes in humidity inside experimental chambers (for discussions of methods, see Wygoda 1984; Shoemaker et al. 1992). Estimates of absolute rates of evaporative water loss can be reliably compared only if measurements have been made using exactly the same techniques. Nevertheless, several general patterns now seem clear.

Ground-Dwelling Amphibians

Amphibians that spend most of their time on the ground generally lack morphological or physiological adaptations for retarding evaporative water loss and do not differ greatly from species that spend most of their time in or near water. For example, plethodontid salamanders have very high rates of evaporative water loss. Differences among species are due almost entirely to differences in body mass and body shape, with larger, more rotund species losing water more slowly than smaller or more elongate species (N. Cohen 1952; Spight 1968; M. Houck and Bellis 1972; Spotila 1972; Feder 1983b). Spotila and Berman (1976) constructed agar models of salamanders for comparison with living salamanders of the same size and shape. They found little difference in water loss from living animals and the models, which essentially were free water surfaces. This indicates that skin resistance to water loss in these animals is negligible. In fact, skin resistance in plethodontids is several hundred times less than that of turtles, lizards, or crocodilians (table 2.1). The only way these salamanders can avoid desiccation is by selecting appropriate microhabitats or by adopting postures that alter surface-to-volume relationships (see "Behavioral Modification").

Having a highly permeable skin allows plethodontids to use the skin as the primary site of respiratory gas exchange (see chapter 4). It also is advantageous in allowing for rapid rehydration following periods of desiccation (see "Water Uptake"). The lack of resistance to water loss is not unique to lungless species. Salamanders such as *Triturus, Salamandra,* and *Ambystoma* all have high rates of water loss, and are no better adapted to desiccating conditions than are plethodontids (Cohen 1952; Spight 1968; Warburg 1971b; Marangio and Anderson 1977; Warburg and Degani 1979; J. Gillis and Breuer 1984).

The same general pattern is found in terrestrial anurans. Wygoda (1984) measured rates of evaporative water loss for a given surface area of skin in two toads (*Bufo terrestris* and *B. marinus*), three ranid frogs (*Rana catesbeiana, R. pipiens,* and *R. utricularia*), a semiaquatic cricket frog (*Acris gryllus*), and a fossorial spadefoot toad (*Scaphiopus holbrookii*). He found that rates of water loss were statistically indistinguishable among these species, and none had rates significantly different from that of the aquatic frog *Xenopus laevis* under the same conditions. Another fosso-

Table 2.1 Cutaneous resistance to water loss in ectothermic vertebrates

Species (source no.)	Resistance (s/cm)
Lizards, turtles, crocodilians	
Xantusiid lizards (9)	190–3,080
Mabuya, 3 species (10)	1,442
Sauromalus ater (1)	1,400

rial species, *Gastrophryne carolinensis,* and a tropical rainforest toad, *Atelopus varius,* had slightly higher rates of water loss (table 2.2). Wygoda's work is the best comparative study to date because he immobilized the animals temporarily with the drug curare to control for the effects of activity, but other studies have produced similar results. For example, Thorson (1955) measured evaporative water loss in *Rana catesbeiana, R. clamitans, Bufo boreas,* and *Spea hammondii* under equivalent conditions and did not find any major differences that could be correlated with habitat. The same was true for comparisons between two European anurans, *Bufo viridis* and *Rana ridibunda* (Katz and Graham 1980) and two North American species, *Bufo cognatus* and *Rana pipiens* (Withers, Hillman, and Drewes 1984).

Arboreal Frogs

Although most ground-dwelling amphibians lose water as rapidly as aquatic or semiaquatic species, the same cannot be said for arboreal frogs. Many of these have unusually low rates of evaporative water loss that can be attributed to unusually high skin resistance. Some species are only moderately waterproof, while others are as resistant to evaporative water loss as some squamates, turtles, and crocodilians. Wygoda (1984) compared several North American and Caribbean tree frogs (*Hyla* and *Osteopilus*) with aquatic, semiaquatic, terrestrial, and fossorial anurans from six families. All subjects were immobilized with the drug curare to control for activity. Wygoda found that the arboreal species consistently had rates of evaporative water loss that were 1/3 to 1/2 those of the other species (table 2.2). This was reflected in a much greater skin resistance in the arboreal frogs, while boundary layer resistance was very similar among species (fig. 2.5). Withers, Hillman, and Drewes (1984) reported resistances of the same general magnitude for several New World hylids, including *Hyla gratiosa, H. arenicolor, Osteopilus septentrionalis,* and *Agalychnis callidryas,* while Bentley and Yorio (1979) reported that the hylid *Pachy-*

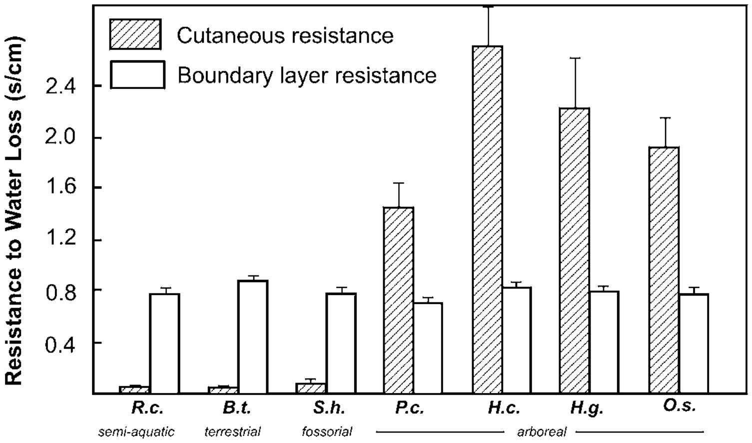

Fig. 2.5. Cutaneous and boundary layer resistance to water loss in selected North American anurans. Skin resistance is measured as the reciprocal of the rate of water movement (cm/s) through the skin. Bars show means + 1 SE. Arboreal species have much higher cutaneous resistance than do other anurans, but boundary layer resistance does not differ among species. *R.c. = Rana catesbeiana. B.t. = Bufo terrestris. S.h. = Scaphiopus holbrookii; P.c. = Pseudacris crucifer. H.c. = Hyla cinerea. H.g. = Hyla gratiosa. O.s. = Osteopilus septentrionalis.* Plotted from data in Wygoda (1984).

medusa dacnicolor had much lower rates of water loss than *Bufo* or *Rana*. Unusually high skin resistance is not characteristic of the whole family Hylidae, because the nonarboreal hylid *Acris gryllus* has a surface-area-specific rate of water loss that is about the same as that of other terrestrial or semiaquatic anurans (Wygoda 1984). In one hylid, *Hyla cinerea,* increased cutaneous resistance to water loss appears at the stage at which metamorphosing juveniles are just emerging from the water, so even the smallest juveniles are somewhat protected from evaporative water loss (Wygoda and Garman 1993).

Arboreal frogs from other regions also have high resistance to evaporative water loss, and some of these are not closely related to hylids. African leaf-folding frogs (family Hyperoliidae), including *Afrixalus fornasinii, A. pygmaeus,* and *A. quadrivittatus,* have resistances similar to those of North American hylids (Withers, Hillman, and Drewes 1984). These are small frogs that frequent swamps and grassy shores of pools and ditches. Although they live near water, they often sit in exposed positions on dry vegetation during the day (Stewart 1967). These frogs are not well adapted to extremely dry conditions and generally seek shelter during the dry season in moist locations such as the leaf axils of banana plants (Loveridge 1976).

Reed frogs in the genus *Hyperolius* are found throughout much of sub-Saharan Africa. They often spend the day exposed to the sun on the leaves of plants, and must cope with prolonged dry seasons as well. Some species, such as *H. argus, H. pusillus,* and *H. tuberlinguis,* are moderately waterproof, with resistances about 5–10 times those of *Afrixalus* or North American hylids (Loveridge 1976; Withers, Hillman, and Drewes 1984; Geise and Linsenmair 1988). These species spend the dry season sheltered in moist microhabitats such as leaf axils and piles of vegetation (Loveridge 1976). Others, including *Hyperolius nasutus, H. marmoratus,* and members of the *H. viridiflavus* complex, are 20 to 250 times more resistant to water loss than North American hylids. These species are some of the most waterproof of all anurans (Loveridge 1976; Withers et al. 1982; Withers, Louw, and Nicholson 1982; Withers, Hillman, and Drewes 1984; Geise and Linsenmair 1986, 1988; Kobelt and Linsenmair 1986; Schmuck and Linsenmair 1988; Schmuck, Kobelt, and Linsenmair 1988). These frogs undergo seasonal changes in skin structure and metabolic physiology (see the following discussion) that enable them to remain in exposed locations during the prolonged dry seasons of the African savannas. Breeding adults appear to be less capable of making these adjustments than juvenile frogs, and few survive for more than one breeding season (Geise and Linsenmair 1986, 1988; Kobelt and Linsenmair 1986).

Rhacophorid tree frogs of the genus *Chiromantis* also are remarkable in their ability to remain in exposed locations during the dry season. The three species in this genus, *C. petersii, C. rufescens,* and *C. xerampelina,* are all relatively large tree frogs found in southern and eastern Africa in moderately to extremely dry climates. They have explosive breeding seasons commencing with the onset of heavy rains (Coe 1974). For much of the rest of the year, their environment is hot and dry and seemingly inhospitable to amphibians, yet these frogs can be found in exposed locations during most months of the year (Loveridge 1970; Drewes et al. 1977). All three species have been shown to have extremely low rates of evaporative water loss, with cutaneous resistance more than 200 times that of North American tree frogs and exceeding that of *Anolis* lizards (Loveridge 1970; Drewes et al. 1977; Withers, Hillman, and Drewes 1984). Water conservation is further enhanced by excretion of nitrogenous wastes in the form of uric acid (see "Nitrogen Excretion").

The most unusual of all waterproof arboreal frogs are several species of South American hylids in the genus *Phyllomedusa,* which also are uricotelic. As mentioned previously, several species, including *P. sauvagii, P. iherengii, P. hypochondrialis, P. boliviana,* and *P. bicolor* have glands in the skin that secrete a waxy lipid coating (Blaylock, Ruibal, and Platt-Aloia 1976; Ruibal and Shoemaker 1984). Another species, *P. azurae,* also produces a lipid secretion, but the skin glands have not been investigated (Withers, Hillman, and Drewes 1984). These frogs have an elaborate wiping behavior in which both the front and back legs are used to smear a coating of lipid evenly over the surface of the skin (fig. 2.6). This behavior has been reported not only in adults, but also in newly metamorphosed juveniles of one species, *P. hypochondrialis* (Alamillo and Pramuk 2002). The frogs then sit quietly on an exposed branch or leaf, with the legs folded against the body. In this condition they exhibit rates of evaporative water loss and skin resistance equivalent to those of *Chiromantis* (Shoemaker et al. 1972; Shoemaker and McClanahan 1975; Blaylock, Ruibal, and Platt-Aloia 1976; McClanahan, Stinner, and Shoemaker 1978). Nearly identical wiping behavior has been reported in a rhacophorid tree frog, *Polypedates maculatus* (Lillywhite et al. 1997a, b). Glandular secretions of this frog are composed primarily of mucus, with some lipids as well. This suggests that wiping behavior evolved as a means of spreading mucus on the skin surface, with the evolution of lipid secretions being a later development.

At least one Australian hylid, *Litoria caerulea,* produces lipid secretions and engages in wiping behavior similar to

Fig. 2.6. *Phyllomedusa sauvagii* wiping lipid secretions on skin. Photos by Rudolfo Ruibal.

that of *Phyllomedusa* and *Polypedates* (Christian and Parry 1997). This species is widely distributed from relatively mesic to semiarid habitats and sometimes is subjected to hot, dry conditions. Early work by Warburg (1967) had shown that this species has an unusually low rate of evaporative water loss, but the mechanism for retarding water loss was not known (see also Christian and Green 1994). Buttemer (1990) found that skin resistance in this species is two to three times greater than in North American hylids, but not nearly as high as in the lipid-secreting *Phyllomedusa* species. Subsequent work showed that secretions exuded from glands in the skin and wiped over the body are responsible for increased resistance (Christian and Parry 1997). These secretions contain relatively low concentrations of lipids (5%) and a high concentration of protein (85%). Christian and Parry (1997) suggested that the proteins play a significant role in retarding water loss, in addition to the lipids, but this has yet to be demonstrated experimentally. Several hylid treefrogs from Florida that experience prolonged dry seasons also exhibit wiping behavior, but the behavior is less elaborate than that of *Phyllomedusa.* Skin secretions contain a mixture of mucus, lipid, and possibly protein, and resistance to evaporative water loss in much lower than in the true waterproof frogs (Barbeau and Lillywhite 2005).

Several other Australian hylids have moderately high resistance to water loss. *Litoria chloris* has an even higher resistance than *L. caerulea* at temperatures below 40° C, despite the fact that it lives in rain forests (Buttemer 1990). At temperatures above 40° C, skin resistance declines, apparently because of periodic discharge of mucus onto the surface of the skin to facilitate evaporative cooling (fig. 2.7). This reduction in resistance at high temperatures and the frog's small size make it poorly suited to hot, dry conditions. Another tree frog from the same coastal region of Australia, *L. gracilenta,* has skin resistance about twice as high as *L. chloris,* but it is considerably smaller and therefore susceptible to higher water loss under the same conditions (Withers, Hillman, and Drewes 1984). Two other species, *Litoria fallax* and *L. peronii,* also have moderately high resistance to water loss (Amey and Grigg 1995).

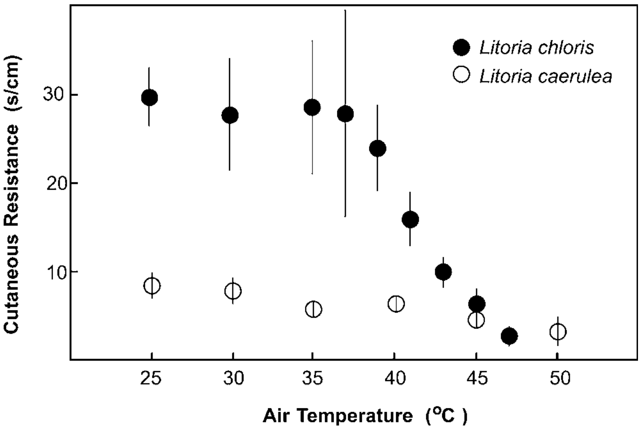

Fig. 2.7. Change in cutaneous resistance to water loss as a function of temperature in two Australian treefrogs, *Litoria chloris* and *L. caerulea.* Circles are means; vertical lines show 95% confidence intervals. After Buttemer (1990).

A surprising finding by Christian and Parry (1997) is that a terrestrial frog, *Cyclorana australis,* has a resistance to evaporative water loss higher than that of any other terrestrial frog that has been studied, but not as high as arboreal frogs such as *Litoria caerulea* (table 2.1). It had skin secretions with a composition similar to that of *Litoria,* about 10% lipids and 78% protein. This is a burrowing species, and during very dry weather, it retreats underground and forms a cocoon that provides even greater resistance to water loss (see "Cocoon Formation," following). The occurrence of similar strategies for retarding water loss in arboreal frogs and *Cyclorana* without cocoons probably is a function of their close phylogenetic relationship. *Cyclorana* is so unlike other hylids in morphology that it once was placed in the family Myobatrachidae (which was called Leptodactylidae at the time). Later work showed it to be a hylid, a member of the subfamily Pelodryadinae, as are all other Australian hylids. It is possible that in evolving terrestrial and fossorial habits, members of this genus have retained an ancestral mechanism for retarding water loss inherited from arboreal ancestors, or similar mechanisms evolved independently. Several phylogenetic analyses have indicated a close relationship between the subfamily Pelodryadinae in Australia and phyllomedusine hylids in South America, the only New World hylids known to produce concentrated lipid secretions (Ruvinsky and Maxson 1996; Darst and Cannatella 2004; Faivovich et al. 2005).

There is no evidence for lipid coatings being applied to the skin in other species of frogs, but it is possible that other frogs will be found with similar behavior (for example, see Barbeau and Lillywhite 2005). Nevertheless, lipids contained within the skin are major barriers to water loss in many other vertebrates (Lillywhite and Maderson 1988), so it seems reasonable to expect the same would be true of frogs. Attempts to correlate lipid content of skin with rates of water loss have produced mixed results. Bentley and Yorio (1979) extracted lipids from the skin of *Pachymedusa dacnicolor* and several nonarboreal species. They did not find any quantitative difference in lipid content that would explain the differences in rates of water loss, but it is possible that differences in the structural configuration of lipids in the skin are responsible for differences in skin resistance. Withers, Hillman, and Drewes (1984) found a variety of lipids in the skin of frogs, but none was unique to arboreal species with high resistance to evaporative water loss. They did not measure lipid content quantitatively, nor did they investigate structural differences in lipid layers. They did find that wiping the skins of two species, *Chiromantis rufescens* and *Hyperolius kivuensis*, with a lipid solvent increased the rate of evaporative water loss. The same was true for *Litoria peronii* (Amey and Grigg 1995). This species has a relatively thick lipid layer located in the *tela subcutanea* of the dorsal skin, but its position below the well-vascularized layers of the skin suggest that it would not provide a major barrier to water loss. *Leptodactylus fallax* has a much thinner lipid layer located just below the epidermis of the dorsal skin, where it would be more effective in retarding water loss. Indeed, this species exhibited a greater reduction in water loss compared to an agar model than did *L. peronii,* but cutaneous resistance to water loss was not calculated.

There is little evidence of unusual lipid layers in the skin of the highly waterproof species of *Chiromantis* and *Hyperolius.* They do have other structural peculiarities that seem to be related to low evaporative water loss, but the precise mechanism is unclear. Drewes et al. (1977) found a nearly continuous layer of specialized pigment cells (iridophores) in the dermis of two species that live in arid environments, *Chiromantis petersii* and *C. xerampelina.* These cells also have been found in *Hyperolius viridiflavus taeniatus* (Kobelt and Linsenmair 1986). In this species, the iridophores undergo a dramatic seasonal change, becoming much more abundant during the dry season (fig. 2.1 B). The iridophores contain many plates of highly reflective purine crystals, which give the frogs a chalky white appearance during the dry season. The main biological role of these iridophores apparently is to increase the reflectance of the skin and decrease radiant heat loads in animals exposed to the sun. This in turn would tend to reduce rates of evaporative water loss. It also is possible that the iridophores provide a physical barrier to water loss, although this has not been conclusively demonstrated. In addition, the synthesis of purines to form the iridophores provides a sink for storage of excess nitrogenous compounds that otherwise would have to be excreted. Temporary storage of nitrogenous wastes in this form saves both water and energy during the harsh dry season (Schmuck, Kobelt, and Linsenmair 1988).

Another possible mechanism for reducing evaporative water loss is formation of a layer of dried mucus on the outer surface of the skin. Geise and Linsenmair (1986) reported that a layer of dried mucus on the skin of *Hyperolius* helped seal the frogs to the substrate and increased cutaneous resistance to water loss. Wygoda (1988) observed increased discharges of mucus onto the skin surface in *Hyla cinerea* in response to desiccation stress. Periodic discharge of mucus is a thermoregulatory response to heat stress in many frogs that remain exposed to the sun, allowing for enhanced evaporative cooling (Lillywhite 1971b, 1975; Lillywhite and Licht 1975; McClanahan, Stinner, and Shoemaker 1978; Withers et al. 1982; Withers, Louw, and Nicholson 1982; Geise and Linsenmair 1986; Kaul and Shoemaker 1989; Shoemaker, Baker, and Loveridge 1989; Buttemer 1990; see also chapter 3). Periodic mucus discharges also could be advantageous in building up a dried layer that could increase cutaneous resistance to water loss. Christian and Parry (1997) suggested that mucus secretions contain proteins that retard water loss.

It is not yet clear how widespread these adaptations for reducing evaporative water loss are among arboreal frogs. Most of the work has concentrated on species known to experience prolonged dry seasons or that sit in exposed positions for long periods of time. There are other tree frogs, such as arboreal species of *Eleutherodactylus,* some tropical microhylids, some centrolenids, and a wide variety of tropical hylids and rhacophorids that might be exposed periodically to desiccation stress and would benefit from increased resistance to evaporative water loss. Wygoda (1984) recalculated data for *Polypedates leucomystax* collected by Shoemaker and McClanahan (1980) and found that this species has moderately high resistance to water loss. In contrast, preliminary data for *Eleutherodactylus coqui* and *E. cooki* from Puerto Rico indicate that these species have low cutaneous resistance to water loss (< 1 s/cm), comparable to those of terrestrial amphibians (Rogowitz, Cortés-Rivera, and Nieves-Puigdoller 1999). Additional studies involving broader comparisons among closely related species from different habitats would be useful in clarifying patterns of evolutionary change in water-conservation strategies.

Behavioral Modification of Water Balance

For amphibians that lack morphological or physiological adaptations for retarding water loss, the only means of avoiding desiccation is through changes in behavior. These include: (1) selection of moist microhabitats that allow the animal to balance water loss with water uptake; (2) sheltering in moist retreats in leaf litter, piles of debris, or natural cavities; (3) burrowing into soil during dry periods, or making use of burrows constructed by other animals; (4) postural changes; and (5) aggregation with other individuals.

Microhabitat Selection

One way that amphibians can avoid excessive water loss is to select microhabitats that provide sufficient moisture for water uptake through the skin to balance evaporative water loss (see also "Water Uptake"), or to limit activity to periods with favorable moisture conditions. Every herpetologist knows that amphibians are most easily captured on rainy nights, when they can be found crossing roads or moving about in wet leaf litter. Certainly this is the usual pattern for terrestrial plethodontid salamanders, most of which are nocturnal and seldom seen except in wet weather (Test 1946; Hairston 1949; Ralph 1957; Heatwole 1962b; Jaeger 1980a). Spotila (1972) tested responses of salamanders to humidity in a laboratory gradient consisting of a series of interconnected chambers with screen wire floors, in which relative humidity of the air varied from 0% at one end to 100% at the other. Several species of *Plethodon, Desmognathus,* and *Eurycea* selected relative humidity above 60%, although most species exhibited considerable individual variation in humidity preference. There was some correlation between the level of humidity chosen in the gradient and microhabitats chosen in nature, but the relationship was not exact. Highly terrestrial species such as *Plethodon dorsalis* and *P. serratus* generally selected lower humidity and were found in drier microhabitats than some of the other species. Three species of *Eurycea* that were either semiaquatic *(E. multiplicata)* or associated with microhabitats such as caves and wet ledges (*E. lucifuga, E. longicauda*) consistently selected only the highest humidity.

For most terrestrial salamanders, the moisture content and water-holding characteristics of the soil probably are more important determinants of microhabitat choice than relative humidity of the air, because soil moisture provides the major avenue for water uptake. Field studies and laboratory investigations using soil-moisture gradients have shown that plethodontids, ambystomatids, and salamandrids exhibit specific preferences for soils of certain moisture content, often avoiding both very dry and nearly saturated substrates (Vernberg 1955; Rosenthal 1957; Heatwole 1960, 1962b; Taub 1961; Jaeger 1971b; J. Anderson 1972; Marangio and Anderson 1977; Degani 1984; Wyman 1988; Grover 1998). Soil moisture affects both the horizontal dispersion of salamanders and their vertical distribution in the soil, with individuals moving deeper as the surface layers dry out (Hendrickson 1954; Stebbins 1954b; Rosenthal 1957; P. Anderson 1960; Cunningham 1960; Taub 1961; Heatwole 1962b).

Moisture preferences can be modified by the hydric condition of the salamander, with dehydrated individuals generally showing a stronger preference for wet substrates. Preferences also can be affected by breeding condition. J. Anderson (1972) found that breeding adult *Ambystoma macrodactylum* preferred wetter substrates than did nonbreeding adults, perhaps because they move toward water to breed. In contrast, *A. opacum* adults showed a random preference for soil moisture content during the fall breeding season, perhaps because these animals do not follow a moisture gradient to their terrestrial oviposition sites (Marangio and Anderson 1977).

There have been fewer studies of the role of moisture in microhabitat selection by anurans. Some anurans are strictly nocturnal (Stille 1952; Cree 1989), while others are active both day and night when moisture conditions are suitable (Dole 1965a). Anurans undoubtedly are sensitive to humidity of the air, although this has seldom been investigated experimentally. Stewart (1985) reported that Puerto Rican tree frogs (*Eleutherodactylus coqui*) were seen foraging in the forest canopy most frequently on nights when humidity was high and vegetation was wet. The same pattern was apparent in studies of leiopelmatid frogs in New Zealand, where the number of active frogs was related to relative humidity, rainfall, and wetness of the vegetation (Cree 1989). Juszczyk (cited in Nöllert 1984, p. 44) found more European spadefoot toads (*Pelobates fuscus*) emerging to forage on very humid nights than on drier nights. The activities of ground-dwelling anurans probably are influenced as much by soil moisture as by relative humidity of the air (Tracy et al. 1993). Brekke, Hillyard, and Winokur (1991) showed that *Bufo punctatus,* a desert toad from the southwestern United States, is sensitive to the water potential of the substrate, and preferentially selects those that allow water to be taken up through the skin. Substrate water potential apparently is sensed at least in part through the feet; when the feet were covered, the toads were less selective in choice of substrates. Subsequent work with this species and *Bufo marinus* demonstrated that toads can sense the osmotic concentration of water directly through the ventral skin, and avoid substrates that would tend to draw water out of the body (Hillyard, von Seckendorff Hoff, and Propper 1998; Maleek et al. 1999; Nagai et al. 1999).

Soil moisture content is of critical importance in determining patterns of movement by leopard frogs (*Rana pipiens*). These are more terrestrial than many other temperate-zone ranid frogs and often venture many meters from standing water. Frogs studied during the summer in a Michigan meadow generally limited their activities to portions of the meadow that were visibly wet throughout the summer (Dole 1967). Indeed, Tracy (1975, 1976) found that even the driest soils in the area of the pasture frequented by leopard frogs were wet enough to allow for continuous uptake of water to balance losses through evaporation. For much of the summer, leopard frogs were not very active, often sitting for days in shallow depressions in the moist soil. Movements into drier parts of the pasture were limited to periods of heavy rain (Dole 1965a). Similar rainy-weather excursions outside of normal home ranges have been observed in other frogs (Martof 1953b; Sinsch 1988c; see also chapter 6).

Sheltering

When conditions on the surface are too dry for amphibians to be active, they often retreat into sheltered sites that protect them from excessive water loss. Most amphibians are smaller than other vertebrates (Pough 1980; Feder 1983b), so they can use microhabitats not available to larger animals. Nearly every conceivable type of retreat is used by some species of amphibian. Many forest-dwelling salamanders make use of surface cover provided by leaf litter, logs, rocks, or piles of debris. Jaeger (1980b) found that *Plethodon cinereus* moved back and forth between litter and retreat sites under logs, with the number in the litter increasing in rainy weather. This species is selective in its choice of retreat sites, generally favoring large cover objects that provide a stable thermal and hydric environment (Mathis 1990a). They also prefer chunky decayed logs to more fibrous or crumbly ones, probably because these provide numerous cracks into which the salamanders can retreat in dry weather (Heatwole 1962b). *Plethodon glutinosus* exhibits a similar preference for chunky logs, with individuals sometimes wedging themselves into cracks and insect tunnels (Wells and Wells 1976). Some members of the genus *Aneides* are highly dependent on logs for shelter, where they are found mainly in cracks under exfoliating bark (T. Davis 2002a). Some small Neotropical salamanders (*Thorius, Chiropterotriton, Bolitoglossa*) live in spaces under the bark of fallen logs (D. Wake and Lynch 1976; Feder 1982b) or under moss mats on rocks, tree trunks, or the ground (D. Wake 1987).

In tropical rain forests, many species of frogs can be found living on or near the ground (N. Scott 1976, 1982; Toft 1980a, b, 1982; Toft, Rand, and Clark 1982). Some of these are terrestrial breeders (see chapter 7), but others must return to water to breed. Ground-dwelling anurans are scarce in most temperate-zone forests, perhaps because the leaf litter is drier for much of the year. In the Neotropics, species diversity of litter anurans tends to increase with increasing rainfall (see fig. 15.2 in chapter 15), suggesting that moisture content of the leaf litter limits the distribution of some species. Many ground-dwelling anurans hide in leaf litter even in relatively dry weather (Toft 1980b; Lynch and Myers 1983), but they use other types of retreats as well. A Puerto Rican frog, *Eleutherodactylus coqui,* is particularly fond of curled, dead leaves of *Cecropia* trees and the rolled petioles of fallen palm fronds, sites that also are used as oviposition sites (Townsend 1989b). The availability of retreat sites apparently limits population size in this species, because addition of bamboo frog houses increased the number of frogs in the forest (Stewart and Pough 1983). Other species of *Eleutherodactylus* hide under rocks, logs, piles of debris, or in crevices along stream banks (Rivero 1978; Stewart 1979; Stewart and Martin 1980; Lynch and Myers 1983).

Terrestrial microhylids from tropical Australia and New Guinea are ecologically similar to *Eleutherodactylus* and often live in the network of roots and tangled vegetation on the forest floor or hide in crevices at the bases of trees (Menzies and Tyler 1977; Zweifel and Tyler 1982; Zweifel 1985). In Queensland, the introduced toad *Bufo marinus* uses rock crevices, hollow logs, and cavities under tree roots or along riverbanks as daytime retreat sites. Toads preferentially select sites with high soil moisture content (Cohen and Alford 1996), and the use of such sites in dry weather can reduce rates of desiccation and increase survivorship (Schwarzkopf and Alford 1996; Seebacher and Alford 2002). In wet weather, the toads often shelter in dense vegetation and often move around in open, grassy areas at night (Seebacher and Alford 1999). The toads also tend to move longer distances in wet weather, when soil moisture levels are high.

A radio-tracking study of a ranid frog (*Hoplobatrachus occipitalis*) in a West African savanna revealed that these frogs often use the same shelters repeatedly for up to two weeks (Spieler and Linsenmair 1998). These frogs are active only at night and spend the daylight hours in crevices under rocks along riverbanks, or under bushes or patches of grass. Shelters that were used by several individuals had more constant temperatures and higher humidity than did similar shelters that were not used by frogs.

Some amphibians find shelter in holes and crevices of rock formations (fig. 2.8 B). Some are rock-dwelling specialists, while others use such sites opportunistically. Specialist crevice-dwelling salamanders include *Aneides aeneus* (R. Gordon 1952), *Eurycea lucifuga* (Hutchison 1958) and *Hydromantes platycephalus* (L. Adams 1942), all of which have flattened heads and bodies that enable them to enter narrow spaces. Other small salamanders, such as *Desmognathus ocoee,* sometimes live in rock crevices in wet areas, but they have few morphological specializations for this habitat (Huheey and Brandon 1973). Two terrestrial-breeding frogs that live in humid crevices and grottos of large boulder fields are *Cophixalus saxatalis,* an Australian microhylid (Zweifel 1985), and *Eleutherodactylus cooki,* a Puerto Rican leptodactylid (Rivero 1978; Joglar 1998). Both *Bufo vertebralis* (Bufonidae) and *Phrynomantis annectans* (Microhylidae) live in rocky, arid regions of southern Africa, and find shelter in spaces under exfoliating layers of granite boulders (Channing 1976a). Both have relatively flattened bodies that facilitate entry into narrow crevices (Passmore and Carruthers 1995). A rock-dweller from a much wetter habitat is *Dendrobates azureus,* which is found only in forest islands in the savannas of Surinam. These frogs are always associated with large boulders, and find shelter in cavities beneath the rocks (Hoogmoed 1969, 1972). Another dendrobatid frog, *Colostethus panamensis,* lives along rocky streams in Panama. Males and females retreat into moist crevices during the dry season (fig. 2.8 A) and defend them vigorously against intruders of both sexes (Wells 1980a).

Arboreal amphibians generally find shelter in spaces un-

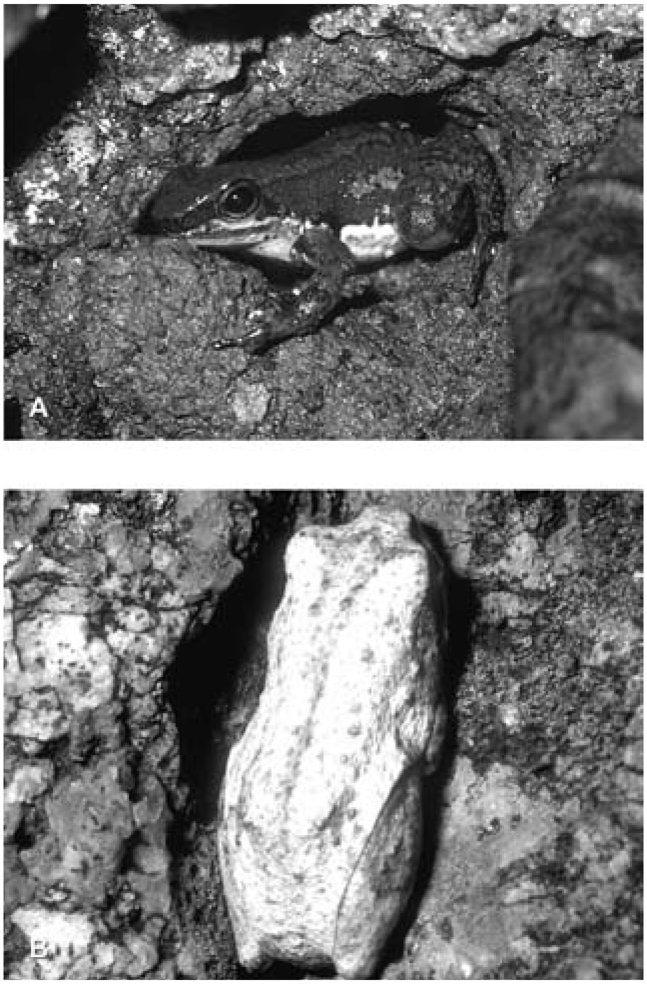

Fig. 2.8. (A) *Colostethus panamensis* sheltering in a mud bank during dry weather. (B) *Hyperolius orkarkarri* sheltering in a rock crevice during dry season. The whitening of the skin helps to reduce the heat load on the frog when exposed to sunlight. Photos by Kentwood D. Wells (A) and Robert Drewes (B).

der bark or moss on tree trunks, in tree holes, or in the axils of epiphytic plants. *Eleutherodactylus hedricki* of Puerto Rico is a tree-hole specialist, using them for both shelter and reproduction, whereas other species such as *E. coqui* use them occasionally (Rivero 1978). Microhylid frogs from Madagascar in the genera *Platyhyla, Plethodontohyla, Anodonthyla, Platypelis,* and *Paracophyla* live and lay eggs in tree holes, hollow bamboo stems, and the axils of various kinds of epiphytes (Blommers-Schlösser 1975b). An East African microhylid, *Hoplophryne uluguruensis,* also is a bamboo-dweller (Barbour and Loveridge 1928; Lamotte and Lescure 1977), as is *Fritziana ohausi,* a hylid from Brazil (Heyer et al. 1990). Another Brazilian hylid, *Trachycephalus resinifictrix,* is reported to lay eggs in small holes high in trees, including old hymenopteran nests (Goeldi 1907; Lamotte and Lescure 1977). Whether they also use these as permanent shelter sites is not known. Some North American tree frogs use knothole cavities as shelters outside the breeding season (McComb and Noble 1981; Ritke and Babb 1991).

Many tree frogs in the families Hylidae, Leptodactylidae, Rhacophoridae, and Hyperoliidae use the axils of bromeliads, pineapples, bananas, palmettos, and other plants for shelter and sometimes for reproduction (Picado 1913; Dunn 1937; W. Lynn and Grant 1940; W. T. Neill 1951; Slevin 1955; Schiøtz 1967; Stewart 1967; D. Lee 1969; Duellman 1970; Loveridge 1976; Lamotte and Lescure 1977; Rivero 1978; Garrick, Sutton, and Lang 1985; Hedges 1987; Heyer et al. 1990; Ovaska 1991; Duellman and Yoshpa 1996; Meshaka 1996). Retreat sites are located on the ground or in aerial plants high in the forest canopy. An unusual report of a plant used for shelter by frogs is a brief note by W. T. Neill (1946), who found groups of up to two dozen tree frogs (*Litoria* sp.) inside the cavities of ant-plants (*Hydnophytum,* Rubiaceae) in New Guinea. These are epiphytes that grow on the trunks of trees and develop globular swellings on their roots up to 30 centimeters in diameter. They contain a network of interconnected passages inhabited by ants (for an illustration of ant chambers in a related genus, see Hölldobler and Wilson 1990). Neill reported that many ants were present when he discovered the frogs, but how the frogs avoid being bitten is not known.

Some frogs that find shelter in holes have the skin on top of the head tightly co-ossified with the skull (Trueb 1970). This appears to be an adaptation for reducing water loss. Neotropical treefrogs in several genera (*Triprion, Trachycephalus, Corythomantis, Aparasphenodon, Gastrotheca*) use their bony heads to plug holes in logs or tree trunks and spaces in the axils of bromeliads (Lutz 1954; Duellman and Klaas 1964; Bokermann 1966b; Duellman and Trueb 1986; Jared et al. 1999). Seibert, Lillywhite, and Wassersug (1974) reported that evaporative water loss from the head of one species, *Trachycephalus jordani,* was only about a third as high as losses across the dorsal skin and much less than losses from the heads of tree frogs without co-ossified skulls. De Andrade and Abe (1997) reported that in two species, *Aparasphenodon brunoi* and *Corythomantis greeningi,* individuals sheltered in small chambers with the head blocking the entrance had rates of evaporative water loss that were 85–90% lower than those of exposed frogs. Nevertheless, skin co-ossification appears to be less important in reducing water loss than is reduction of evaporative water loss from the skin and behavioral selection of moist retreat sites (Navas, Jared, and Antoniazzi 2002). Cranial co-ossification has evolved in some burrowing anurans as well, including hylid frogs in the genus *Pternohyla* (Duellman 1970; Trueb 1970), some toads in the genus *Bufo* (formerly in a separate genus, *Peltophryne*), and an Old World spadefoot toad, *Pelobates syriacus.* At least one toad, *Bufo empusus,* is known to use its head to block burrow entrances (T. Barbour 1926).

Burrowing

Many other amphibians spend much of their time below ground. Some species are obligate burrowers that exhibit morphological specializations for digging (see chapter 1), but others are opportunistic burrowers that make use of natural holes, crevices, or tunnels made by other animals. These retreats provide more stable temperature and humidity conditions than do more exposed locations (Denton and Beebee 1993a). Among the most specialized fossorial amphibians are the caecilians. Five of the six living families are specialized for burrowing, with reduced eyes and modified skull morphology (see chapter 1). The other family is largely aquatic, but appears to be derived from fossorial ancestors. Very little is known about the water relations of these animals. The limited data available indicate that rates of evaporative water loss in air are very high (Steele and Louw 1988), and all terrestrial caecilians are restricted to wet soils in the tropics.

Terrestrial salamanders are active on the surface most often on wet nights, and often retreat below ground during dry periods. Most salamanders are not well adapted for digging their own burrows, but generally must rely on previously existing holes and passages in the soil. Terrestrial plethodontids such as *Plethodon jordani, P. glutinosus, P. cinereus,* and *Batrachoseps attenuatus* make use of root tracks, earthworm burrows, and other natural cavities, and are able to enlarge these for their own use (Chadwick 1940; M. Brooks 1946; Cunningham 1960; Heatwole 1960). The desmognathine salamander *Phaeognathus hubrichti* (fig. 1.32 B) spends nearly all of its time in underground burrows. These salamanders have elongate bodies and reduced limbs, suggesting morphological specialization for subterranean life, but they have limited abilities to construct their own burrows in undisturbed soil. Instead, they use natural cavities that they enlarge by wriggling the body from side to side (Brandon 1965a). The same is true of most of the mole salamanders in the family Ambystomatidae, some of which have been found up to a meter below the surface. *Ambystoma tigrinum* is capable of digging its own burrows in loose soil or sand, and *A. talpoideum* has limited burrowing abilities, but *A. annulatum, A. maculatum,* and *A. opacum* can only enlarge preexisting holes (Gruberg and Stirling 1972; Semlitsch 1983b). Loredo, Van Vuren, and Morrison (1996) reported that both adult and juvenile California tiger salamanders (*Ambystoma californiense*) dispersing from a breeding pond spent at least one day in burrows of ground squirrels within 130 m of the pond, while tiger salamanders (*A. tigrinum*) in South Dakota appeared to use prairie dog burrows for more extended periods (Kolbe, Smith, and Browning 2002). Spotted salamanders (*A. maculatum*) also use small mammal burrows as retreats, especially those of shrews (*Blarina brevicauda;* Madison 1997; Regosin, Windmiller, and Reed 2003a).

Burrowing is common in many anuran families (see chapter 1). In contrast to caecilians and urodeles, which are largely restricted to burrowing in moist soils, many frogs spend considerable periods of time in relatively dry soils. Burrowing probably is the single most common adaptation for avoiding excessive water loss among anurans from deserts, savannas, and other dry environments (Main, Littlejohn, and Lee 1959; Bentley 1966a; Main 1968; Mayhew 1968; Shoemaker 1975, 1988; Channing 1976a; Loveridge 1976; Tyler, Watson, and Martin 1981; Lamotte 1983; Heatwole 1984; Warburg 1997), but burrowing is not restricted to anurans from arid regions. There are, for example, numerous burrowing microhylids in the wet forests of New Guinea (Menzies and Tyler 1977; Zweifel and Tyler 1982).

Anurans exhibit a broad spectrum of burrowing behaviors that serve to protect the animals from both desiccation and diurnal predators. Some species, including many toads (*Bufo*), are essentially terrestrial, but often dig temporary shallow burrows to which they retreat in hot, dry weather (Stille 1952; R. Clarke 1974a; Hemmer and Jakobs 1974; Strijbosch 1980; Niekisch 1982; Brinkmann and Podloucky 1987; Hoffman and Katz 1989; Sinsch 1989b; Denton and Beebee 1993a; Rosset and Alcalde 2004). A North American tree frog, *Hyla gratiosa,* escapes from dry conditions by digging shallow burrows in sandy soil; they have been found more than a meter below the surface in winter (W. T. Neill 1952). Other frogs live in more permanent holes or burrows during the day, but emerge at night to forage. Eastern spadefoot toads (*Scaphiopus holbrookii*) behave this way when conditions are sufficiently wet to permit surface activity (S. Ball 1936). Individuals have several relatively permanent burrows within their home ranges (Pearson 1955). European spadefoots (*Pelobates fuscus*) also live in burrows up to two meters deep during the day (Savage 1942), but they often dig a new burrow each morning after a night of foraging (Nöllert 1984). The large Neotropical frog *Leptodactylus pentadactylus* builds relatively permanent burrows, and the same individual can be seen night after night sitting at a burrow entrance waiting for prey to come by (N. Scott 1983; personal observations). Many forest-dwelling microhylids from New Guinea also live in holes and emerge at night to feed (Zweifel and Tyler 1982).

Frogs can save themselves the trouble of digging their own holes by using burrows constructed by other animals. The use of preexisting burrows not only saves energy, but enables anurans to escape from desiccating conditions more rapidly than they would if they dug their own burrows

(M. Parris 1998). Some anurans use the burrows of invertebrates for shelter. For example, some New World microhylid and leptodactylid frogs use the burrows of spiders and crabs as regular daytime retreats (fig. 2.9), apparently coexisting quite peacefully with the original inhabitants (W. Blair 1936; Hunt 1980; Powell, Little, and Smith 1984; Cocroft and Hambler 1989; McIntyre 2003). A South African microhylid, *Phrynomantis bifasciatus,* takes refuge in termite mounds (Loveridge 1976). *Phynomantis microps* has been found in ant nests, as have the hyperoliid frogs *Kassina fusca* and *K. senegalensis* (Dejean and Amiet 1992; Rödel and Braun 1999). Both *Phrynomantis* and *Kassina* have been found in burrows of scorpions as well (Rödel and Braun 1999). A South American leptodactylid, *Lithodytes lineatus,* regularly inhabits and even calls from the nests of leaf-cutter ants (*Atta;* Schlüter and Regös 1981; Regös and Schlüter 1984; Hoogmoed 1986; Lamar and Wild 1995). All of these anurans apparently are protected from attacks by spiders, scorpions, or ants by noxious skin secretions. The association of frogs with noxious animals such as spiders, scorpions, and ants provides antipredator benefits to the frogs (see chapter 14), but they could use the burrows of these animals to maintain a proper water balance as well.

Fig. 2.9. Microhylid frogs, *Chiasmocleis ventrimaculata,* from Peru use the burrows of tarantulas, *Xenesthis immanis,* as daytime retreats. The burrows provide the frogs with protection from desiccation, while association with the spider provides protection from predators. (A) A group of frogs emerging from a spider burrow. (B) A single frog foraging on the forest floor underneath a spider. Photos by Reginald B. Cocroft.

Anurans often use the burrows of other vertebrates as retreat sites. European common toads (*Bufo bufo*) occasionally use rabbit holes for shelter (Denton and Beebee 1993a). North American gopher frogs (*Rana areolata, R. capito,* and *R. sevosa*) spend most of their time outside of the breeding season living in the burrows of crayfish, small mammals, and gopher tortoises (D. Lee 1968; Eisenberg 1983; Jackson and Milstrey 1989; Stevenson and Dyer 2002). Gopher tortoise burrows also are frequently used by *Eleutherodactylus planirostris* and occasionally by *Bufo terrestris* and *Gastrophryne carolinensis* (Lips 1991; Witz, Wilson, and Palmer 1991). Narrow-mouthed toads (*Gastrophryne olivacea*) also have been found in the burrows of moles and skinks (Freiburg 1951). The New World treefrogs *Pachymedusa dacnicolor* and *Hyla gratiosa* sometimes use rodent burrows as retreats during dry weather (D. Lee 1968; Wiewandt 1971), and *Rana luteiventris* has been reported in rodent burrows as well (Blomquist and Tull 2002). The burrows of a large South African lizard, *Cordylus giganteus,* are dry season retreats for ranid (*Cacosternum boettgeri*) and hyperoliid frogs (*Kassina wealii*), with up to 20 individuals living in the same burrow (W. Branch and Patterson 1975). Two other South African frogs, *Kassina senegalensis* and *Breviceps verrucosus,* have been found in the tunnels of mole rats (*Cryptomys hottentotus*) and golden moles (*Amblysomus hottentotus;* Loveridge 1976; Poynton and Pritchard 1976).

Many anurans from arid regions remain inactive in deep burrows for many months each year and emerge only after heavy rains for brief periods of breeding and foraging. Frogs with this type of life history include the spadefoot toads (*Scaphiopus, Spea, Pelobates*); Australian myobatrachids (*Notaden, Neobatrachus, Heleioporus,* some *Limnodynastes*) and hylids (*Cyclorana*); African ranids (*Pyxicephalus, Tomopterna, Hildebrandtia*), hemisotids (*Hemisus*), hyperoliids (*Leptopelis*), and microhylids (*Breviceps*); South American leptodactylids (*Lepidobatrachus, Ceratophrys*) and hylids (*Pternohyla*), and the Mexican burrowing frog, *Rhinophrynus dorsalis.* Other species are almost completely subterranean, sometimes even obtaining food underground. These include microhylids from New Guinea in the genera *Barygenys, Choerophryne, Copiula,* and *Xenobatrachus* (Menzies 1976; Menzies and Tyler 1977; Zweifel and Tyler 1982), African shovel-nosed frogs in the genus *Hemisus*

(Wager 1965; Emerson 1976; Passmore and Carruthers 1979), two Australian myobatrachids, *Myobatrachus gouldii* and *Arenophryne rotunda* (J. Roberts 1981, 1984; M. Tyler, Watson, and Martin 1981), and two North American hylid frogs, *Pseudacris streckeri* and *P. ornata* (L. Brown, Jackson, and Brown 1972; Brown and Means 1984). *Pseudacris streckeri* is capable of feeding underground, but feeds on the surface as well (L. Brown 1978). Both species of *Pseudacris* breed in surface bodies of water like all other species in the genus, whereas the other subterranean species listed above lay eggs underground.

Water Relations of Burrowing Anurans

Studies of water relations in burrowing anurans have focused mainly on desert-dwelling species that experience the most extreme conditions to which amphibians are exposed (Warburg 1997). Burrowing frogs generally store large amounts of water in the bladder while underground (see "Water Storage"). These stocks are resorbed into the tissues as dry-season dormancy progresses. In addition, these frogs have various strategies for avoiding excessive loss of water to the soil. One way is to be highly selective in choice of soils for burrowing, avoiding extremely dry conditions and favoring soils that retain water for much of the dry season (Mayhew 1965, 1968; Heatwole, Cameron, and Webb 1971). Another is to construct burrows near the bases of bushes and other plants, where the soil is wetter than in surrounding areas (W. T. Neill 1952; van Beurden 1984), or next to rocks that channel rainwater into the soil (Bentley, Lee, and Main 1958). Burrowing frogs also could follow soil moisture gradients, digging deeper into the soil as surface layers dry out (Ruibal, Tevis, and Roig 1969).

Many desert anurans, including spadefoot toads, have highly permeable skin that facilitates water uptake when moisture is available (see "Water Uptake"), but this can be a serious problem when the animal is underground. If the soil becomes very dry, water actually can be drawn out of the animal. One way of coping with this problem is for the animals to increase the osmotic concentration of their body fluids, thereby lowering their own water potential (Katz and Hoffman 1990). This not only retards water loss through the skin, but also can reverse the osmotic gradient and allow the animals to take up water from the soil. Spadefoot toads (*Scaphiopus* and *Spea*) from the deserts of the southwestern United States are able to accumulate both urea and electrolytes in their plasma, thereby maintaining a favorable osmotic gradient even during very dry periods (McClanahan 1967, 1972; Shoemaker, McClanahan, and Ruibal 1969). This could be accomplished by a cessation of urine excretion, resorption of urea, acceleration of urea production, or a combination of all three. Accelerated urea production would require a shift from catabolism of stored lipids to catabolism of proteins during periods of osmotic stress (R. M. Jones 1980). McClanahan (1972) demonstrated that the rate of urea accumulation is a direct function of the severity of osmotic stress; spadefoots buried in dry soil accumulated urea more quickly than those in moist soil (fig. 2.10), and he interpreted these results as evidence for increased urea production.

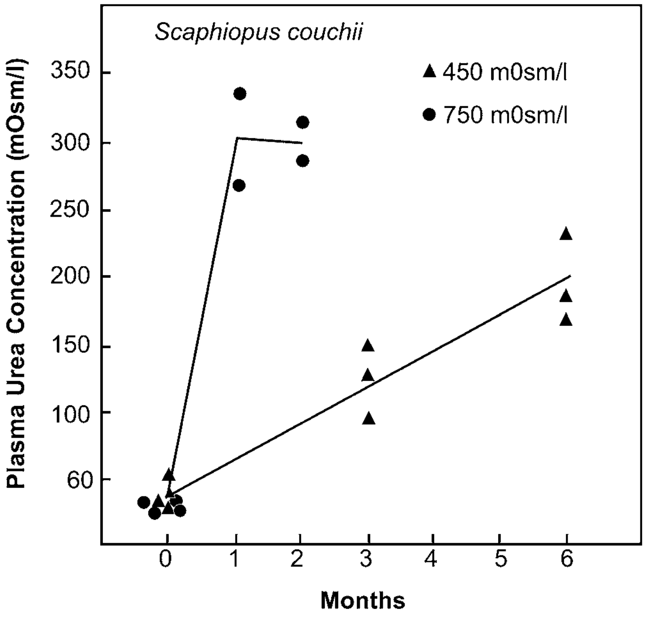

Fig. 2.10. Plasma urea concentrations of spadefoot toads (*Scaphiopus couchii*) kept in soils with different water potentials (450 or 750 milliosmoles/liter) as a function of number of months in the ground. The higher number (750 mOsm/l) indicates a lower water availability in the soil. Toads in drier soil accumulated urea more rapidly in the plasma and reached higher total urea concentrations. After McClanahan (1972).

C. B. Jørgensen (1997a, b) questioned this interpretation for spadefoot toads and other amphibians that accumulate urea under osmotic stress. He argued that apparent increased synthesis of urea in water-stressed amphibians is due mainly to a reduction in excretion of urea. He further argued that amphibian species that regularly experience osmotic stress typically are more tolerant of high urea concentrations, and this represents the principal adaptation to dry conditions. Indeed, spadefoot toads can tolerate high osmotic concentrations of urea in part because their muscle tissues are less impaired by high urea concentrations than those of more aquatic species such as *Rana pipiens* (McClanahan 1964). This means they can continue to use their muscles for digging even after many months underground. Old World spadefoot toads (*Pelobates syriacus*) also can raise body fluid concentrations by accumulating urea (Degani, Goldenberg, and Warburg 1983; Degani and Nevo 1986). Their osmoregulatory capacity is more limited than that of some other desert anurans, and they do not live in the driest habitats (Shpun et al. 1993).

This type of response is not limited to pelobatids. Green toads (*Bufo viridis*) from arid regions of Israel can remain buried for several months in relatively dry soil, although they also can remain active under very dry conditions. Green toads develop plasma urea concentrations equaling or exceeding those measured in spadefoot toads (Degani, Silanikove, and Schkolnik 1984; Katz and Gabbay 1986; Hoffman, Eliath, and Katz 1988; Hoffman, Katz, and Eliath 1990; Katz and Hoffman 1990; Hoffman and Katz 1991, 1994, 1997, 1999). This is accomplished by retention of urine and apparently a short-term increase in synthesis of urea (Hoffman and Katz 1994). Three genera of burrowing frogs from Australia, *Neobatrachus, Heleioporus,* and *Cyclorana,* also accumulate urea during estivation, reaching plasma concentrations similar to those of *Scaphiopus* and *Bufo viridis* (Withers and Guppy 1996). The accumulation of urea by *Neobatrachus* and *Cyclorana* is the first to be reported in species that form cocoons. These frogs presumably do not derive an osmotic benefit from urea accumulation because of the impermeable nature of their cocoons, which would prevent water uptake from the soil. Nevertheless, there are other benefits of accumulating urea. One is that increases in intracellular ion concentrations are minimized. Experiments with spadefoot toads have shown that high concentrations of ions (potassium chloride) have a much greater effect in suppressing tissue enzyme activities than do high concentrations of urea, so accumulation of urea actually protects against the more harmful effects of high ion concentrations (Storey 2002).

The highly aquatic frog *Xenopus laevis* sometimes spends dry periods encased in mud at the bottom of drying ponds, and accumulates urea in the plasma (Balinsky et al. 1967). Several other species of anurans exhibit modest increases in plasma urea concentrations when subjected to osmotic stress, such as exposure to salt water (see "Osmoregulation in Saline Environments"). Most of these species have maximum plasma concentrations of urea less than 10% of those found in estivating burrowing anurans (Ackrill, Hornby, and Thomas 1969; Abe and Bicudo 1991; Withers and Guppy 1996). Accumulation of urea in body fluids also has been reported in tiger salamanders (*Ambystoma tigrinum*) left in dry soil in the laboratory for up to nine months (Delson and Whitford 1973a). These salamanders were from a desert-dwelling population that had surface water available only after heavy rains. Etheridge (1990b) reported an increase in plasma urea concentration in *Siren lacertina* estivating in relatively moist soil, but plasma concentrations of urea in estivating sirens were only 5 to 10 percent of those found in estivating desert anurans. The ability to tolerate relatively high levels of urea appears to be widespread in amphibians, at least in anurans, but the ability to actively increase urea concentrations in the body is much less common (Shpun, Hoffman, and Katz 1992).

Cocoon Formation

The strategy of increasing body fluid concentrations to maintain a positive osmotic gradient with the soil is viable only for species that burrow in soils that have sufficiently high water potentials during the dry season to permit continued uptake of water across the skin. Some types of soils, such as clay, have very low water potentials even when water remains in the soil, making it difficult for amphibians to take up water through the skin. In addition, some species are incapable of digging deep enough into the soil to reach a permanently moist layer.

A number of amphibians deal with this problem by forming relatively impermeable cocoons around their bodies during dormancy (fig. 2.11). Cocoon formation has been reported in anurans from several different families. In Australia, five burrowing hylids in the genus *Cyclorana* form cocoons, including *C. alboguttata,* which sometimes has been classified as *Litoria alboguttata.* Nine myobatrachids in the genus *Neobatrachus* also form cocoons (A. K. Lee and Mercer 1967; van Beurden, 1984; Withers 1995, 1998). Lee and Mercer (1967) reported cocoon formation by another myobatrachid, *Limnodynastes spenceri,* but Withers (1995) was unable to induce cocoon formation in this species or another species in the same genus. Cocoon formation has been reported in an African ranid (*Pyxicephalus adspersus*) and two hyperoliids (*Leptopelis bocagei* and *L. viridis;* Loveridge 1976; Parry and Cavill 1978; Loveridge and Crayé 1979; Loveridge and Withers 1981). Two South American leptodactylids (*Ceratophrys ornata* and *Lepidobatrachus llanensis*) and two New World

Fig. 2.11. A leptodactylid frog, *Lepidobatrachus llanensis,* from Argentina, in a cocoon of dried skin layers. Normally the frog would produce such a cocoon while buried in soil. Photo by Rudolfo Ruibal.

hylids (*Pternohyla fodiens* and *Smilisca baudinii*) also form cocoons (McClanahan, Shoemaker, and Ruibal 1976; McClanahan, Ruibal, and Shoemaker 1983; Ruibal and Hillman 1981; McDiarmid and Foster 1987). *Leptopelis, Pternohyla,* and *Smilisca* are largely arboreal during the wet season, whereas the other species are terrestrial. Cocoon formation also has been reported in two urodeles, *Siren intermedia* and *S. lacertina.* These animals are aquatic, but live in swamps that often dry up during the summer. They survive dry periods by burrowing into the mud and forming cocoons around their bodies (Reno, Gehlbach, and Turner 1972; Gehlbach, Gordon, and Weems 1973; Etheridge 1990a, b).

The structure of the cocoon is similar in all of the anurans, being composed of successive layers of stratum corneum that are molted by the animal but not removed from the body. Deposits of dried mucus that are produced during the normal molting cycle are found between the layers of skin (McClanahan, Shoemaker, and Ruibal 1976; McClanahan, Ruibal, and Shoemaker 1983; Loveridge and Crayé 1979; Ruibal and Hillman 1981; McDiarmid and Foster 1987; Withers 1995). McClanahan, Ruibal, and Shoemaker (1983) reported that layers of shed skin were added to the cocoon of *Lepidobatrachus llanensis* at the rate of one per day, with as many as 38 layers being produced. Cocoons with up to 36 layers have been reported in *Pyxicephalus* (Loveridge and Crayé 1979), up to 43 layers in *Pternohyla* (Ruibal and Hillman 1981), up to 40 layers in *Smilisca* (McDiarmid and Foster 1987), and from 50 to more than 100 layers in *Cyclorana* and *Neobatrachus* (Withers 1995).

All cocoon-forming anurans for which data are available exhibit dramatic reductions in evaporative water loss when measured with cocoons intact, ranging from a 77% reduction in *Cyclorana alboguttata* to 97% in *Pyxicephalus adspersus* (table 2.3). McClanahan, Ruibal, and Shoemaker (1983) found that rates of water loss declined rapidly with the addition of new layers of skin to the cocoon in *Lepidobatrachus.* A frog with a 35-layer cocoon exhibited a total resistance to water loss about 10 times that of a frog without a cocoon. Since boundary layer resistance did not change, this was due entirely to an enormous increase in cutaneous resistance (fig. 2.12). Loveridge and Withers (1981) found a continual reduction in evaporative water loss in cocooned *Pyxicephalus* for at least two months after the cocoon was first formed, presumably reflecting a similar addition of skin layers. All of the measurements of evaporative water loss in these frogs were made in dry air, not in soil. Actual water loss would be even lower for species that burrow into soil. The cocoon of *Siren lacertina* appears to provide less resistance to water loss than those of burrowing frogs, and estivating animals continue to lose some water if the surrounding soil has a low water potential (Gehlbach, Gordon, and Weems 1973; Etheridge 1990b).

Table 2.3 Reduction in evaporative water loss (EWL) with aestivational cocoons

	EWL (mg/g/h)		
Species (source no.)	Without Cocoon	With Cocoon	Percent change
Hylidae			
Cyclorana alboguttata (1)			77
Cyclorana australis (7)	8.0	0.5	94

Notes: Evaporative water loss was measured in air, and absolute rates for different species may not be comparable because of differences in techniques. Percent change is either the maximum or the average for each species, depending on the study.

*Evaporative water loss in cocooned frogs estimated from measurements on isolated pieces of cocoon for comparison with water loss by intact frogs without cocoons.

Postural Changes and Aggregation

Many amphibians reduce rates of evaporative water loss by making postural adjustments that reduce the surface-to-volume ratio of the animal. Salamanders sometimes respond to dry air by coiling the body (Ray 1958; Spotila 1972). However, this probably is relatively ineffective unless the animal can coil up very tightly. Coiling behavior might be used as an emergency response by salamanders unable to escape from desiccating conditions, but most species probably seek shelter before reaching this stage. A more common response is for salamanders to aggregate under cover with other individuals. Often the animals are found tightly intertwined, in some cases forming balls of salamanders that ef-

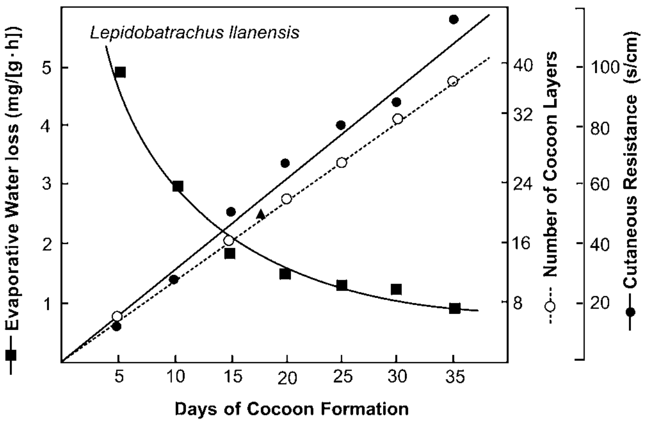

Fig. 2.12. Number of cocoon layers, mass-specific rate of evaporative water loss, and cutaneous resistance to water loss in *Lepidobatrachus llanensis* as a function of number of days of cocoon formation. Rate of evaporative water loss and cutaneous resistance to water loss were measured in air. Curves were fitted by eye. Cutaneous resistance to water loss increased as a linear function of number of cocoon layers, resulting in an exponential decrease in mass-specific evaporative water loss. Plotted from data in McClanahan, Ruibal, and Shoemaker (1983).

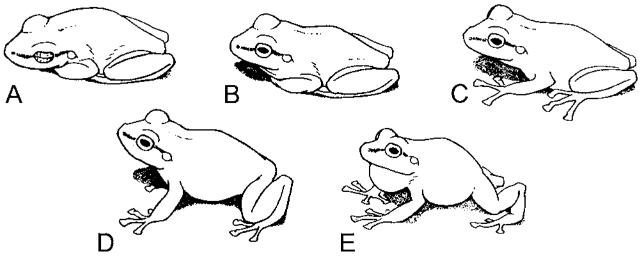

Fig. 2.13. Water-conserving and active postures of the Puerto Rican treefrog, *Eleutherodactylus coqui,* on dry and wet nights. (A) Water-conserving. (B) Chin up. (C) Low alert. (D) High alert. (E) Calling. After Pough et al. (1983).

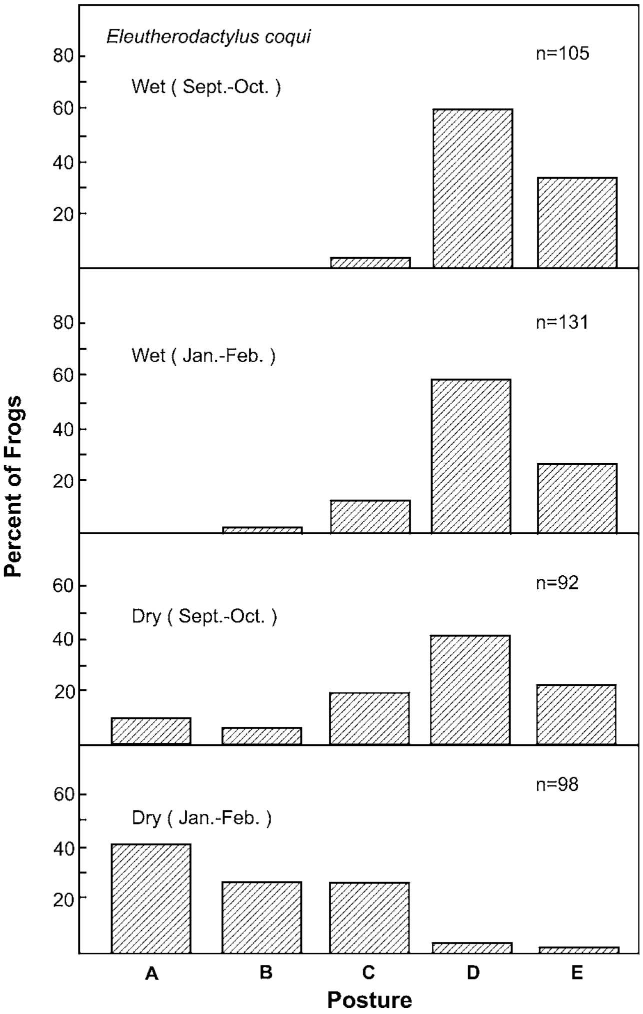

Fig. 2.14. Percentage of adult male *Eleutherodactylus coqui* adopting the postures shown in fig. 2.13 on wet and dry nights in the summer and fall (September and October) and in winter (January and February). Frogs are active, alert, and often calling on wet nights in all seasons. On dry nights, frogs are more likely to be active in the summer and fall than in winter, when temperatures are lower and breeding activity is reduced. After Pough et al. (1983).

fectively reduce the surface-to-volume ratio of the whole group. Species observed to aggregate in dry weather include *Plethodon cinereus* (Test 1955; Heatwole 1960), *P. glutinosus* (Humphries 1956; Wells and Wells 1976), *Batrachoseps attenuatus* (J. Cunningham 1960), *Ambystoma macrodactylum* (Alvarado 1967; J. Anderson 1967), *A. tigrinum* (Alvarado 1967; Gehlbach, Kimmel, and Weems 1969), *A. maculatum* (Pough and Wilson 1970), and terrestrial juvenile efts of *Notophthalmus viridescens* (Rohr and Madison 2003).

Arboreal frogs that remain in the open during dry weather adopt water-conserving postures that minimize the area of exposed skin. Generally the legs are folded under the body and the entire ventral surface is pressed tightly to the substrate. Often the eyes are retracted as well. The same basic water-conserving posture is adopted by frogs in several different families, including hylids (Duellman and Trueb 1986; Buttemer 1990), rhacophorids (Loveridge 1976; Drewes et al. 1977), hyperoliids (Withers et al. 1982; Geise and Linsenmair 1986), and leptodactylids (Heatwole et al. 1969; Pough et al. 1983). Some species of *Phyllomedusa* are an exception; they usually remain in a relatively upright, alert posture after coating themselves with lipid secretions, even when conditions are very dry (Blaylock, Ruibal, and Platt-Aloia 1976). The Puerto Rican tree frog *Eleutherodactylus coqui* adopts a variety of postures, depending on the relative humidity of the air and the wetness of the vegetation (fig. 2.13). The full water-conserving posture is adopted during very dry weather, but the frogs become progressively more alert and upright, with more surface area exposed, as hydric conditions improve (fig. 2.14).

Nonarboreal frogs generally do not adopt water-conserving postures when subjected to desiccation stress, although Heatwole, Cameron, and Webb (1971) observed this type of response by *Notaden bennetti* when they were prevented from burrowing in the laboratory. Most terrestrial anurans respond to desiccation by seeking shelter or by burrowing. This often leads to increased activity by frogs subjected to dehydration in laboratory chambers, where they are unable to escape desiccating conditions (Packer 1963a; Heatwole, Cameron, and Webb 1971; Heatwole and Newby 1972; Putnam and Hillman 1977; Schmajuk and Segura 1982). C. Johnson (1969a) and Heatwole, Cameron, and Webb (1971) also observed aggregation responses by *Limnodynastes* and *Notaden* in the laboratory, but it seems likely that these species would simply enter individual burrows in the field. Frogs are sometimes found huddled together under cover objects or in holes, crevices, and other retreats (W. T. Neill 1946, 1951; Slevin 1955; D. Lee 1968; Branch and Patterson 1975; Van Berkum et al. 1982). For example, Cohen and Alford (1996) reported finding large aggregations of *Bufo marinus* in hollow logs and other cavities during dry weather in northern Australia. Gray and Green (2000) reported aggregations of *Dendrobates auratus* in rock crevices and a litter-filled depression in Panama during an unusually dry period in an El Niño year. Newly metamorphosed anurans sometimes aggregate along the shores of ponds. Heinen (1993b) concluded that this type of aggregation in *Bufo americanus* was more important in protecting the toads from desiccation than from predators.

Water Uptake and Storage

Amphibians are unique among vertebrates in their capacity to take up water through the skin. The highly permeable skin that makes these animals so vulnerable to evaporative water loss also provides a distinct advantage when moisture is available. In fact, nearly all amphibians rely exclusively on the skin for rehydration and never drink water by ingesting it through the mouth (Shoemaker et al. 1992). An exception is the lipid-secreting frog *Phyllomedusa sauvagii,* which responds to raindrops by holding its snout in the air and pumping water into its mouth with the throat muscles. This enables these arboreal frogs to take up water without having to search for pools or wet surfaces (McClanahan and Shoemaker 1987).

Uptake from Standing Water

When terrestrial amphibians become dehydrated, they often restore body water reserves by moving to streams, ponds, or water-filled tree holes. Carpenter and Gillingham (1987) reported that *Bufo marinus* in Puerto Rico used permanent water holes for rehydration during the dry season, some moving nearly 200 meters from their regular home ranges and visiting water holes about once a week. The toads also rehydrated at ephemeral sites such as water-filled tire tracks. Tevis (1966) observed toads (*Bufo punctatus*) moving several hundred meters up a dry canyon to rehydrate in pools before returning to dry areas to forage. Another canyon-dwelling species, *Pseudacris cadaverina,* made daily trips between daytime resting sites on dry rocks and nightime foraging sites at the edge of a stream, where the frogs could rehydrate before searching for food (R. T. Harris 1975). Studies of a dendrobatid frog in Panama, *Colostethus panamensis,* showed that individuals often left their regular territories on rocky hillsides during the dry season and moved to the few remaining pools in the stream bed to soak up water. After heavy rains, the frogs moved rapidly back up the hill and reoccupied their original territories (Wells 1980a). Some frogs make use of water on the surfaces of leaves, rather than pools or streams. For example, *Rana pipiens* can rehydrate while sitting on dew-covered grass (Dole 1967). *Leiopelma archeyi,* a frog from New Zealand, emerges from daytime retreats only in wet weather and is able to take up water rapidly from wet leaves (Cree 1989).

In some species, periodic rehydration is essential for successful reproduction. For example, in phyllomedusine tree frogs, females carry males on their backs to ponds and absorb water through the skin before ascending into surrounding trees and bushes to lay eggs on the surfaces of leaves. Females often lay eggs in small batches, returning to water as many as six times to rehydrate before completing oviposition (Pyburn 1970, 1980b; Wiewandt 1971; Bagnara et al. 1986). In *Eleutherodactylus coqui,* brooding of eggs by males is critical in providing sufficient water for eggs to complete development (Taigen, Pough, and Stewart 1984; Townsend, Stewart, and Pough 1984). Males periodically leave nest sites and have been seen visiting water sources before returning to the nest (Drewry 1970). Similarly, male *Dendrobates auratus* have been observed sitting in pools or pressing their ventral surfaces against wet leaves immediately before sitting on egg clutches (Wells 1978b; Summers 1989).

All amphibians rehydrate rapidly in fresh water, whether they are completely submerged or have only the ventral skin in contact with the water, but there are interspecific differences in rates of rehydration. In general, terrestrial amphibians take up water more quickly than species that live in or near water (C. B. Jørgensen 1950a; Warburg 1965, 1971a, b, 1972; Spight 1967b; Bentley 1966a, 1971, 1973; Spotila 1972; Mullen and Alvarado 1976; Shoemaker and Nagy 1977; Alvarado 1979). Arboreal anurans usually rehydrate very quickly, even when they live in relatively mesic environments (Shoemaker et al. 1992), and some species of *Hyperolius* have the fastest rehydration rates measured for any amphibian (Geise and Linsenmair 1988). These patterns seem to make adaptive sense because species that are most likely to become dehydrated can replace body water stores quickly. However, such comparisons are complicated by the use of representative aquatic and terrestrial species that are not closely related: *Bufo* and *Xenopus* (Ewer 1952); *Bufo* and *Ascaphus* (Mullen and Alvarado 1976); *Hyla, Rana,* and *Bufo* (W. Schmid 1965); *Neobatrachus, Pelobates, Limnodynastes, Litoria* (Warburg 1972). Not only does phylogenetic history become confounded with habitat differences, but also there often is no replication of species representing different habitat types, making the statistical power of the comparison weak (Garland and Adolph 1994).

Comparisons among closely related species are more convincing, but have produced mixed results. Shoemaker and McClanahan (1980) found a reasonably good correlation between rate of rehydration and degree of terrestrialism in six species of *Rana* from Borneo. Comparisons of Puerto Rican *Eleutherodactylus* from low-altitude (dry) and high-altitude (wet) sites showed that *E. antillensis* took up water more quickly from solutions that varied in water potential than did *E. coqui* (fig. 2.15). The former is found only at low altitudes, whereas the latter is found over a wide range of altitudes and moisture conditions. There was no significant difference in rehydration rates of *E. coqui* from high- and low-altitude sites, suggesting that local populations of this species have not adapted physiologically to different moisture regimes (Van Berkum et al. 1982). A comparison of rehydration rates in four Australian tree frogs did not show a clear correlation with habitat aridity. *Litoria moorei,* a species found only in relatively wet areas, was least tolerant of desiccation, but it also had the highest rehydration rate. *Litoria rubella,* which is found in much drier habitats, had the lowest rehydration rate, whereas *L. caerulea,* another arid-region species, was intermediate (Main and Bentley 1964). In studies of Australian burrowing frogs, Bentley, Lee, and Main (1958) found that rehydration rate was positively correlated with habitat aridity among four species of *Neobatrachus,* but not among species of *Heleioporus.* The latter burrow into deep soil that remains relatively moist during the dry season, whereas the *Neobatrachus* dig relatively shallow burrows and therefore are subjected to greater hydric stress.

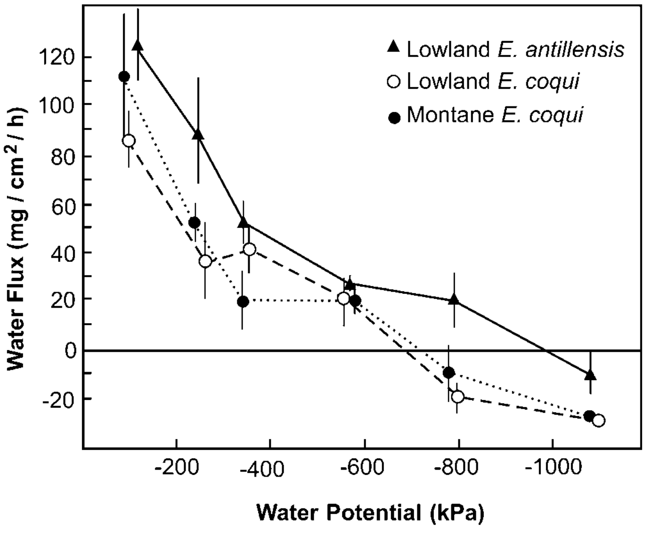

Fig. 2.15. Rates of rehydration in Carbowax solutions of different water potentials in three populations of Puerto Rican *Eleutherodactylus.* Data are shown as means ± 2 SE. Larger negative numbers indicate lower water availability. *Eleutherodactylus antillensis,* a grassland species, had higher rehydration rates at all water potentials than did *E. coqui,* which lives in wet forests. There was no difference in rehydration rates of *E. coqui* from different elevations. After Van Berkum et al. (1982).

Uptake from Soil

Amphibians often do not have ready access to standing water, especially when they are away from aquatic breeding sites, and the ability to take up water from soil or other moist substrates is an important adaptation for terrestrial life. Stille (1952) and Tamsitt (1962) observed toads (*Bufo fowleri* and *Bufo hemiophrys*) moving to lakeshore beaches at night to soak up water from wet sand, but they did not present any quantitative data on rates of water uptake. Other studies have confirmed that both anurans and urodeles can absorb water from moist soil, in some cases at rates nearly equal to those of animals sitting in water (Heatwole and Lim 1961; Packer 1963a; Dole 1967; Spight 1967b; A. K. Lee 1968; McClanahan and Baldwin 1969; Ruibal, Tevis, and Roig 1969; Fair, 1970; R. Walker and Whitford 1970; Spotila 1972; C. Tracy 1976; Bundy and Tracy 1977; Marangio and Anderson 1977; Walters and Greenwald 1977; Degani and Warburg 1980).

Interspecific variation in rates of water uptake from soil seems to be related in part to habitat moisture availability, although there are phylogenetic differences as well. Terrestrial salamanders appear to have lower rates of water uptake than many anurans (Spotila 1972; Marangio and Anderson 1977), although there have not been any studies comparing anurans and urodeles under identical conditions. There is not much information on the relationship between habitat and rate of water uptake from soil among different species of urodeles. Walters and Greenwald (1977) found that the terrestrial eft stage of the red-spotted newt, *Notophthalmus viridescens,* had a somewhat higher rate of rehydration than did aquatic adults. Several studies have shown that fossorial (*Scaphiopus* and *Cyclorana*) and terrestrial anurans (*Bufo*) tend to take up water from soil very rapidly, and can absorb water from drier substrates than can less terrestrial frogs such as *Rana pipiens* (Ruibal, Tevis, and Roig 1969; Walker and Whitford 1970; van Beurden 1984). An exception is the Australian turtle frog (*Myobatrachus gouldii*), which exhibits a less pronounced water balance response than do other burrowing anurans. This species is unusual in that it lives its entire life in habitats where it seldom encounters standing water (Withers and Roberts 1993).

The rate at which an amphibian takes up water from moist soil depends on a number of factors, including the water content and physical characteristics of the soil. Soils vary considerably in the tendency for particles to bind with water. For example, clay soils tend to bind water more tightly than sandy soils, so clay would have lower water potential than sand even when the percentage of water in the soil is the same. In other words, it would be more difficult for an amphibian to extract water from clay than from sand, even if the water content of the soil is identical (C. Tracy 1976; Shoemaker et al. 1992; Spotila et al. 1992). There also are local differences in hydric properties of soil, depending on size of soil particles, degree of compaction, temperature, and water content, so comparisons among species are meaningful only when measurements are made under identical conditions.

The rate of water uptake from soil also is influenced by the condition of the animal. As an amphibian dehydrates, the osmotic concentration of its body fluids increases. In burrowing species, this effect is increased by the retention of urea, as described previously. Consequently, dehydrated amphibians typically take up water more quickly than fully hydrated individuals, and they can absorb water from drier soils (Spight 1967a; Ruibal, Tevis, and Roig 1969; Walker and Whitford 1970; P. Brown, Hastings, and Frye 1977; Marangio and Anderson 1977; Geise and Linsenmair 1988). In *Bufo punctatus,* severely dehydrated individuals show a more pronounced water absorption response than do fully hydrated toads (Brekke, Hillyard, and Winokur 1991; Hillyard, von Seckendorff Hoff, and Propper 1998). Studies of green toads (*Bufo viridis*) showed that the water absorption response also can be induced by injecting toads with saline to increase the osmotic concentration of the body (Hoffman and Katz 1999). The water absorption response of toads involves spreading the hind legs and pressing the pelvic region of the skin (the "pelvic patch" or "seat patch") into the soil. This insures that the highly vascularized pelvic patch is in contact with the substrate (Hillyard von Seckendorff Hoff, and Propper 1998). Similar water-absorbing postures are seen in many anurans, although some species tend to press the entire ventral surface against the substrate (Stille 1958; Dole 1967; C. Johnson 1969b; McClanahan and Baldwin 1969; R. Seymour 1972; Lillywhite and Licht 1974). Salamanders, which lack a specialized pelvic patch, take up water from moist soil by spreading the legs to the sides of the body and flattening the entire ventral surface onto the substrate (Gehlbach, Kimmel, and Weems 1969; Marangio and Anderson 1977).

The rates of water uptake can be affected by morphological features of the skin other than the presence of highly vascularized ventral areas. Hillyard (1976a) found that soil tends to adhere more tightly to skin of burrowing frogs such as *Scaphiopus* than to more aquatic species. This in turn facilitated transfer of water by capillary action. In addition, many terrestrial anurans have elaborate epidermal sculpturing consisting of a network of warts and grooves (fig. 2.3). These channel water by capillary action from the ventral surface onto the dorsal skin (Lillywhite and Licht 1974). Terrestrial salamanders such as *Taricha* and the red eft stage of *Notophthalmus viridescens* also have rough epidermal sculpturing that serves the same function. Most other terrestrial urodeles have costal grooves at intervals along the sides of the body; these function as capillary tubes that draw water onto the dorsal surface of the skin (Lopez and Brodie 1977; S. Brown and P. Brown 1980).

Hormonal Regulation of Water Uptake

Rehydration from either water or soil is enhanced by physiological adjustments to dehydration, known collectively as the *water balance response.* Early work by Brunn (1921) demonstrated that frogs increased in mass when placed in water after being injected with extracts of the neurohypophysis, a portion of the pituitary gland. Subsequent work confirmed this, and by the 1950s, hormonal control of amphibian water balance had become a major focus of endocrine research (Heller 1974). Some 40 years after Brunn's initial discovery, arginine vasotocin (AVT) was identified as one hormone controlling water uptake (Sawyer, Munsick, and van Dyke 1959; Sawyer 1960a, b; Archer et al. 1960; Heller and Pickering 1961). This hormone is evolutionarily conservative, having the same structure in a variety of vertebrates from agnathans to amphibians, reptiles, and birds (Bentley 1974; Archer, Chauvet, and Rouillé 1997). It is distinct in structure from the mammalian antidiuretic hormone, arginine vasopressin (AVP), but has analogous physiological effects. Many amphibians also are sensitive to AVP, and this hormone has been widely used to investigate the water balance response (e.g., Ewer 1952; Bentley and Heller 1964; Heller and Bentley 1965; Hillman 1974; P. Brown and S. Brown 1977; P. Brown, Hastings, and Frye 1977). Quantitative comparisons among species are difficult because some species respond more strongly to AVT than to AVP, while others exhibit similar responses (Heller and Bentley 1965). There also is considerable variation in dosages of hormones used by different investigators to test the water balance response.

The role of arginine vasotocin in regulating amphibian water balance has been reviewed by many authors (Deyrup 1964; Gorbman 1964; Bentley 1969; 1974; Pang 1977; Sawyer and Pang 1979; Shoemaker et al. 1992; Archer, Chauvet, and Rouillé 1997), and only a brief summary will be given here. Dehydration triggers release of AVT from the neurohypophysis, and this in turn alters water balance by increasing the osmotic permeability of the skin to water (fig. 2.4) and the permeability of the bladder wall to water. AVT also enhances movement of urea across the bladder wall and decreases the rate of urine production by the kidneys (an antidiuretic effect; see "Water Storage" and "Kidney Function"). Some amphibians exhibit all of these responses, while in others AVT affects only the bladder or kidneys. As discussed in the section on skin structure and function, not all regions of the skin are equally sensitive to AVT, at least in anurans. Generally, pelvic skin shows a large increase in osmotic permeability to water in response to AVT, whereas skin from the dorsal surface, legs, or pectoral region does not (Bentley and Main 1972a; R. Baldwin 1974; Yorio and Bentley 1977; Parsons et al. 1978; Cree 1988a, b).

Several investigators have attempted to relate variation in responsiveness to neurohypophyseal hormones to differences in phylogenetic history or ecology. Bentley and Heller (1964) and Bentley (1973) found that the urodeles they tested exhibited little or no cutaneous response to these hormones, but they did show a decrease in urine production. This was taken as evidence that urodeles as a group have a less fully developed water balance response than most anurans, an interpretation that has been repeated in several general reviews (e.g., Heller 1965; Bentley 1969, 1971, 1974; Perks 1987). All of the urodeles used in these studies were either fully or largely aquatic (*Triturus, Siren, Amphiuma, Necturus, Ambystoma mexicanum*). Subsequent work demonstrated that some more terrestrial salamandrids and plethodontids do exhibit a cutaneous water balance response equivalent to that of many anurans (Warburg 1971a; Hillman 1974; P. Brown and S. Brown 1977; P. Brown, Hastings, and Frye 1977; S. Brown and P. Brown 1980). In newts (*Triturus* and *Notophthalmus*), individuals in the terrestrial stage of the life history exhibit stronger water balance responses than do those in the aquatic breeding stage (Warburg 1971a; P. Brown et al. 1983). Bentley and Yorio (1977) reported a modest increase in skin permeability in response to AVT in *Necturus.* These investigators used a more sensitive measurement technique than that employed by Bentley and Heller (1964). It is now clear that lack of a cutaneous response to AVT is not a general characteristic of urodeles.

Heller and Bentley (1965) compared the responses of anurans from several different families to neurohypophyseal hormones. They found little or no cutaneous response in *Xenopus* and *Discoglossus* and a relatively weak response in *Pelobates cultripes,* whereas species of *Hyla, Rana,* and *Bufo* had relatively strong responses. Following Noble's (1931) view of anuran phylogeny, they suggested that a poorly developed water balance response was characteristic of frogs in the more primitive families (Pipidae, Discoglossidae, Pelobatidae), whereas the more derived hylids, ranids, and bufonids had a more highly developed response. Their analysis was confounded by the fact that both *Xenopus* and *Discoglossus* are largely aquatic. The relatively weak response obtained with *Pelobates* might have been due to the condition of the animals. Hillyard (1975, 1976b) found that the skin of *Scaphiopus couchii* was responsive to AVT only in the first few days after emerging from dormancy, but not during the breeding season or after being held in the laboratory for several weeks. Later work by Cree (1985b, 1988a) convincingly refuted the idea that the lack of a cutaneous water balance response is an ancestral trait in frogs. Two species of *Leiopelma,* long considered the most primitive living anurans, show responses to AVT equivalent to those of more derived anuran families.

Many authors have suggested that variation in responsiveness to AVT is related to differences in habitat, with terrestrial species from dry environments showing stronger responses than aquatic species or terrestrial species from more mesic environments. This was first proposed by Steggerda (1937), who compared the responses of *Bufo americanus, Rana pipiens, R. clamitans,* and *Necturus maculosus* to pituitary extracts. The toads showed a rapid increase in water uptake, the frogs a lesser response, and *Necturus* showed no response at all. Subsequent comparisons of *Rana* with *Bufo* (C. B. Jørgensen 1950a; Heller and Bentley 1965; Degani 1985a), *Bufo* with *Xenopus* (Ewer 1952), *Bufo, Rana, Agalychnis,* and *Xenopus* (Yorio and Bentley 1978), and *Crinia* with several other genera (Bentley and Main 1972a) produced similar results. All of these comparisons suffer from the common problem of confounding phylogeny with ecology, since species representing different ecological adaptations also come from different families.

In general, comparisons of water balance responses among closely related species support the idea that terrestrial species are more responsive to neurohypophyseal hormones, but only a few studies have been done. P. Brown, Hastings, and Frye (1977) used AVP to compare responses of *Desmognathus quadramaculatus,* a largely aquatic plethodontid salamander, and four species of terrestrial *Plethodon. Desmognathus quadramaculatus* took up water relatively slowly after dehydration and showed no significant change in response to AVP. All of the other species had higher rehydration rates and responded to AVP by increasing water uptake. Furthermore, two species found in drier microhabitats, *Plethodon hoffmani* and *P. punctatus,* showed stronger responses than did closely related congeners of similar size, *P. cinereus* and *P. glutinosus,* both of which prefer wetter microhabitats. The aquatic and terrestrial species used in this study are in different subfamilies, so it still is possible that phylogenetic history is responsible for the differences in response to the hormone treatments. A comparison of *Desmognathus quadramaculatus* with more terrestrial members of the same genus, such as *D. ochrophaeus* and *D. wrighti,* would be most instructive.

Studies of *Leiopelma* in New Zealand by Cree (1985b, 1988a) are of particular interest because these frogs are thought to represent an ancient lineage. Earlier work by Cameron (1974; cited in Cree, 1988a) had shown that *L. hochstetteri* did not respond to hormone treatments by increasing water uptake, a result supporting Heller and Bentley's (1965) hypothesis that primitive frogs never evolved a water balance response. *Leiopelma hochstetteri* is the most aquatic of the three living species in the genus. Cree showed that the two more terrestrial species, *L. archeyi* and *L. hamiltoni,* not only had much higher rehydration rates than did *L. hochstetteri,* but they also exhibited a cutaneous response to AVT equivalent to that observed in myobatrachids, hylids, bufonids, and ranids. The strength of the water balance response in these species is somewhat surprising, since they are active only in relatively wet microhabitats (Cree 1989) and lack morphological specializations for water uptake, such as epidermal sculpturing and ventral warts (Cree 1985b).

In contrast to these studies, a comparison of several species of Australian frogs in the genus *Litoria* suggests that phylogenetic history sometimes can be more important than ecology in determining the nature of the water balance response. Two species in this genus, *L. aurea* and *L. raniformis,* are ranidlike semiaquatic frogs that frequent the banks of streams, whereas most other species in the genus, including *L. ewingi,* are arboreal. *Litoria aurea, L. raniformis,* and *L. ewingi* all exhibit strong cutaneous responses to AVT, irrespective of the habitat in which they are found (Cree 1985a, 1988b). Furthermore, *L. aurea* retains the well-vascularized, warty ventral skin characteristic of arboreal frogs, despite its semiaquatic habits. Since this species appears to be derived from an arboreal ancestor, Cree suggested that the lack of congruence among ecology, morphology, and hormonal responses is a product of phylogenetic history. Alternatively, she speculated that *L. aurea* spends much of its time basking along the shoreline, resulting in high rates of evaporative water loss that would make rapid rehydration advantageous.

Although most work on hormonal control of water balance in amphibians has focused on the role of arginine vasotocin, this hormone is not the only one that affects water balance. Indeed, C. B. Jørgensen (1992a) argued that dosages of AVT required to elicit a water balance response in experimental studies are many times higher than circulating levels of AVT found in dehydrated anurans. He suggested that AVT is less important in regulating water balance than previously thought, or that it acts in conjunction with other hormones to affect rates of water uptake.

Another class of neurohypophyseal hormones, termed hydrins, has been found in several families of anurans. These are structurally related to vasotocin and have a similar effect on the permeability of the skin and bladder (Rouillé et al. 1989). They do not, however, have the same antidiuretic effect on kidney function as AVT (Archer, Chauvet, and Rouillé 1997). Another hormone, prolactin, has an effect opposite to that of AVT, reducing osmotic permeability of the skin and retarding water uptake. This has been studied mainly in aquatic salamandrids, and is discussed in more detail in the section on adaptations to aquatic life. Epinephrine (adrenaline), which is produced in the medulla of the adrenal gland, can have several β-adrenergic effects on tissues, including dilation of blood vessels. β-adrenergic effectors have been shown to increase the osmotic permeability of the skin in some amphibians (Hillyard 1979; de Sousa and Grosso 1982; Yokota and Hillman 1984). The action of these hormones apparently is independent of AVT and has an even stronger effect on skin permeability. However, very little is known about the physiological significance of these effects or their relationship to amphibian ecology (Shoemaker et al. 1992).

Another hormone, angiotensin II, appears to be of primary importance in regulating the water absorption behavior of anurans (Hillyard, von Seckendorff Hoff, and Propper 1998; Hillyard 1999), as well as water-seeking behavior (Viborg and Rosenkilde 2001). In other vertebrates, including mammals, this hormone regulates drinking behavior. Anurans do not drink by taking water into the mouth, but the behavior of pressing the highly permeable pelvic skin to a wet substrate serves the same physiological function. Hoff and Hillyard (1991) injected fully hydrated toads (*Bufo punctatus*) with different dosages of the human form of angiotensin II. Even very low dosages elicited water absorption behavior. This was inhibited by injection of saralasin, an inhibitor of angiotensin II. In a subsequent study, Hoff and Hillyard (1993) showed that injection of saralasin into dehydrated toads inhibited water absorption behavior, whereas dehydrated toads in the control treatment continued to take up water from a wet substrate. This indicated that angiotensin II is involved in water absorption behavior. Subsequent work has shown that angiotensin II regulates water absorption mainly by inducing anurans to place the pelvic patch onto a substrate (Goldstein, Hoff, and Hillyard 2003). W. Johnson and Propper (2000) reported that dehydration alone is not sufficient to increase circulating levels of angiotensin II in spadefoot toads (*Scaphiopus couchii*), even though dehydrated toads exhibit an increased water absorption response. Indeed, dehydrated toads exhibit a stronger water absorption response than do hydrated toads injected with angiotensin II (Goldstein, Hoff, and Hillyard 2003).

Tran, Hoff, and Hillyard (1992) used a form of angiotensin II derived from bullfrogs (*Rana catesbeiana*) to induce a water absorption behavior in *Bufo woodhousii.* The same form of the hormone induced a water absorption response in *Bufo cognatus* and *Scaphiopus couchii* when injected into the peritoneal cavity (Propper and Johnson 1994) or directly into the brain (Propper, Hillyard, and Johnson 1995). Injection of AVT into the peritoneal cavity failed to induce a water absorption response, however. Angiotensin II also increases blood flow to the pelvic patch, as well as water uptake across the pelvic patch (Slivkoff and Warburton 2001), perhaps in conjunction with regulation of water uptake by bladder volume. Toads with empty bladders initiate water absorption behavior and have a higher rate of water uptake, and when toads with full bladders are injected with angiotensin II, they also take up more water (Parsons et al. 1993). It is possible that stretch receptors monitor bladder volume and trigger production of angiotensin II in toads with decreased bladder volume, but the precise mechanism is not known (Parsons 1994). Actual water uptake by the pelvic skin appears to be triggered by direct contact with water on the substrate (Viborg and Rosenkilde 2004). Anurans have chemical detectors in the pelvic skin that are highly sensitive to the salt concentration of soil, and they avoid sitting on hyperosmotic substrates that would make water uptake impossible (Kostinsky, Miller, and Stewart 2000; Koyama et al. 2001; Hillyard et al. 2004).

Water Storage

When the explorer and anthropologist Baldwin Spencer traveled through the Australian Outback in the late nineteenth century, the local aborigines demonstrated how they made use of an unusual water-holding frog, *Cyclorana platycephala,* by squeezing the body to bring forth “a wine glass full of sweet water” (B. Spencer 1896, pp. 163–64). Although he later revised his estimate downward to “one or two teaspoons” of water (B. Spencer 1928, vol. 1, p. 45), Spencer remained impressed by the ability of this frog to store water in one of the driest deserts on earth. The water-storing capacity of this species is impressive, with bladder contents sometimes being more than 130% of the remaining body mass in frogs excavated from burrows in the field (van Beurden 1984). This is by no means unique, however; many amphibians store large amounts of water that serve as important reserves during dry periods. Some water is stored in the tissues, and fully hydrated amphibians have somewhat higher body water content than most other vertebrates (Shoemaker and Nagy 1977), but the principal water reserves are stored in the urinary bladder.

Some fishes have urinary bladders, but these are not homologous to the urinary bladder of tetrapods, which is an amphibian innovation. The amphibian urinary bladder is formed as a ventral outpocketing of the cloaca, and urine produced by the kidneys first enters the cloaca before moving into the bladder (Bentley 1966b). Precise measurements of bladder capacity are difficult because it readily expands as it is filled. Most authors agree that aquatic anurans and urodeles have smaller bladder volumes (< 5% of total body mass) than terrestrial and arboreal species (25–50% of total body mass; Bentley 1966b; W. Schmid 1969; Espina and Rojas 1972; Claussen 1974; Shoemaker et al. 1992). The aquatic urodele *Siren lacertina,* which often is forced to estivate in drying mud during the summer, has a maximum bladder volume of about 10% of total body mass (Etheridge 1990b), approaching that of the semiaquatic frog *Rana clamitans* (Schmid 1969; Claussen 1974). The largest bladder capacities are found in burrowing anurans from arid regions, including species of *Bufo, Scaphiopus, Spea, Neobatrachus,* and *Cyclorana.* In some cases, the mass of bladder water in estivating individuals exceeds total body mass with bladder water removed (Shoemaker et al. 1969; van Beurden 1984).

It is assumed that all amphibians with relatively large bladder storage capacities can make use of the stored water by resorbing it across the bladder wall, thereby maintaining a relatively stable body fluid osmotic concentration at least during the early stages of desiccation. Experiments with *Bufo, Scaphiopus, Cyclorana, Phyllomedusa,* and *Ambystoma* have shown that body fluid concentrations rise more rapidly in animals subjected to desiccation after removal of bladder water reserves than in individuals with bladder reserves intact (Ruibal 1962; Shoemaker 1964; McClanahan 1967; Alvarado 1972; Shoemaker and Bickler 1979; van Beurden 1984; Katz and Gabbay 1986). As long as the animals do not lose a substantial amount of water to the surrounding soil, bladder water reserves often are sufficient to sustain burrowed amphibians for many months.

In both anurans and urodeles, the resorption of water from the bladder is enhanced by the action of neurohypophyseal hormones such as AVT. These hormones have several effects, including increasing the permeability of the bladder wall to water, increasing the rate of active transport of sodium across the bladder wall, and increased permeability of the bladder wall to urea (Bentley 1966b; Shoemaker et al. 1992). Active transport of sodium into the tissues from bladder water reserves allows the animal to maintain a positive osmotic gradient for passive diffusion of bladder water into the tissues, counteracting the increase in osmotic concentration inside the bladder as water reserves are drawn down. The accumulation of urea in the plasma also facilitates water resorption by further increasing the osmotic gradient. In some amphibians, the bladder wall appears to be more sensitive to neurohypophyseal hormones than the skin (Bentley 1966b), and a bladder response is present even in some urodeles that exhibit a relatively weak cutaneous water balance response (Warburg 1972). The strength of the bladder response does not seem to be clearly correlated with habitat, at least in urodeles. Some aquatic and terrestrial salamanders, including *Notophthalmus, Triturus, Salamandra,* and *Aneides,* show a substantial increase in bladder water resorption in response to AVT (Bentley and Heller 1965; Warburg 1971b; Hillman 1974; P. Brown and S. Brown 1977). In terrestrial species such as *Plethodon glutinosus,* the effect on the bladder appears to be minimal (P. Brown, Hastings, and Frye 1977).

The Physiology of Desiccation Tolerance

Despite the various means employed by amphibians to avoid excessive water loss, many species are exposed to dehydrating conditions on a regular basis, and their ability to survive in a particular habitat depends on their ability to tolerate desiccation. Severe dehydration has a detrimental effect on many physiological systems, but changes in osmotic concentration, ion balance, and the circulatory system have received the most attention (Shoemaker et al. 1992). As water is lost from the body, the concentration of solutes in the body necessarily rises. As long as bladder water is available to the animal, the effect on tissues is minimal. Excessive dehydration, on the other hand, can result in sharp rises in concentrations of urea, sodium, potassium, and other solutes in the plasma and body tissues (Shoemaker 1964; Ruibal, Tevis, and Roig 1969; Shoemaker, McClanahan, and Ruibal 1969; Alvarado 1972; McClanahan 1972; Degani and Warburg 1984; Degani, Silanikove, and Schkolnik 1984; Degani 1985b, c; Hillman 1978a, 1982a, 1988; Katz and Gabbay 1986). Physiological regulation of water content in critical sites such as brain tissue minimizes the detrimental effects of increased osmotic concentration (Hillman 1988). Nevertheless, severe dehydration clearly affects organ and tissue function and reduces an animal's capacity for muscle contraction, locomotion, and aerobically supported activity (McClanahan 1964; Hillman 1982a, 1984, 1987; Pough et al. 1983; Beuchat, Pough, and Stewart 1984; Feder and Londos 1984; Gatten 1987a; Gatten and Clark 1989; Moore and Gatten 1989; Stefanski, Gatten, Jr., and Pough 1989). In addition to direct effects on muscle tissue, dehydration reduces heart rate and increases blood viscosity, resulting in a decrease in blood flow to the tissues (Hillman 1978b, 1987; Hillman et al. 1985; Hillman, Zygmunt, and Baustian 1987; Shoemaker et al. 1992). Anurans that have relatively large heart ventricles in relation to body size tend to be more tolerant of dehydration than are those with relatively smaller ventricles (Hillman, Withers, and Drewes 2000). This could be due to the higher stroke volume of species with large ventricles and a greater capacity to pump viscous blood to body organs.

Most comparative studies have focused on the physiological tolerance of amphibians, the point at which a desiccated animal is physiologically incapacitated and likely to die if not removed from the desiccating conditions. Various measures of physiological desiccation tolerance have been used. These include the percentage of body mass or body water lost at death (Thorson and Svihla 1943; Bentley, Lee, and Main 1958; Ray 1958; Main and Bentley 1964; Schmid 1965; Jaeger 1971b) and the percentage lost when the animal can no longer right itself when turned on its back (Ray 1958; Whitford 1968; Farrell and MacMahon 1969; Larson 1971; Ralin and Rogers 1972; Hillman 1980b; Pough, Stewart, and Thomas 1977; Layne, Romano, and Guttman 1989). The second criterion, termed the critical activity point (CAP) by Ray (1958), has proven to be the more easily replicated measure and has become the standard for most such studies.

Broad comparative studies involving anurans from several families, including ascaphids, pipids, ranids, hylids, bufonids, and pelobatids, have shown a positive correlation between desiccation tolerance and degree of terrestrialism (Thorson and Svihla 1943; Thorson 1955; Schmid 1965; Claussen 1973b; Hillman 1980b). Aquatic and semiaquatic species such as *Xenopus, Ascaphus,* and *Rana* generally cannot tolerate a loss of more than 40% of total body mass. Some arboreal, terrestrial, and fossorial species of *Hyla, Bufo,* and *Scaphiopus* can tolerate losses of 45–50% of total body mass, and up to 60% of total body water content. The problem of ecological adaptations being confounded with phylogenetic effects is again evident in these cross-family comparisons.

Studies comparing desiccation tolerance within families, within genera, or even among populations of the same species generally have confirmed that amphibians from drier environments tend to be more tolerant of desiccation, although this is not always true (e.g., Bentley, Lee, and Main 1958). For example, comparisons among plethodontid salamanders have shown that aquatic species of *Desmognathus* and *Eurycea* are less tolerant of desiccation than are more terrestrial species of *Plethodon, Aneides, Ensatina,* and *Batrachoseps* (Littleford, Keller, and Phillips 1947; Ray 1958). M. Houck and Bellis (1972) reported that *Desmognathus ochrophaeus* is more tolerant of desiccation than is the more aquatic *D. fuscus.* Similarly, Jaeger (1971b) found that *P. shenandoah* is more tolerant of dry conditions than is *P. cinereus,* and can occupy rocky habitats unsuitable for the latter species. Even within species, such differences are evident; the terrestrial eft stage of the newt *Notophthalmus viridescens* tolerates greater water loss than does the aquatic adult stage (Walters and Greenwald 1977).

Several studies of leptodactylid and hylid frogs, including many arboreal species, have shown that species from dry habitats tend to tolerate greater loss of water than do those from wet habitats. Pough, Stewart, and Thomas (1977) found that two frogs introduced into Jamaica, *Eleutherodactylus planirostris* and *E. johnstonei,* tolerated much higher levels of water loss than did two native species, *E. cundalli* and *E. gossei,* and were found in correspondingly drier habitats. The Australian tree frog *Litoria caerulea,* which lives in hot tropical areas, is more tolerant than are species living in temperate areas (Main and Bentley 1964). Among North American hylids, semiaquatic species such as *Acris* are the least tolerant of desiccation, whereas semifossorial species such as *Hyla gratiosa* and *Pseudacris streckeri* are the most tolerant; arboreal species are intermediate (Farrell and MacMahon 1969; Ralin and Rogers 1972). A genetic basis for differences in desiccation tolerance was indicated by a comparison of *Hyla gratiosa, H. cinerea* and their hybrids. *Hyla gratiosa* was more tolerant than was *H. cinerea.* Hybrids were intermediate and showed a wide range of variation depending on the relative genetic contribution of the two parental species (Layne, Romano, and Guttman 1989).

Experimental studies of physiological desiccation tolerance provide some information on the ability of amphibians to tolerate extreme environmental conditions, but most amphibians probably retire to shelters or burrows before approaching their physiological limits. It is much more difficult to measure a species' ecological tolerance—the level of dehydration the animals will accept while continuing routine activities such as foraging or advertising for mates. Even submaximal levels of desiccation can depress metabolic rates (Pough et al. 1983; Gatten 1987a; Hillman 1987) and measures of behavioral performance such as stamina, sprint speed, or foraging ability (Beuchat, Pough, and Stewart 1984; Feder and Londos 1984; Gatten and Clark 1989; F. Moore and Gatten 1989; Stefanski, Gatten, and Pough 1989). Most amphibians probably restrict their activities well before they reach a level of dehydration sufficient to produce such effects. For example, the use of water-conserving postures by free-ranging *Eleutherodactylus coqui* limits water loss even on relatively dry nights to about 8% of initial values (Pough et al. 1983), a level that has relatively little effect on either oxygen consumption or jumping ability (Beuchat, Pough, and Stewart 1984). Similarly, cricket frogs (*Acris crepitans*) in the field averaged more than 97% hydration, a level more than sufficient for maximum jump performance (Walvoord 2003). Feder and Londos (1984) found that salamanders (*Desmognathus ochrophaeus*) maintained in the laboratory in relatively dry air would stop foraging and seek out moist retreat sites after losing only 3–4% of their initial body mass. That level of dehydration had little or no effect on foraging ability or several measures of locomotor performance. This suggests that the long-term benefits of maintaining water reserves outweigh the short-term benefits of continuing to forage under less-than-ideal conditions.

Osmoregulation in Aquatic Environments

Life in the water presents amphibians with fewer challenges than life on land, but it is not free of difficulty. Amphibians in fresh water always have an internal osmotic concentration that is higher than the surrounding environment. Because the skin is highly permeable to water in all amphibians, water tends to be drawn into the body, threatening to upset the water and ion balance of the animal. To compensate for this excess water uptake, amphibians produce large quantities of urine, sometimes voiding the urine as frequently as every 10–15 minutes. Excess water cannot be eliminated without cost, however. Increased production of urine can increase metabolic energy expenditures considerably (Potts 1954). Production of large volumes of urine also creates problems for ion balance, because sodium, potassium, chloride, and other ions are lost with the urine. Further ion losses occur through diffusion across the skin. The principal challenge for amphibians in freshwater habitats is to balance water uptake with water loss while maintaining internal ion concentrations at relatively stable levels. This can be accomplished in several ways: (1) by reducing the rate of water intake, (2) by actively taking up ions from the water to compensate for ion loss, or (3) by reclaiming ions in the urine before they are eliminated from the body. The last two processes further add to the energetic cost of osmoregulation, because they require movement of ions against concentration gradients (Shoemaker and Nagy 1977; Shoemaker 1987; Boutilier, Stiffler, and Toews 1992).

Skin Permeability and Hormonal Control of Water Balance

As discussed in the section on water uptake in terrestrial amphibians, the skin of aquatic amphibians tends to have a lower osmotic permeability to water than that of terrestrial species. For example, Yorio and Bentley (1978) found that isolated skin from *Xenopus laevis* and *Necturus maculosus,* both highly aquatic species, was 5–20 times less permeable to water than that of *Rana pipiens, Bufo marinus or Pachymedusa dacnicolor.* Both Schmid (1965) and Bentley and Yorio (1976) found that permeability of isolated skin was positively correlated with degree of terrestrialism in a comparison of several ranid and bufonid species. Lower skin permeability in aquatic anurans and salamanders results in lower rates of osmotic water uptake (Mullen and Alvarado 1976; G. Baldwin and Bentley 1982). Comparison of osmotic water flux in a terrestrial caecilian (*Ichthyophis kohtaoensis*) with that of an aquatic species (*Typhlonectes compressicauda*) showed the same pattern; the aquatic caecilian had a much lower rate of water uptake when the animals were submerged in water (Stiffler, DeRuyter, and Talbot 1990).

Pruett, Hoyt, and Stiffler (1991) used data from published literature to compare osmotic flux of water across the skin in aquatic and terrestrial amphibians after correcting for the effects of body size (osmotic flux increases with body size). They could make statistical comparisons only for terrestrial anurans and aquatic salamanders because of small sample sizes, so there is a serious problem of comparing phylogenetically distant groups in this study. Nevertheless, the analysis supported the conclusions of previous workers that aquatic amphibians have lower osmotic flux. Aquatic amphibians also tend to exhibit less change in osmotic permeability in response to neurohypophyseal hormones, presumably because there is little advantage for amphibians living in water to increase rates of water uptake (see further discussion in the earlier section on "Hormonal Control of Water Uptake").

In at least some species that make seasonal movements between water and land, the skin undergoes a corresponding seasonal change in osmotic permeability. This has been studied primarily in newts (Salamandridae). In *Triturus carnifex,* osmotic water flux across the skin is much lower in aquatic animals collected in winter compared to terrestrial animals collected in the summer (fig. 2.16). This reduction in permeability can be induced in terrestrial-phase newts by treating them with the hormone prolactin (Lodi, Biciotti, and Viotto 1982). Similar results have been obtained with North American newts (*Notophthalmus, Taricha;* P. Brown and S. Brown 1973, 1982, 1987; Harlow 1977; S. Brown and P. Brown 1980; P. Brown et al. 1983). A reduction in permeability is seen only after relatively long-term exposure to prolactin, and is assumed to be adaptive in reducing problems of excess hydration in aquatic-phase animals. Several authors have reported that short-term exposure to prolactin actually increases osmotic water uptake in some amphibians (Goldenberg and Warburg 1977, 1983; Warburg and Goldenberg 1978). P. Brown and S. Brown (1987) attributed these results either to pharmacological effects of extremely high dosage levels, or to contamination of hormone preparations used in the experiments. Prolactin also is thought to be responsible for inducing a "water drive" in newts and other amphibians, causing them to search for water at the beginning of the breeding season (Dent 1985), but this has been questioned by some workers (Ishii et al. 1989; Hasumi and Iwasawa 1992).

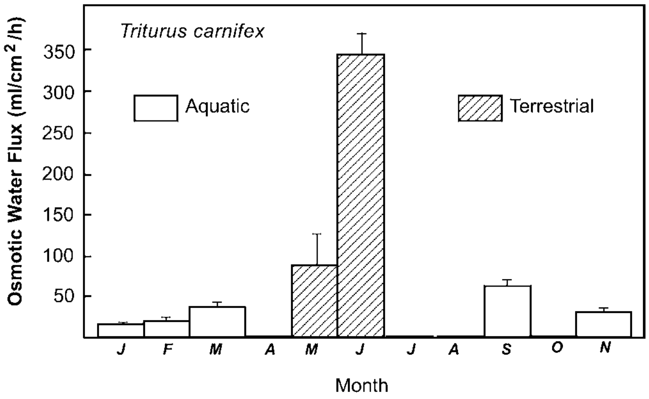

Fig. 2.16. Change in osmotic water flux across the isolated skin of Alpine crested newts, *Triturus carnifex,* collected in different months in the terrestrial and aquatic phases of the life history. Bars show means + 1 SE. Terrestrial newts collected in the summer had much higher skin permeability to water than did those collected in water at other seasons. Plotted from data in Lodi, Biciotti, and Viotto (1982).

Regulation of Ions in Fresh Water

If amphibians were not able to regulate internal ion concentrations by compensating for loss of ions through the skin and urine, then prolonged exposure to fresh water could be fatal. Some species are able to survive long periods of severe hydration stress without apparent detrimental effects. For example, semiaquatic frogs such as *Rana clamitans, R. pipiens,* and *R. esculenta* can survive for several months in distilled or deionized water, even when they are not provided with food (Krogh 1937; Schmid 1965; McAfee 1972). In contrast, Schmid (1965) found that terrestrial or arboreal species of *Bufo, Hyla,* and *Pseudacris* did not do as well under the same conditions, generally lasting less than 10 days. *Rana sylvatica,* a semi-terrestrial species, was intermediate between semiaquatic ranids and terrestrial and arboreal frogs, surviving for about 20 days in distilled water. The deaths of these frogs probably resulted from excessive loss of sodium and other ions and the inability of the animals to compensate their losses by intake of ions in food or through the skin. The greater survival of the more aquatic species could have been due to lower rates of water uptake and sodium loss across the skin, a greater capacity for reclaiming ions in the urine, or a greater capacity to take up ions across the skin.

The ability of amphibian skin to take up ions, particularly sodium and chloride, against a highly unfavorable osmotic gradient was first demonstrated by the pioneering work of Krogh (1937, 1938) and Ussing (1949). Since then, frog skin has been widely used as a model system to understand basic processes of ion exchange across epithelial membranes, and there is a vast literature on the mechanisms of ion exchange. A thorough discussion of ion exchange mechanisms is beyond the scope of a book on amphibian ecology, and the subject has been reviewed in detail several times (Alvarado 1979; Kirschner 1983; Katz 1986; Stiffler 1988; Boutilier, Stiffler, and Toews 1992; Katz and Nagel 1994). Briefly, work on ion exchange has shown that both sodium (NA^+) and chloride (CL^-) ions are actively transported from the external environment. Transport of these ions is independent, with NA^+ being exchanged for ammonium (NH_4^+) ions and CL^- being exchanged for bicarbonate (HCO_3^-) ions to maintain electroneutrality across the membrane.

All amphibians have some capacity for active ion uptake, even when ion concentrations in the environment are 1/100th those inside the animal. Studies of anurans and urodeles have shown that aquatic species often have a greater capacity for active ion uptake than do terrestrial or arboreal species (Greenwald 1972; Mullen and Alvarado 1976). These data must be interpreted with caution, since different genera and even different families have been used to represent different habitats. A comparison of the aquatic caecilian *Typhlonectes compressicauda* and a terrestrial species, *Ichthyophis kohtaoensis,* did not show the same pattern. The aquatic species had neither a higher apparent affinity for sodium nor a higher maximum capacity for sodium transport than the terrestrial species (Stiffler, DeRuyter, and Talbot 1990). One must be cautious in extrapolating from this two-species comparison, because these caecilians not only live in different habitats, but also are members of different clades (see chapter 1). Furthermore, the aquatic species is thought to have evolved from terrestrial, burrowing ancestors.

There is some evidence for evolutionary adaptation of purely aquatic species to environments with different ionic concentrations. Mullen and Alvarado (1976) found that the skin of *Ascaphus truei,* an inhabitant of mountain streams with very low solute content, could take up sodium from more dilute solutions than could the skin of pond-dwelling anurans. A phylogenetically controlled comparison is virtually impossible in this case, because closely related pond-dwelling species are not available. In general, larval amphibians have lower rates of sodium uptake than do adults. Larvae also tend to have lower rates of water intake and lower rates of sodium loss, so less compensation is required (Alvarado and Kirshner 1963; Bentley and Baldwin 1980). In most amphibian larvae, gills are thought to be more important sites for ion exchange than the skin (Alvarado and Moody 1970; Dietz and Alvarado 1974; Cox and Alvarado 1979; T. Cox 1986; Boutilier et al. 1992).

The ability to take up ions from the water is an important adaptation for aquatic life, but this alone would not be sufficient to prevent disruption of the internal osmotic environment if amphibians lost vast quantities of ions in their urine. Amphibians have a remarkable ability to reclaim ions from the urine before it is eliminated, thereby helping to maintain a stable ion balance in the body. Initial resorption of sodium, chloride, and potassium ions takes place in the kidney tubules and involves active transport of ions against a concentration gradient. Again, there is a large literature on the precise mechanisms of ion resorption that need not be discussed here (see Boutilier et al. 1992 for a review). Quantitatively the resorption of ions by the amphibian kidney is impressive. Studies of various aquatic salamanders have shown that 90–96% of the sodium and chloride and a slightly lower proportion of the potassium ions in the urine are reclaimed, making the final product extremely dilute (Wiederholt et al. 1971; Stiffler and Alvarado 1974, 1980; Boutilier, Stiffler, and Toews 1992). Ion conservation is further enhanced by active transport of ions across the bladder wall, and the anuran bladder has been widely used as a model system for studying ion transport (Bentley 1966b; McKnight, DiBona, and Leaf 1980). Most work on resorption of ions by the bladder has been done on bladders removed from the animals, but Sinsch (1991c) reported results on intact animals demonstrating active transport of ions across the bladder wall in fully hydrated frogs. He also found that resorption of ions was somewhat more efficient in semiaquatic ranids (*Rana ridibunda* and *R. lessonae*) than in a more terrestrial species (*R. temporaria*).

Osmoregulation in Acidic Environments

A number of environmental variables can affect rates of ionic exchange between amphibians and their surroundings. Of special concern is the effect of acidification of aquatic habitats by acid rain (Dunson, Wyman, and Corbett 1992). Low pH (high acidity) can adversely affect osmoregulation in larval amphibians by substantially increasing rates of sodium ion loss through the skin and by inhibiting the active uptake of sodium from the water (Freda and Dunson 1985a, 1986a; McDonald, Ozog, and Simons 1984; Freda 1986, 1991). For some species, exposure to water with pH below 4.0 can result in the loss of more than 50% of total body sodium, with fatal consequences. Other species are somewhat more tolerant. For example, *Rana clamitans* tadpoles had lower rates of sodium ion loss at low pH than did *R. pipiens* or *R. catesbeiana* tadpoles exposed to the same conditions (fig. 2.17). *Rana clamitans* also had higher initial concentrations of sodium in the body, perhaps allowing it to survive longer in environments that induce rapid sodium loss (Freda and Dunson 1984). A few species of amphibians, including *Hyla andersoni, H. femoralis, Rana virgatipes,* and *Xenopus gilli* have eggs and larvae

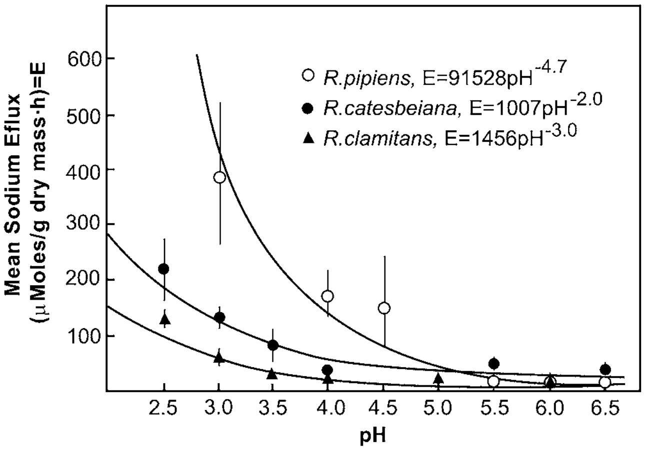

Fig. 2.17. Comparison of rates of sodium ion loss at different pH levels in tadpoles of North American leopard frogs (*Rana pipiens*), bullfrogs (*R. catesbeiana*), and green frogs (*R. clamitans*). Increased water acidity (lower pH) results in higher rates of ion loss in all three species. After Freda and Dunson (1984).

with unusually high tolerance to low pH, and consequently can live in acidic swamps and bogs not inhabited by other amphibians (Warner, Dunson, and Travis 1991; Picker, McKenzie, and Fielding 1993).

Ecological consequences of low pH in breeding ponds include direct effects such as delayed hatching of eggs and increased mortality of eggs and larvae. There also can be indirect effects, such as alterations in growth rate, changes in the outcome of competitive interactions among different species of larvae, and changes in predator-prey interactions (Pough 1976; Pough and Wilson 1977; Tome and Pough 1982; Freda and Dunson 1985b, 1986b; Pierce 1985; Cummins 1986, 1989; Warner, Dunson, and Travis 1991; Warner, Travis, and Dunson 1993; Beattie and Tyler-Jones 1992; Karns 1992; Pierce and Wooten 1992; Sadinski and Dunson 1992; K. Grant and Licht 1993; see also chapters 15 and 16). Some amphibian larvae are capable of avoiding highly acidic microhabitats (Freda and Taylor 1992), but it is not clear whether adults actively avoid breeding in such sites (Karns 1992).

Osmoregulatory problems caused by acidic conditions are not limited to aquatic amphibians. Studies of terrestrial salamanders have shown that acidic soil can induce the same osmoregulatory responses seen in aquatic amphibians. *Plethodon cinereus, Eurycea bislineata,* and *Desmognathus ochrophaeus* all suffered rapid loss of sodium ions when exposed to substrates with pH below 4.0 (Frisbie and Wyman 1991, 1992). Terrestrial efts (*Notophthalmus viridescens*), on the other hand, were relatively tolerant of acid conditions and suffered much lower rates of sodium loss. These data are consistent with field and laboratory studies showing a strong tendency for *P. cinereus* and other terrestrial plethodontids to avoid acidic substrates (Vernberg 1955; Mushinsky and Brodie 1975; Wyman and Hawksley-Lescault 1987; Wyman 1988; Wyman and Jancola 1992). Although terrestrial ecosystems are better buffered against the effects of manmade acid rain than are many aquatic habitats, there is a possibility that further acidification of terrestrial environments could have serious consequences for many amphibian species (Wyman 1990; see also chapter 16).

Osmoregulation in Saline Environments

Amphibians do not normally frequent environments with high salt concentrations, where they would be subjected to excessive water loss and high rates of sodium and chloride uptake through their permeable skin. Most species are killed very quickly by immersion in full-strength seawater. This intolerance of saline environments undoubtedly has been the major barrier to dispersal of amphibians onto distant oceanic islands. However, some amphibians are surprisingly tolerant of high salt concentrations. Some species venture into saline environments only occasionally, perhaps while foraging along a beach or at the margins of a salt marsh (W. T. Neill 1958). Others make use of moderately saline environments on a regular basis and exhibit various physiological adaptations to elevated salt concentrations (Ruibal 1959, 1962; J. Balinsky 1981; U. Katz 1989; Katz and Hoffman 1990; Shoemaker et al. 1992; Markow 1997; Gomez-Mestre and Tejedo 2003).

The best known of these salt-tolerant species is the crab-eating frog (*Fejervarya cancrivora*) of Southeast Asia. It has been known since the nineteenth century that this frog is found in peculiar habitats for an amphibian, including estuarine mudflats and mangrove swamps, although it also is widely distributed in freshwater habitats such as rice fields (Premo and Atmowidjojo 1987). The physiological mechanisms that allow this species to survive in saline environments were first described in classic work by Malcolm Gordon and his colleagues in the early 1960s. Adult crab-eating frogs can live in full-strength seawater and often feed on crabs and other marine invertebrates. These frogs can maintain plasma osmotic concentrations above that of the environment even in nearly full-strength seawater (fig. 2.18). They do so by retaining large quantities of solutes, including urea, sodium and chloride ions, and free amino acids. Urea accounts for about 60% of the increase in osmolality of the plasma, with the rest being mainly sodium and chloride ions. These ions are maintained at relatively low levels inside the cells of muscles and other tissues, but intracellular concentrations of free amino acids can be nearly three times higher in seawater than in fresh water. Urea concentrations can be nearly 10 times higher (M. Gordon, Schmidt-Nielsen, and Kelly et al. 1961; M. Gordon and Tucker 1968).

Because crab-eating frogs move frequently between fresh-

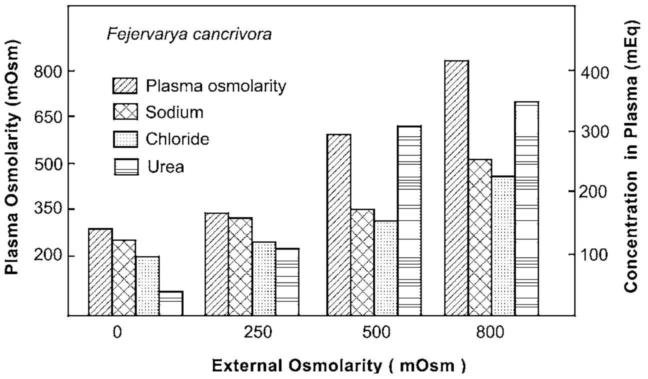

Fig. 2.18. Change in plasma urea, chloride, and sodium ion concentration and total plasma osmolality as a function of external osmotic concentration in the Southeast Asian crab-eating frog, *Fejervarya cancrivora.* Urea contributes the most to increased plasma osmolarity when the frogs are in salty water. After Gordon and Tucker (1965).

water and saltwater habitats of different concentrations, they need to respond to changes in salinity relatively quickly. One short-term response is to reduce rates of urine production by the kidneys, thereby retaining more urea as it is produced. Crab-eating frogs show a relatively small reduction in urine production compared to other species subjected to osmotic stress. This frog apparently does not resorb urea in the kidney tubules, an osmoregulatory adaptation found in marine elasmobranchs (Schmidt-Nielsen and Lee 1962). Urea retention is enhanced by increased permeability of the bladder wall to urea, brought about by a rapid increase in circulating levels of the hormone AVT (Chew, Elliot, and Wong 1972; Elliot and Chew 1973). AVT does not increase permeability of the skin to water in this species as it does in many other amphibians, a response that would be maladaptive because it would result in increased water loss across the skin (Dicker and Elliot 1970). Longer-term adaptation to high salinity involves increased synthesis of urea, brought about by increased activity of urea cycle enzymes in the liver (Balinsky, Dicker, and Elliot 1972).

Most amphibian larvae are even less tolerant of high salinity than adults (Shoemaker et al. 1992), but the tadpoles of *Fejervarya cancrivora* are an exception. They can tolerate very high salt concentrations and have been found living in brackish water pools at temperatures approaching 40° C without apparent detrimental effects (M. Gordon, Schmidt-Nielsen, and Kelly 1961; Dunson 1977). This high salinity tolerance is achieved without increasing plasma urea concentrations, because the tadpoles apparently do not acquire the capacity to synthesize urea until just before metamorphosis (Balinsky 1981). The tadpoles do increase plasma concentrations of sodium and chloride ions, but these are maintained below the level of the environment at high salinity. Apparently the tadpoles osmoregulate by taking in salty water with their food and then excreting excess salts by active transport across the gill membranes, a strategy common in saltwater fishes (M. Gordon and Tucker 1965).

Other ranid frogs are found mainly in freshwater habitats, but some species are capable of living in brackish springs, tidal streams, or salt marshes (Annandale 1907; Bertin 1920; Brues 1932; W. T. Neill 1958; Ruibal 1959, 1962; Christman 1974). They survive in such environments by increasing internal solute concentrations. Other frogs in this family are not known to accumulate levels of urea in the plasma and tissues approaching those found in crab-eating frogs. In fact, the concentrations of urea in the muscle tissue of *Fejervarya cancrivora* would be sufficient to incapacitate the muscles of most other frogs (Thesleff and Schmidt-Nielsen 1962; McClanahan 1964). None of the other ranids that have been tested can survive prolonged exposure to very high salinity. These include *Hoplobatrachus tigerinus* (M. Gordon, Schmidt-Nielsen, and Kelly 1961), *R. pipiens* (Homan 1968; Bentley and Schmidt-Nielsen 1971; Jungreis 1971), *R. utricularia* (Christman 1974), *R. temporaria* (Bertin 1920; Duval 1928; Ackrill et al. 1969; Viertel 1999), *R. esculenta* (Ackrill, Hornby, and Thomas 1969), and *R. ridibunda* (Katz 1975; Degani 1985b).

A number of other amphibian species have some capacity to tolerate high salinity, but none habitually lives in marine environments as concentrated as those frequented by *Fejervarya cancrivora.* One such species is *Bufo viridis,* a toad found throughout eastern and southern Europe, western Asia, and the Mediterranean coast of Africa. Although mainly a terrestrial species, it sometimes can be found in brackish marshes and other saline environments. It can tolerate salinity up to about 80% seawater and exhibits many of the same responses seen in *Fejervarya cancrivora.* Concentrations of urea, sodium, and chloride all rise dramatically in the plasma, while intracellular osmotic concentrations are increased mainly by accumulating urea and free amino acids (M. Gordon 1962, 1965; Katz 1973, 1975, 1978; Katz and Gabbay 1984; Hoffman, Eliath, and Katz 1988; Hoffman and Katz 1994; Shpun and Katz 1995). Urine excretion ceases when the frogs are exposed to high salinity (Shpun and Katz 1999). These changes are accompanied by increased activity of urea cycle enzymes, as seen in *Fejervarya cancrivora* (Lee et al. 1982).

The so-called marine toad (*Bufo marinus*) lives mainly in lowland tropical areas, but sometimes can be found along ocean beaches or the margins of mangrove swamps and tidal mud flats (Covacevich and Archer 1975; Zug and Zug 1979; van Beurden and Grigg 1980). It has a relatively poor ability to accumulate urea and other solutes and can tolerate salt concentrations less than half those tolerated by *Bufo viridis* (Liggins and Grigg 1985). This species tends to avoid saline substrates (Maleek et al. 1999). The European natterjack toad (*Bufo calamita*) sometimes inhabits coastal dunes and even breeds in slightly saline water (Andrén and Nilson 1985; Beebee 1985; Gomez-Mestre and Tejedo 2003). It has some capacity to increase plasma urea concentrations, but does not match *Bufo viridis* in its ability to tolerate high salinity (Sinsch and Sherif 1989; Sinsch, Seine, and Sherif 1992). Tadpoles of *B. calamita* can tolerate moderately brackish water, and like *Fejervarya cancrivora,* do so by elevating internal sodium and chloride concentrations, not by accumulating urea (Gomez-Mestre et al. 2004). Tadpoles from the most brackish habitats exhibit higher salinity tolerance than do those from less saline environments, and this variation appears to be genetically based (Gomez-Mestre and Tejedo 2004). The European common toad, *Bufo bufo,* has little ability to tolerate saline environments or to elevate internal solute concentrations (Ferreira and Jesus 1973). Many other species of toads have been reported in brackish water, and a few species, such as *Bufo fowleri,* sometimes breed in moderately saline coastal dune ponds (Markow 1997).

The only other anuran in which salt tolerance has been studied intensively is *Xenopus laevis,* the African clawed frog. This species can tolerate salinity equivalent to about 60% seawater. Responses of *Xenopus* to high salinity are similar to those seen in *Fejervarya cancrivora* and *Bufo viridis.* These include elevation of plasma concentrations of urea, sodium, and chloride and a reduction in rate of urine production (Janssens and Cohen 1968; McBean and Goldstein 1970a, b; Funkhouser and Goldstein 1973; Ireland 1973; Schlisio, Jurss, and Spannhof 1973; Romspert 1976; Seiter, Schultheiss, and Hanke 1978; J. Balinsky 1981). In its natural environment, this species is not normally found near marine habitats, although an introduced population has been reported living in brackish water in California (Munsey 1972). Instead, this species is subjected to periodic osmotic stress when it seeks refuge in drying mud during the dry season. Many of the responses seen in animals exposed to high salt concentrations also are seen in estivating frogs (Balinsky 1981; Katz 1989; Shoemaker et al. 1992). The same is true of *Bufo viridis* (Degani, Silanikove, and Schkolnik 1984; Hoffman, Eliath, and Katz 1988; Hoffman, Katz, and Eliath 1990; Katz and Gabbay 1986; Katz 1989; Hoffman and Katz 1991, 1994), and the ability of these species to tolerate high salinity probably is a by-product of selection for desiccation tolerance.

Relatively few salamanders can tolerate high salinity. However, populations of two terrestrial salamanders, *Batrachoseps attenuatus* and *B. major,* can be found on ocean beaches under piles of salty vegetation (Licht, Feder, and Bledsoe 1975). Plasma concentrations of both sodium and urea are increased in response to high salinity (Jones and Hillman 1978). Some ambystomatid salamanders in western North America breed successfully in ponds and lakes that are both moderately saline and alkaline (Larson 1968; Brandon, Maruska, and Rumph 1981). Some populations exhibit low-level salinity tolerance that is achieved by elevations in plasma concentrations of ions and sometimes urea as well (Kirschner et al. 1971; Gasser and Miller 1986). Moderate salinity tolerance also is seen in several urodeles that do not inhabit saline environments, but are exposed to periodic osmotic stress during estivation (*Ambystoma tigrinum:* Romspert and McClanahan 1981; *Salamandra salamandra:* Degani 1981, 1982, 1985c; *Siren intermedia:* Asquith and Altig 1986).

Osmoregulation at Low Temperatures

When frogs and toads emerge from hibernation, they often appear bloated, with a large quantity of water present in the tissues and subcutaneous lymph sacs. This increase in water content often is accompanied by a decrease in blood hematocrit and changes in the concentrations of various ions in the tissues and extracellular fluid compartments. These changes are particularly evident in species that hibernate underwater. Excessive hydration also can be induced in terrestrial hibernators such as *Bufo bufo* by placing them in water at low temperatures (C. B. Jørgensen 1950b; Hong 1957; Deyrup 1964; D. Miller, Standish, and Thurman 1968; Zamachowski 1968, 1977; C. B. Jørgensen, Brems, and Geckler 1978; Bradford 1984c; Nielsen and Jørgensen 1990; Sinsch 1991a). Several authors have argued that increased water retention is an adaptive response analogous to that seen in dehydrated anurans, benefiting the animals in some way either during hibernation or during the breeding period immediately following emergence (C. B. Jørgensen et al. 1978; Nielsen and Jørgensen 1990; Sinsch 1991a). The fact that the change in osmotic balance seen in hibernating animals does not impair the functioning of the cardiovascular system (Weathers 1975; Lillo 1980) has been cited as evidence for an adaptive response, but the presumed benefits of excess water accumulation have yet to be identified. An alternative explanation is that the need for precise regulation of body fluid concentration is relaxed at low temperatures, when the animals are physiologically inactive (C. B. Jørgensen 1991; Pinder, Storey, and Ultsch 1992).

The Lymphatic System and Osmoregulation

Anurans are unusual among vertebrates in having an extraordinarily large lymphatic system, including a series of large lymph sacs located beneath the skin and connected by thin-walled vessels. Fluid accumulates in the lymph sacs and is circulated by lymphatic hearts located throughout the system, although contraction of skeletal muscles probably also plays a role in lymph circulation (Hillman et al. 2004).

Nineteenth-century anatomists described the lymphatic system of European frogs (mainly *Rana esculenta*) in considerable detail, but the function of the system remained unclear. Early workers discovered that enormous volumes of fluid pass freely between the lymphatic system and the blood (Conklin 1930a, b). It was suggested that the lymphatic system might serve as a water reservoir, much like the urinary bladder, that could be used to replenish body water lost through evaporation (Ewer 1952; Deyrup 1964; Middler, Kleeman, and Edwards 1968). Carter (1979) examined the morphology of the lymphatic systems of a large number of anurans with aquatic, terrestrial, fossorial, and arboreal habits. These included Australian myobatrachids and hylids, introduced *Bufo marinus,* a species of semiaquatic *Rana* from New Guinea, *Ascaphus truei,* an aquatic species from North America, and the aquatic African frog *Xenopus laevis.* He found that lymph sacs were larger in aquatic and semiaquatic frogs than in terrestrial, fossorial, or arboreal species. Fossorial species generally had well-developed lymph sacs in the pelvic region, the site of water uptake from moist soil, but dorsal sacs were virtually nonexistent.

The greater development of the lymphatic system in aquatic frogs suggests that it does not serve as a water reservoir to protect against desiccation. Instead, it probably functions mainly to eliminate excess fluid taken up when the frogs are immersed in water, either through the kidneys or by direct diffusion of water across the bladder wall (Carter 1979; A. Baldwin, Rozum, and Gore 1990; Boutilier, Stiffler, and Toews 1992). This hypothesis was supported by Wentzell, McNeil, and Toews (1993), who placed toads (*Bufo marinus*) in a bath containing tritiated water and monitored the activity of the radioactive marker in the lymphatic system, plasma, and urine. Activity of the marker increased more rapidly in the lymphatic system than in the plasma or urine. This indicated that water taken up through the skin probably enters the lymphatic system and is drained by the renal portal system into the kidneys, where excess water is eliminated. Wentzell, McNeil, and Toews also found evidence for some diffusion of water from the lymphatic system directly into the bladder.

Kidney Function and Nitrogen Excretion

As in all vertebrates, the amphibian kidney performs a number of interrelated functions, including the elimination of nitrogenous and other waste products of metabolism, regulation of internal water, ion, and acid-base balance, and resorption of some nutrients such as glucose. The literature on the physiology of amphibian kidneys is immense because kidneys of frogs have been widely used as a model system for understanding mechanisms of kidney function in vertebrates (Deyrup 1964). I will briefly discuss those aspects of kidney function most directly related to amphibian ecology, but I will not say much about physiological mechanisms. More detailed treatments of several aspects of kidney physiology can be found in Shoemaker and Nagy (1977), Toews and Stiffler (1989), Shoemaker et al. (1992), and especially Boutilier, Stiffler, and Toews (1992).

All amphibians are capable of producing large volumes of dilute urine when they are fully hydrated. This is brought about by a very high glomerular filtration rate (the rate at which fluid is filtered out of the blood) and a high capacity to resorb solutes from the urine in the kidney tubules. Terrestrial amphibians tend to have higher glomerular filtration rates than do aquatic species (Stiffler, DeRuyter, and Talbot 1990; Pruett, Hoyt, and Stiffler 1991), probably because they must rely mainly on the kidneys to eliminate nitrogenous wastes, whereas aquatic amphibians can eliminate most of their nitrogenous wastes across the skin (see the following). One of the first physiological responses of most amphibians to desiccating conditions is to reduce urine production by dramatically decreasing glomerular filtration rate (Schmidt-Nielsen and Forster 1954; Shoemaker and Bickler 1979; Yokota, Benyajati, and Dantzler 1985; Tufts and Toews 1986; Shoemaker et al. 1992). Some species also substantially increase resorption of water by the kidney tubules. Both responses are mediated by the antidiuretic hormone AVT, and renal responses to AVT occur even in some species of amphibians that do not exhibit a pronounced cutaneous water balance response (Bentley 1974; Sawyer and Pang 1975; Pang 1977; Pang, Uchiyama, and Sawyer 1982 (see also "Hormonal Regulation of Water Uptake"). Several other hormones also affect kidney function, and these are discussed by Boutilier, Stiffler, and Toews (1992).

Amphibians are carnivorous or insectivorous as adults, and they produce large amounts of nitrogenous wastes as a byproduct of protein metabolism. The way in which these wastes are eliminated depends on the availability of water. Energetically, the cheapest way to eliminate such wastes is by excreting ammonia, and most fishes and strictly aquatic amphibians are ammoniotelic. In some aquatic amphibians, up to 90% of the ammonia is excreted across the skin, with the kidneys playing a relatively minor role (e.g., *Necturus maculosus;* Fanelli and Goldstein 1964). A study of an aquatic caecilian, *Typhlonectes natans,* is particularly interesting, because typhlonectids are thought to have evolved from fully terrestrial ancestors, which probably excreted most of their nitrogenous wastes as urea. This species excretes ammonia more rapidly than urea, but because urea contains more nitrogen, the contribution of ammonia and urea to total nitrogen excretion is about the same. This is a higher proportion of nitrogen eliminated as urea than in most aquatic amphibians studied so far, perhaps a legacy of the terrestrial ancestry of this species. About 90% of the ammonia and 70% of the urea is eliminated across the skin, so the kidneys are not very important for nitrogen excretion (Stiffler and Manokham 1994).

Ammonia is relatively toxic and cannot be stored in the body in large amounts, so it must be eliminated immediately with large volumes of water. When water availability is restricted, as it is for many terrestrial amphibians, excretion of ammonia becomes impossible. Most semiaquatic and terrestrial amphibians excrete urea, or a combination of urea and ammonia. Excretion of urea requires more energy than excretion of ammonia, and it also requires the presence of appropriate urea-cycle enzymes. Urea is much less toxic than ammonia and therefore can be stored for considerable periods of time when water is scarce, then eliminated when water becomes available (Balinsky 1970, 1981; Jungreis 1976; Shoemaker and Nagy 1977; Shoemaker 1987; Shoemaker et al. 1992). This makes possible the common strategy of retaining urea during periods of osmotic stress, which was discussed in an earlier section.

Amphibians that move between aquatic and terrestrial environments exhibit varying degrees of plasticity in their nitrogen excretion strategies. *Xenopus laevis* is among the world's most aquatic frogs and normally excretes 60–80% of its nitrogenous wastes as ammonia. Most of the ammonia is excreted by the kidneys, not the skin, as in some aquatic salamanders and caecilians (Balinsky and Baldwin 1961). When subjected to desiccation stress during the dry season, it can readily switch almost entirely to production of urea (Balinsky, Cragg, and Baldwin 1961). The Bornean toad *Bufo quadriporcatus* is primarily a forest-floor species. While on land, it excretes approximately 60% of its nitrogenous wastes as urea and the rest as ammonia, but when placed in water, it can excrete up to 91% of its wastes as ammonia (Shoemaker and McClanahan 1980). Other anurans studied by Shoemaker and McClanahan (1980) in Borneo are much less flexible, but the degree of plasticity does not correlate very well with habitat preferences. For example, a toad (*Bufo asper*) and a frog (*Limnonectes blythii*) found along stream banks are ureotelic both on land and in the water, as are several arboreal rhacophorid frogs (fig. 2.19). On the other hand, *Limnonectes kuhlii,* a close relative of *L. blythii,* is mainly ammoniotelic in water and cannot greatly increase production of urea, as is *Rana signata.* Consequently, these species die quickly if completely deprived of water.

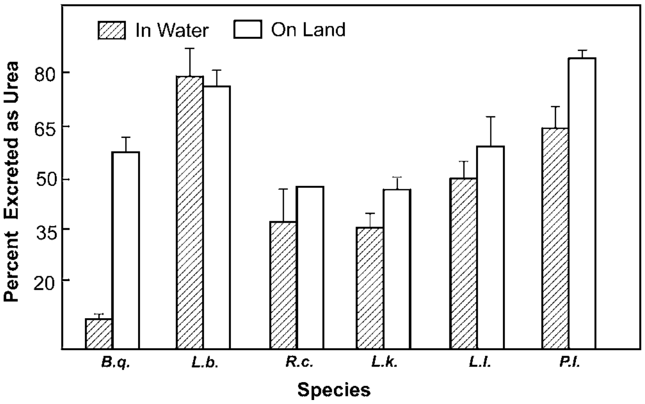

Fig. 2.19. Proportion of nitrogenous wastes excreted as urea by various anurans from Borneo in water and on land. The remainder of waste is excreted as ammonia. Bars show means + 1 SE. *B.q. = Bufo quadriporcatus. L.b. = Limnonectes blythii. L.k. = Limnonectes kuhlii. L.l. = Limnonectes limnocharis. P.l. = Polypedates leucomystax. R.c. = Rana chalconota.* Plotted from data in Shoemaker and McClanahan (1980).

Aquatic amphibian embryos and larvae generally excrete mostly ammonia, but those that develop in enclosed environments or under dry conditions face a special problem in eliminating nitrogenous wastes without poisoning themselves. In at least one species with terrestrial eggs, *Geocrinia victoriana,* up to 86% of nitrogenous wastes are in the form of urea (A. Martin and Cooper 1972). Many leptodactylid frogs lay eggs in foam nests placed in terrestrial burrows (see chapter 9), and the larvae remain in the nests for some time. Shoemaker and McClanahan (1973) measured concentrations of urea and ammonia in three foam nests of *Leptodactylus bufonius* from Argentina for six weeks. The tadpoles were primarily ureotelic, especially after the first three weeks of development (fig. 2.20). The tadpoles of an African pig-nosed frog, *Hemisus marmoratus,* which develop inside a burrow, are similarly ureotelic, with about 80% of nitrogren being excreted in the form of urea (Grafe, Kaminsky, and Linsenmair 2005). Urea excretion also occurs in amphibian larvae that develop in pouches on the back of a female or inside the female's reproductive tract (Alcocer et al. 1992; Schindelmeiser and Greven 1981).

Accumulation of ammonium ions to toxic levels also can be a problem in ephemeral breeding pools that dry up as amphibian larvae develop in them. Tadpoles of *Hyperolius viridiflavus,* a species that breeds in ephemeral ponds in West Africa, increased the production of urea in response to increased ammonium ion concentrations. Juveniles that metamorphosed under drying conditions were able to survive dry conditions better than were those that metamorphosed under wet conditions, probably because they had already switched to excretion of urea (Schmuck et al. 1994). Tadpoles of another species, *Hyperolius marmoratus,* did not show this response, but they were able to tolerate higher ammonium ion concentrations. Even bullfrog tadpoles (*Rana catesbeiana*), which are not normally exposed to high ammonia concentrations in their permanent pond habitats, have the capacity to switch to urea excretion when exposed to elevated ammonia levels (Wright and Wright 1996). This plasticity in excretion is retained in adults, which are even

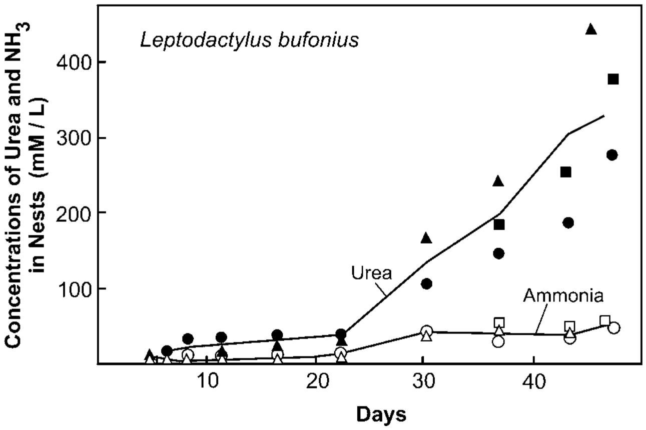

Fig. 2.20. Change in the concentration of ammonia and urea in the foam nests of a South American frog, *Leptodactylus bufonius,* during tadpole development. Different symbols indicate data collected from three different nests. The tadpoles exhibit a dramatic increase in urea production as development progresses. After Shoemaker and McClanahan (1973).

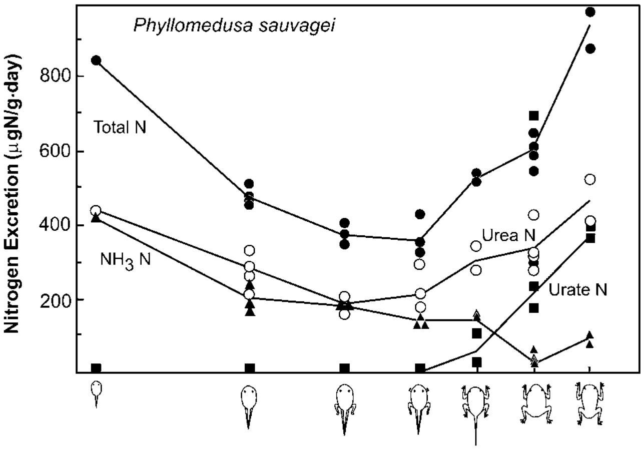

Fig. 2.21. Ontogeny of nitrogen excretion in tadpoles and metamorphs of a South American treefrog, *Phyllomedusa sauvagii,* that excretes both uric acid (urate N) and urea as an adult. Total nitrogen excretion increases late in tadpole development, with the proportional contributions of urea and uric acid increasing, while the proportion of ammonia (NH_3N) decreases. After Shoemaker and McClanahan (1982).

less likely to be exposed to high ammonia concentrations in nature. This suggests that the ability to switch between ammonia and urea excretion in response to elevated ammonia levels is a general amphibian or anuran trait, and not necessarily a specific adaptation to environments with high ammonia concentrations.

The most unusual form of nitrogen excretion in amphibians is the excretion of uric acid. This is the predominant mode of excretion in squamates and birds, and is advantageous because uric acid is relatively nontoxic and also relatively insoluble in water. This allows much of the water in the excreted material to be resorbed in the kidney, bladder, or cloaca, thereby conserving scarce water in dry environments. For most amphibians, uricotelism would be of limited benefit, because under dry conditions, water loss through the skin greatly exceeds losses in the urine. This is not true for waterproof frogs in two unrelated genera, *Chiromantis* and *Phyllomedusa,* which are uricotelic (Loveridge 1970; Shoemaker et al. 1972; Shoemaker and McClanahan 1975). This shift in mode of excretion is accompanied by a reduction in urea-cycle enzymes in the liver and an increase in uric-acid-cycle enzymes, which usually are not detectable in other amphibians (Balinsky et al. 1976; Shoemaker and McClanahan 1982). These enzymes appear only in metamorphosed frogs, at least in *Phyllomedusa;* tadpoles excrete approximately equal amounts of ammonia and urea early in development, but gradually switch to mostly urea until just before metamorphosis (fig. 2.21). Because excretion of uric acid allows these frogs to resorb most of the water in the urine before it is eliminated, they do not exhibit the dramatic drop in glomerular filtration rates seen in most other anurans that are deprived of water. This means that nitrogen excretion can continue in these frogs even under extremely dry conditions, whereas most amphibians simply stop excreting nitrogen until water becomes available (Shoemaker and Bickler 1979). In many respects, the water balance and excretion strategies of these frogs are more similar to those of squamate reptiles than those of other amphibians.

Summary and Conclusions

Amphibians usually are associated in the popular imagination with water and aquatic habitats such as ponds, marshes, lakes, and rivers. Even many biologists consider amphibians to be largely tied to water. Yet all three major clades of amphibians (salamanders, frogs and toads, and caecilians), have aquatic, semiaquatic, and fully terrestrial species. Many of the most successful lineages, including frogs in the genus *Eleutherodactylus,* most plethodontid salamanders, and most caecilians, are fully terrestrial and do not even return to water to breed. Much of the research conducted on amphibian water relations has focused on adaptations of amphibians to various sorts of terrestrial environments.

Most aquatic, semiaquatic, and ground-dwelling amphibians lack mechanisms to retard evaporative water loss from the skin, and their activity patterns, movements, and behavior are constrained by the availability of moist microhabitats. One of the most important discoveries in the study of amphibian water balance in the last 30 years is the extent to which arboreal frogs differ from typical aquatic or terrestrial species. Arboreal species in several families have evolved mechanisms to increase the resistance of the skin to evaporative water loss, and the so-called waterproof frogs have skin resistances approaching those of some reptiles. Arboreal habits have evolved independently in many different anuran families (chapter 1), and adaptations that reduce rates of evaporative water loss undoubtedly have evolved independently as well. Rates of evaporative water loss have yet to be investigated in many arboreal leptodactylids, microhylids, centrolenids, bufonids, and ranids, and it seems likely that other moderately waterproof frogs will be discovered in the future.

Nonarboreal amphibians that lack adaptations to retard water loss must depend on behavioral adjustments to maintain the proper water balance in harsh terrestrial conditions. Many species, such as plethodontid salamanders, carefully select microhabitats that remain moist throughout the year, and are active above ground only in relatively wet weather. Amphibians also make use of a wide variety of refugia that provide more stable conditions of temperature and humidity than do more exposed locations. Amphibians find shelter under leaf litter, logs, rocks, or other debris, and they often make use of specialized retreat sites such as the leaf axils of bromeliads and other plants, rock crevices, and burrows constructed by other animals. Burrowing is common in all three major clades of amphibians, although most salamanders are incapable of making their own burrows, and usually rely on root channels or tunnels made by other animals. The frogs and caecilians, on the other hand, include many specialized burrowing species, some of which spend most of their lives underground, emerging occasionally to feed or reproduce.

Burrowing anurans have two distinct strategies that minimize desiccation in underground retreats. Some species, including spadefoot toads (Pelobatidae) and some bufonids, have highly permeable skin that does not provide a barrier to water loss. These species accumulate electrolytes and urea in their plasma, which helps to maintain a favorable osmotic gradient for water uptake, even in relatively dry soil. The aquatic frog *Xenopus laevis* has a similar response when encased in the mud of drying ponds. The alternative strategy is to form a cocoon from layers of shed skin and mucus that provides a physical barrier to water loss. These two strategies are incompatible; species that form cocoons cannot increase water uptake by accumulating urea, because the cocoon would prevent water movement across the skin in both directions.

One of the oddities of amphibian life is that most terrestrial species that live in dry environments have highly permeable skin that does not provide a barrier to water loss. This is advantageous, however, in allowing the animals to rehydrate very rapidly, either by sitting in standing water such as rain pools, or by sitting on moist soil and taking up water through the highly permeable seat patch. Indeed, terrestrial amphibians generally rehydrate more rapidly than aquatic or semiaquatic species, which are less likely to suffer debilitating desiccation. The same is true for arboreal species, which often have low rates of evaporative water loss through the dorsal skin, but high rates of water uptake through the ventral skin, especially in the pelvic region. Excess water is stored in the urinary bladder, and the animals can draw on these water reserves when subjected to desiccation stress.

Work on the hormonal control of water uptake in the past decade has revealed a more complicated picture than is described in most textbooks. For more than 50 years, argenine vasotocin (AVT), a neurohypophyseal hormone, was considered the principal modulator of water balance in amphibians. Many experiments have shown that this hormone, or its mammalian analog, results in increased skin permeability, increased bladder permeability, and increased rates of water uptake. Some workers, such as C. B. Jørgensen (1992a), have questioned the central role of AVT in regulating amphibian water balance, arguing that typical experimental dosages produce pharmacological effects that are much greater than would occur in nature. In addition, a number of additional hormones have been shown to affect various aspects of water balance, especially angiotensin II, a hormone that regulates drinking behavior in other vertebrates, including mammals.

Amphibians that live in or near water are less likely to be subjected to desiccation stress than purely terrestrial species, but they do face osmoregulatory challenges. Because of their highly permeable skin, amphibians in fresh water take up water very rapidly, which is eliminated by production of large amounts of urine. Essential ions tend to be lost in the urine and must be replaced by active uptake of ions across the skin and by resorbing ions before urine is excreted. In general, aquatic amphibians have lower skin permeability and lower rates of water uptake than terrestrial or arboreal species, and their skin is less responsive to the action of hormones such as AVT.

Some aquatic amphibians face special osmoregulatory problems in stressful environments such as acidic or saline water. Many species cannot tolerate highly acidic water, which causes excessive loss of sodium ions to the environment, but a few species have evolved physiological tolerance to acidity that allows them to live in acidic bogs. The sensitivity of most amphibians to high acidity has important conservation implications, because acidification of ponds by acid rain has been cited as a possible cause of declines in amphibian populations in some regions (see chapter 16). Most amphibians are highly intolerant of saline environments as well. A few, such as the crab-eating frog, have managed to penetrate salty mudflats by accumulating urea and other solutes in the plasma, thereby raising their internal osmotic concentration. The crab-eating frog is undoubtedly derived from a typical semiaquatic ancestor, but most of the other anurans that have been shown to tolerate moderate levels of salinity are terrestrial or fossorial species. These species exhibit similar responses to salt stress and desiccation stress, and their ability to tolerate somewhat saline environments probably is a byproduct of selection for tolerance of dry environments.

As with other aspects of water relations, kidney function and strategies of nitrogen excretion by amphibians reflect the environments in which the animals live. Aquatic and semiaquatic species typically excrete most of their nitrogenous wastes in the form of urea, or a combination of urea and ammonia. Because ammonia is toxic in high concentrations, only highly aquatic amphibians excrete most of their nitrogen as ammonia. Some terrestrial species have very plastic nitrogen excretion strategies, switching from excreting mostly ammonia in the water to mostly urea on land, but others are more constrained to one type of excretory product. Excretion of uric acid, which is common in squamate reptiles and birds, is uncommon in amphibians, but has evolved independently at least twice in waterproof frogs in Africa (*Chiromantis*) and South America (*Phyllomedusa*).

The basic features of amphibian water relations have now been rather thoroughly characterized, although it seems likely that there is a considerable amount of natural variation in water balance strategies still to be discovered in the vast array of amphibian species. We also need more explicit connections between physiological traits and the ecology and behavior of amphibians. For example, to what extent is the foraging of terrestrial species constrained by problems of evaporative water loss, as suggested for plethodontid salamanders by Feder (1983b) and others? In arboreal species, what is the relationship between rates of evaporative water loss and the height of foraging sites in the canopy or the choice of calling perches by males? Seasonal calling activity of some frogs that call from elevated perches appears to be limited by problems of evaporative water loss (Pough et al. 1983), but to what extent is nightly calling time constrained by water loss? Are diurnally active amphibians exposed to more severe problems of water loss than more typical nocturnally active species?

A critical need in studies of amphibian water balance, and many other aspects of their physiological ecology, is to ask questions in a more explicit phylogenetic perspective (Huey 1987; Bennett and Huey 1990). The traditional approach to comparative physiological studies has been to choose experimental animals that represent rather broad categories of habitat choice (aquatic, terrestrial, fossorial, or arboreal), with little regard to phylogenetic relationships among the species being studied. Consequently, pairwise comparisons of ranid frogs and bufonid toads or aquatic salamanders and terrestrial anurans are commonplace, even though these animals differ in many features of their biology other than their water relations. While such comparisons have revealed qualitative relationships between physiological traits and habitats, we know almost nothing about the direction of evolution of particular physiological traits that reduce evaporative water loss, facilitate water uptake, or influence osmoregulatory capacities. For example, has the use of concentrated lipid secretions evolved only once in a clade of closely related species within the hylid family Phyllomedusinae, or has it evolved independently several times? How frequently have adaptations to retard evaporative water loss evolved within the diverse family Hyperoliidae? Has there been convergent evolution in physiological traits that reduce evaporative water loss in hylids and other tree frog clades? Is the water balance response that can be elicited by desiccation or by neurohypophyseal hormones in many amphibians an ancestral trait for all amphibians or for all anurans, or has a similar response evolved independently in separately derived clades of terrestrial species? Clearly we are not in a position to answer these questions now, because we lack detailed physiological data on most species of amphibians, and phylogenetic relationships of many major lineages are still unresolved (see chapter 1). Nevertheless, use of phylogenetic information will allow future investigators to make informed choices of experimental animals for comparative studies.

Chapter 3 Temperature Relations

Frogs of various colours are numerous in those parts as far North as the latitude 61°. They always frequent the margins of lakes, ponds, rivers, and swamps; and as the Winter approaches, they burrow under the moss, where they remain in a frozen state till the Spring. I have frequently seen them dug up with the moss (when pitching tents in Winter) frozen as hard as ice; in which state the legs are as easily broken off as a pipe-stem, without giving the least sensation to the animal; but by wrapping them up in warm skins, and exposing them to a slow fire, they soon recover life.
—Samuel Hearne, *A Journey From Prince of Wales Fort, in Hudson's Bay, to the Northern Ocean* (1795)

In the 1760s, the Hudson Bay Company sent a young sailor named Samuel Hearne to the company fort at the mouth of the Churchill River on Hudson's Bay, from which he made a number of exploring trips on foot and by canoe into the interior of the Canadian Arctic. Although not trained as a naturalist, he made detailed notes on the animals of the region, including the description of frozen wood frogs (*Rana sylvatica*) just quoted. His unusual account was mentioned in a number of popular nineteenth-century natural history books (Griffith 1831; Gould 1853; Bingley 1868) and then forgotten. It was not until 200 years later that the physiological mechanism that allows these frogs to survive in a frozen state was understood (Storey and Storey 1984; see discussion at the end of this chapter). Most of the other animals that Hearne observed around the fort were birds and mammals, including large numbers of arctic foxes (*Alopex lagopus*). In contrast to the frogs, the foxes had no difficulty staying active in the coldest winter weather, and in fact, this was the best season for trapping because their coats were in their prime during winter. Arctic foxes can maintain a constant body temperature of 38° C with no increase in metabolic rate, even when exposed to ambient temperatures of −30° C (Scholander et al. 1950).

The ability of these foxes to remain active in even the coldest weather, while the frogs lie frozen under the snow, illustrates one of the key differences between amphibians and mammals. Wood frogs and other amphibians cannot elevate body temperature by metabolic activity, and they lack insulation that would help retain body heat. When cold weather sets in, amphibians are forced to become inactive, either seeking out microhabitats that remain above freezing throughout the winter, or living in a frozen state until warm weather returns. Conversely, as temperatures rise, amphibians gradually become more active until they reach temperatures too high for them to tolerate. At that point, they must again seek out microhabitats that protect them from high temperatures and the associated problem of high evaporative water loss (see chapter 2). The advantage of being ectothermic is that amphibians have very low resting metabolic rates, and hence very low energy requirements compared to birds and mammals (Pough 1980, 1983; see also chapter 5). This low energy lifestyle does come with a cost, however. It means that ambient temperature limits the ability of amphibians to carry on normal activities such as feeding and reproduction.

This chapter reviews the temperature relations of amphibians, with emphasis on the ecological implications of variation in temperature. I first discuss the effects of temperature on various physiological and behavioral processes and how these effects influence the ecology of amphibians. I then discuss aspects of behavioral thermoregulation, temperature acclimation, and responses of amphibians to extreme cold. Details of physiological mechanisms and the biophysics of heat transfer will be mentioned only briefly. Readers should consult the reviews by Hutchison and Dupré (1992); Pinder, Storey, and Ultsch (1992); Rome, Stevens, and John-Alder (1992); and Spotila, O'Connor, and Bakken (1992) for more complete discussions of these topics.

Effects of Temperature on Physiology and Behavior

Because amphibians are ectotherms, nearly every aspect of their physiology and behavior is affected by temperature. However, the temperature sensitivity of physiological and behavioral processes varies considerably. Some functions, such as metabolic rate or embryonic development, show a positive linear relationship to temperature over most of the natural temperature range encountered by these animals. In contrast, locomotion in some species is relatively temperature independent over a narrow range of temperatures (Rome, Stevens, and John-Alder 1992). Other processes, such as anaerobic metabolism, undergo very little change with changing temperature (Bennett 1978). The following section reviews the effects of temperature on selected physiological and behavioral processes that have a direct effect on amphibian ecology. Some of these topics are covered in more detail in other chapters and will be mentioned only briefly here.

Metabolic Rates

Aerobic metabolism is temperature dependent in all amphibians and generally increases in a linear fashion as temperature increases (see fig. 5.1 in chapter 5 for a summary). In general, the slopes of regressions of metabolic rate on temperature are similar during rest and exercise, but activity metabolism is several times higher at any given temperature. Phylogeny also influences the relationship between temperature and metabolism. Anurans and urodeles have similar temperature sensitivity (i.e., the slopes of regressions of metabolic rate against temperature are the same), but urodeles have lower metabolic rates at any given temperature than anurans, resulting in lower energy demands (Gatten, Miller, and Full 1992; see chapter 5 for further details).

For temperate-zone amphibians, energetic demands typically increase in spring and summer, but gradually decrease during the fall and are very low during the winter. In addition, some species that are subjected to wide fluctuations in environmental temperature on a daily basis also undergo major fluctuations in metabolic rate (e.g., Carey 1978, 1979a, b). Tropical amphibians, on the other hand, would be expected to have relatively high energetic demands throughout the year, except during periods of dry-season dormancy, and consequently should have higher yearly food intake than most temperate-zone species. Similar differences are expected in populations of the same species from high and low altitudes. Amphibians from high altitudes will tend to have lower metabolic rates, shorter activity seasons, and smaller total energy requirements than will those from lower altitudes, all of which contribute to longer life spans (e.g., Lüddecke 1997).

Feeding and Digestion

Temperature can affect the ability of amphibians to acquire and process food in several ways. On an ecological level, seasonal and daily variation in temperature sets limits on activity of both amphibians and their prey. For some species, such as plethodontid salamanders, feeding continues at relatively low temperatures even during the winter, but prey availability is low (R. Caldwell and Jones 1973; R. Caldwell 1975; Fraser 1976b). Prey availability for these salamanders also is limited by hot, dry conditions, not necessarily because prey is less abundant, but because salamanders are restricted in their movements (Jaeger 1980b). Anurans in cool climates are limited in both their seasonal and daily activity periods by low temperatures (Mullally and Cunningham 1956; Carey 1978; Bider and Morrison 1981; Smits 1984; Sinsch 1989a). They can compensate by switching from nocturnal to diurnal activity, or by foraging at a wider range of temperatures than species from warmer regions (see "Behavioral Thermoregulation" in a following section). However, species that breed in early spring often depend on stored energy reserves to support reproductive activities because environmental temperatures are too low for their prey to be active (see chapter 5).

Temperature can have direct physiological effects on feeding behavior. Lillywhite, Licht, and Chelgren (1973) provided unlimited numbers of mealworms to juvenile toads (*Bufo boreas*) held at different temperatures and found that toads at 27° C ate more food than those at 14° C and 20° C. Feeding also was suppressed at a temperature above that normally experienced by toads in the field (33° C). Patterns of food ingestion closely paralleled differences in growth rates at these temperatures (growth was maximized at 27° C). The precise reason for the reduced appetite of the toads at low temperatures was not clear, but could have been due to slower rates of food passage through the digestive system. Colder temperatures also could influence rates of movement of their ectothermic prey, which in turn could affect the feeding response of the toads (Ewert 1987). An experiment by Stevens (1988b) avoided this problem by presenting mealworms to toads on a moving circular track at a con-

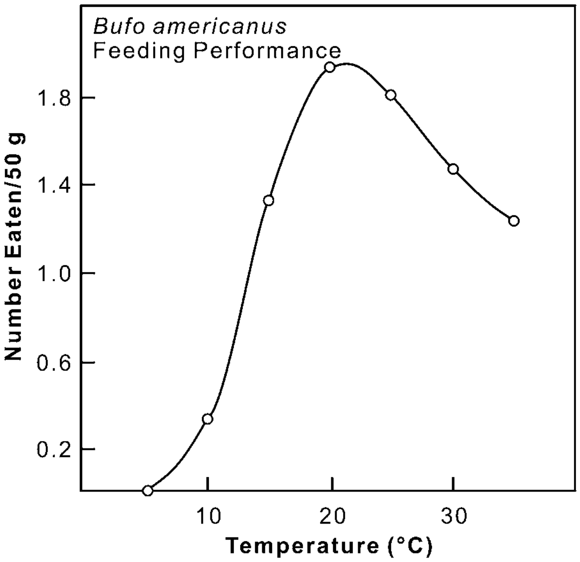

Fig. 3.1. Feeding performance of American toads (*Bufo americanus*) at different temperatures, measured as the number of worms eaten per 50 g of body mass. Feeding performance peaks at about 20°C and declines rapidly at colder temperatures. After E. D. Stevens (1988a).

stant velocity, regardless of temperature. The toads still showed a much reduced feeding performance at low temperatures and a slightly reduced response at high temperatures (fig. 3.1). In another experiment, acclimation to a cool temperature (10° C) for several days resulted in lower food intake by the toads, even when they were tested at 20° C (Stevens 1988a). Possibly this was because food remained in the digestive system longer at the lower temperature, resulting in reduced hunger levels. Preest and Pough (2003) reported that low temperatures resulted in some decreased interest in feeding by American toads (*Bufo americanus*) and an increase in the time required to capture prey, but hydration state had a greater effect on feeding performanc than did temperature.

Both the rate of food passage through the digestive system and the efficiency with which energy is assimilated are affected by temperature. For example, red-backed salamanders (*Plethodon cinereus*) fed on fruitflies (*Drosophila*) assimilated about 90% of ingested energy at 10° C, 85% at 15° C, and only about 80% at 20° C. Since metabolic rate increases with temperature while assimilation efficiency decreases, salamanders at high temperatures can be in negative energy balance, especially if dry conditions keep them from foraging (Bobka, Jaeger, and McNaught 1981). In contrast, G. C. Smith (1976) did not find any difference in assimilation efficiency in *Bufo terrestris* over a range of temperatures from 20° to 30° C. Digestive rates increased with increasing temperature, whereas the time required for food to pass through the gut decreased. This probably is a general pattern for amphibians, as for most ectotherms, enabling the animals to process food more rapidly at higher temperatures. This in turn makes more energy available for production of new tissue or for reproduction (Riddle 1909; Seale 1987; Jiang and Claussen 1993; Schabetsberger 1994). Some amphibians appear to behaviorally elevate body temperatures after feeding as a means of increasing the rate of digestion (Lillywhite, Licht, and Chelgren 1973; Freed 1980; Witters and Sievert 2001).

Development and Growth

Embryonic Development

Rates of embryonic development are strongly affected by temperature in all amphibians. Embryos develop more rapidly at warm temperatures than at cold temperatures (Moore 1939; Douglas 1948; Volpe 1953, 1957; Herreid and Kinney 1967; H. A. Brown 1967, 1975a, b, 1976b; Zweifel 1968b; Bachmann 1969; Guyétant 1969; Salthe and Mecham 1974; Kuramoto 1975; R. D. Howard 1978b; Bradford 1984a, 1990). Size of the egg also influences development rate, with large eggs taking much longer to develop than small eggs (Salthe and Duellman 1973; Salthe and Mecham 1974; Bradford 1990). Consequently, species such as spadefoot toads (*Scaphiopus*) that lay very small eggs in warm desert pools have the fastest rates of development (only about 12 hours for *S. couchii* at 34° C), an obvious advantage for amphibians using breeding sites that are likely to dry up quickly (Zweifel 1968b). In contrast, amphibians that lay eggs in cold streams or ponds typically have larger eggs and much slower development (up to 6 weeks in *Ascaphus truei* at 4–10° C; H. A. Brown, 1975a). Slow rates of development also are characteristic of amphibians that undergo direct development on land at low temperatures, such as many plethodontid salamanders (Hanken 1979; Bradford 1984a) and microhylid frogs in the cool highlands of New Guinea (M. Simon 1983). Although cold-adapted amphibians typically have faster rates of development at cold temperatures than warm-adapted species, absolute rates of development are faster in warm-adapted species at the temperatures normally encountered during the breeding season (J. A. Moore 1939; Bachmann 1969). Even over short distances, variation in thermal regimes of nearby ponds can result in selection for different rates of embryonic development. In wood frogs (*Rana sylvatica*), embryos from shady, closed-canopy ponds have faster development rates at all temperatures than do those from nearby sunny, open-canopy ponds (Skelly 2004). Phylogeny is important as well; urodele eggs take longer to develop than do anuran eggs, even when egg size and temperature are the same (Bradford 1990; see chapter 10 for further discussion of life history strategies).

Larval Development

Differentiation and growth of amphibian larvae also are temperature dependent. Differentiation (the passage from one developmental stage to another) is more sensitive to changes in temperature than growth (the production of new tissue). Consequently, low temperatures can inhibit differentiation while growth continues, albeit at a slow rate. The result is that larvae raised at cold temperatures typically are larger at any given stage of development than those raised at warm temperatures (Smith-Gill and Berven 1979; see fig. 13.20 in chapter 13). This has important implications for individual life histories. Some ranid frogs in northern latitudes spend up to three winters in the tadpole stage before metamorphosing, while tadpoles in more southern populations often do not overwinter at all. Overwintering tadpoles typically continue to grow at a slow rate even when differentiation is inhibited by low temperature and eventually transform at a larger size than nonoverwintering tadpoles (Collins 1979a; Collins and Lewis 1979; Bruneau and Magnin 1980b).

Differences in environmental temperature probably account for much of the geographic and altitudinal variation in length of the larval period and size at metamorphosis seen in various species of amphibians (Berven and Gill 1983; Miaud and Guyétant 1998; Morrison and Hero 2003a). For example, green frogs (*Rana clamitans*) at high altitudes have longer larval periods and metamorphose at a larger size than do those at low altitudes. Low-altitude larvae transplanted to high-altitude ponds had even slower rates of development than did larvae from the high-altitude populations, indicating that populations have undergone selection to minimize the effects of the temperature gradient (Berven, Gill, and Smith-Gill 1979). Similarly, environmental temperature accounted for most of the observed variation in life-history traits between lowland Maryland populations of wood frogs (*R. sylvatica*) and montane populations in Virginia, but there were significant genetic differences between the populations as well (Berven 1982a, b). Canadian tundra populations are less temperature sensitive than are those found farther south. They also have shorter larval periods and smaller size at metamorphosis than do their southern relatives. This suggests that selection has favored shorter larval periods in an environment where temperature limits the time available for growth and development (Berven and Gill 1983).

Tadpoles of *Rana temporaria* in northern Sweden actually experience higher water temperatures than do those in southern Sweden because of rapid warming of ponds after the ice melts and longer daylength. Northern tadpoles grew faster at relatively higher temperatures than did southern tadpoles, presumably an adaptation to the much shorter growing season in the north (Ståhlberg, Olsson, and Uller 2001). In both northern and southern populations, growth rate was less variable under optimum conditions for that population (warm in the north, cool in the south) than under less favorable conditions (Olsson and Uller 2002). Northern tadpoles from warmer ponds also experienced higher mortality at low temperatures than did southern tadpoles from cooler ponds (Olsson and Uller 2003). All of these results suggest that selection has favored adaptation in growth and development to local environmental conditions.

Studies of the same species over a latitudinal gradient from southern Sweden to northern Finland showed that northern tadpoles developed faster than did southern tadpoles in the laboratory under identical temperature and food regimes. Hence, there is evidence for genetically based adaptation to short growing seasons in northern populations. In the field, however, variation in pond temperature at the same latitude tended to override genetic variation in development rate, so actual development rates in particular ponds were not closely correlated with latitude (Merilä et al. 2000; Laugen, Laurila, and Merilä 2002; Laugen et al. 2003).

Environmental temperatures can affect the growth and development of different species in different ways, and variation in environmental temperature affects the distribution and abundance of species in nature. For example, some anurans typically breed in open-canopy ponds that receive a lot of direct sunlight and have higher temperatures than do closed-canopy ponds, and these differences could affect rates of larval development. As canopy cover increases over ponds, some amphibians eventually are excluded from such ponds, at least in part because of changes in temperature regime (Skelly, Werner, and Cortwright 1999; Skelly, Friedenburg, and Kiesecker 2002; Halverson et al. 2003). Local populations can show apparent adaptation to differences in environmental temperature even on relatively short time scales. For example, Skelly and Freidenburg (2000) demonstrated that wood frog tadpoles (*Rana sylvatica*) from closed-canopy ponds were less tolerant of high temperatures, as measured by the critical thermal maximum (CT_{Max}), than were those from more open ponds formed by beaver dams. Nevertheless, at the cold temperatures normally found in wood frog breeding ponds, tadpoles from closed-canopy ponds actually preferred warmer temperatures than did those from open-canopy ponds, even when raised under identical conditions (Freidenburg and Skelly 2004).

Negovetic et al. (2001) studied the effects of temperature on the performance of tadpoles of the *Rana esculenta* complex in Europe. They found that tadpoles of *R. esculenta,* a hybridogenetic species derived from hybridization between *R. lessonae* and *R. ridibunda,* were more likely to survive and reach metamorphosis at 18° C than were those of the parental species *R. lessonae.* Conversely, *R. lessonae* tadpoles were more successful at 24° C than were *R. esculenta* tadpoles. A survey of a natural pond revealed that the relative abundance of *R. esculenta* tadpoles declined with increasing microhabitat temperature, so there is the potential for at least partial microhabitat segregation of the two types of tadpoles.

In addition to effects on growth, survival, and metamorphosis of larvae, environmental temperature also can affect the expression of physiological traits. For example, tadpoles of *Pseudacris regilla* raised at 15° C had higher burst swimming speed than did those raised at 25° C at test temperatures from 5 to 25° C (Watkins 2000). Tadpoles raised at the cooler temperature also had higher activity of myofibrillar ATPase, an enzyme important for anaerobically supported activity such as bursts of swimming. In the presence of predators, tadpoles that select warm microenvironments are at a disadvantage compared to those that select cooler microenvironments because of reduced swimming speed, which is directly related to the ability to escape predators (Watkins 1996). In predator-free environments, however, selection of warmer microhabitats might be advantageous, especially if the main threat to survival is drying of breeding sites.

Growth and Development of Juveniles and Adults

Seasonal temperature regimes also have a major impact on patterns of growth and sexual maturation in metamorphosed amphibians. Amphibians at high latitudes or high altitudes grow more slowly and take longer to reach sexual maturity than do populations of the same species in warmer climates (e.g., Bruce 1972b; Tilley 1980; Bury and Whelan 1984; Hemelaar 1988; Ryser 1988b; Caetano 1990; Tilley and Bernardo 1993; Miaud and Guyétant 1998; Marunouchi, Ueda, and Ochi 2000). Presumably this is due to the direct physiological effect of temperature on growth, reduced prey availability at cool temperatures, and the shorter season available for feeding and growth in cool environments (Martof 1956b; C. B. Jørgensen 1992b). For example, bullfrogs (*Rana catesbeiana*) in Quebec grow much more slowly than do those in Louisiana, they take longer to attain sexual maturity, and they reach smaller adult body size (fig. 3.2). Frogs in New York, Illinois, and Missouri have intermediate growth rates (Raney and Ingram 1941; R. Ryan 1953; Durham and Bennett 1963; Schroeder and Baskett 1968; Bruneau and Magnin 1980a).

Some amphibian species reach larger adult body sizes in cool climates than in warm climates (fig. 3.3), a relatively common trend among ectotherms (Partridge and French 1996; Atkinson and Sibly 1997; K. Ashton 2002). For example, amphibians often are considerably larger at high altitudes than are conspecifics at lower altitudes in both temperate and tropical mountains (Narins and Smith 1986; Hemelaar 1988; Lüddecke 1997; Esteban and Sanchiz 2000; Marunouchi, Ueda, and Ochi 2000). Presumably this is due in part to the greater effect of cool temperatures on development than on growth, which in turn would delay

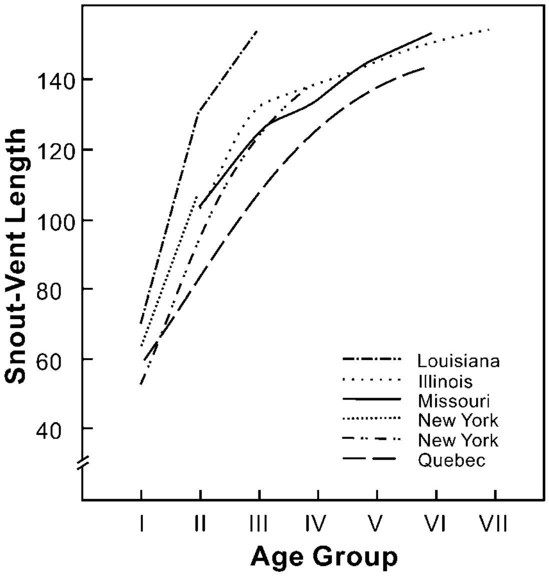

Fig. 3.2. Annual growth of bullfrogs (*Rana catesbeiana*) from several North American populations. The two lines for New York are for two different studies conducted in Ithaca, New York, in the 1940s. Growth was fastest in the southernmost population (Louisiana) and slowest in the northernmost population (Quebec). After Bruneau and Magnin (1980a).

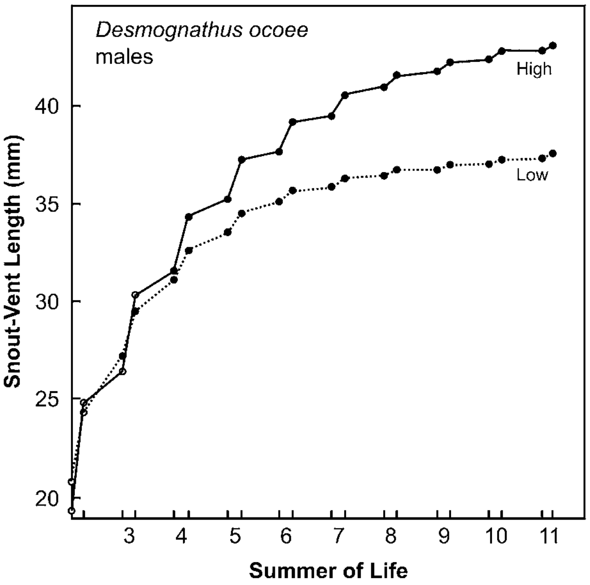

Fig. 3.3. Growth of male Ocoee salamanders (*Desmognathus ocoee*) from high-elevation and low-elevation populations in North Carolina. High-altitude males grew faster than did low-altitude males after the fourth summer, probably because of an earlier age of sexual maturity at low altitudes, after which growth rates are reduced. After Tilley (1980).

sexual maturity (Berven 1982a). Once sexual maturity is reached, growth often slows dramatically as the animals shift energy investment into reproduction. Consequently, some early maturing populations have smaller adult body size than do late-maturing populations of the same species (Tilley 1980; Hemelaar 1988; Miaud and Guyétant 1998; Marunouchi, Ueda, and Ochi 2000).

There also is evidence of genetic adaptation for more efficient growth at high altitudes or latitudes. For example, toads (*Bufo bufo*) from Norway or the mountains of Switzerland have shorter growing seasons than do populations from warmer climates, but they actually grow faster during the summer and are larger at sexual maturity (Hemelaar 1988). A similar pattern was found in a comparison of high- and low-altitude populations of *Rana iberica* in Spain. Adult frogs in the high-altitude population grew faster and were larger at any given age than those from a low-altitude population (Esteban and Sanchiz 2000). In this case, age at sexual maturity did not differ between populations. High-altitude populations of amphibians sometimes live longer than do conspecifics at low altitudes (e.g., Lüddecke 1997; Esteban and Sanchiz 2000; Marunouchi, Ueda, and Ochi 2000). This probably is not related directly to temperature, but to shorter activity seasons and reduced exposure to predators.

Reproductive Cycles and Gametogenesis

Annual cycles of reproduction and gametogenesis in amphibians are strongly temperature dependent. In general, amphibians in wet tropical and subtropical regions have prolonged breeding seasons, in some cases lasting throughout the year (see chapter 10). Males of most of these species probably have continuous production of sperm throughout the year, while females produce single or multiple clutches of eggs during the breeding season (van Oordt 1960; Lofts 1974, 1984; Houck 1977a; Duellman and Trueb 1986; C. B. Jørgensen 1992b; Díaz-Páez and Ortiz 2001). In the Chaco region of Argentina, many anurans show continuous gonadal activity throughout the year, despite some differences in winter and summer temperatures (Cei 1949b, 1980; Pisanó 1957a, b, 1958). However, some species, such as *Lepidobatrachus llanensis, Leptodactylus bufonius,* and *Leptodactylus chaquensis,* have gametogenesis interrupted in winter (Cei 1948, 1949a), and in *L. chaquensis,* gametogenesis also is inhibited by high temperature during the summer dry season. In contrast, *L. ocellatus,* a close relative of *L. chaquensis,* has a continuous gametogenic cycle that is not interrupted in summer or winter (Cei 1948, 1949c, 1980; Rengel 1950). Hot dry seasons also interrupt gametogenesis in *Phyllomedusa sauvagii* (Caruso 1949; Cei 1980).

Most cold-temperate amphibians do not produce gametes during the winter. Females generally complete maturation of their eggs before entering hibernation (C. B. Jørgensen 1973a, 1975, 1992b; C. B. Jørgensen, Hede, and Larsen 1978; C. B. Jørgensen, Larsen, and Lofts 1979; see also chapter 5). In males, spermatogenesis takes place in the late spring or summer. Some species have an internally controlled cycle that results in spermatogenesis stopping during the winter even if the animals are held at warm temperatures. This type of cycle has been found in the northern Eurasian brown frogs (*Rana temporaria, R. arvalis, R. dalmatina*), some plethodontid salamanders, and a cold-adapted South American leptodactylid, *Pleurodema bufonina.* Other amphibians have the potential to continue sperm production throughout the year if temperatures are warm, but sperm production normally is inhibited during winter. Species exhibiting this pattern include European green frogs in the *Rana esculenta* complex, southern European brown frogs such as *R. iberica* and *R. graeca,* the southern European frog *Discoglossus pictus,* and several species of *Triturus.* Among species of leptodactylid frogs in temperate southern South America, warm-adapted populations produce sperm all year, whereas conspecifics in colder climates have spermatogenesis interrupted by winter. Some species that live year-round in cold mountain lakes and streams have continuous spermatogenic cycles, even at temperatures that would inhibit sperm production in other amphibians. Two examples are frogs from far-southern South America, *Telmatobius hauthali* and *Hyla pulchella* (Ifft 1942; Cei 1949d, 1961a, b; van Oordt and van Oordt 1955; van Oordt 1960; J. K. Werner 1969; C. B. Jørgensen 1992b; Lofts 1974, 1984).

Locomotion

In general, locomotor performance of amphibians decreases at cold temperatures, regardless of whether the animals are jumping, hopping, crawling, or swimming (see Rome, Stevens, and John-Alder 1992, for a more detailed discussion of locomotion and temperature). Locomotor performance is not necessarily a simple linear function of temperature, and the precise shape of the performance curve varies among species and among studies of the same species. For example, Huey and Stevenson (1979) reported that jump performance in *Rana clamitans* was relatively independent of temperature between 10° and 25° C, and a similar pattern was reported for *R. pipiens* by Tracy (1979). However, most other studies of these species and other anurans have failed to find a broad range of temperature independence, although narrower performance plateaus have been observed in some species (fig. 3.4). Locomotor performance generally declines rapidly with decreasing temperature and also falls off abruptly at very high temperatures (Putnam

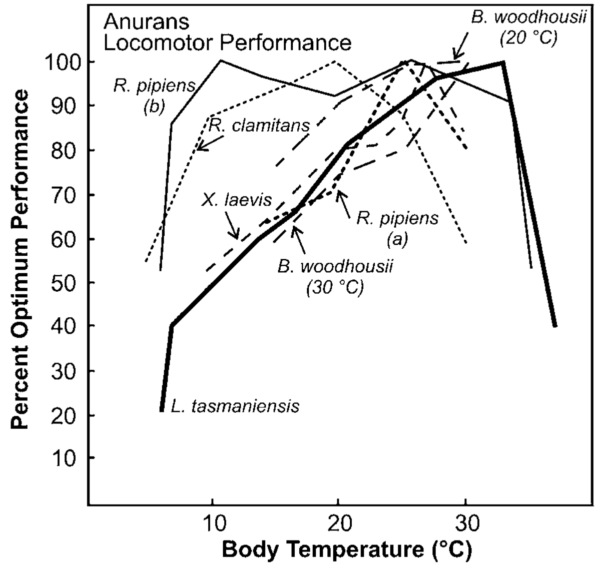

Fig. 3.4. Temperature dependence of locomotor performance in selected anurans, measured as percent of optimum performance. Genera: *B* = *Bufo, L* = *Limnodynastes, R* = *Rana, X* = *Xenopus.* Some species, such as *L. tasmaniensis,* exhibit a relatively narrow temperature range for peak performance, whereas others, such as *R. pipiens* and *R. clamitans,* exhibit a relatively broad range of thermal independence. After Whitehead et al. (1989).

and Bennett 1981; K. Miller 1982; Hirano and Rome 1984; Londos and Brooks 1988; Whitehead et al. 1989; Wilson 2001; Gomes, Bevier, and Navas 2002).

The different results obtained in these studies probably relate to differences in experimental techniques. Both Tracy (1979) and Huey and Stevenson (1979) measured the average of three jumps taken by frogs prodded by the investigator. Both of the ranid frogs they studied rely heavily on anaerobic metabolism for bursts of activity, such as leaping away from a predator (see chapter 5). Since anaerobic metabolism is less affected by changes in temperature than aerobic metabolism, this probably accounts for the plateau in jump performance. The other investigators generally measured the average of more jumps or swimming movements during sustained locomotion, which is more likely to be supported by aerobic metabolism and therefore more likely to be affected by changes in temperature. Unfortunately, differences in the way in which locomotor performance has been measured complicate any attempt to generalize about temperature sensitivity in different species. Measures such as maximum jump distance, mean jump distance, and average distance moved per minute often show different patterns of temperature sensitivity, and it is not immediately obvious which type of measurement is the most ecologically relevant. In fact, all can be relevant, depending on whether one is interested in the animals' ability to escape from predators, search for food, or locate mates (Londos and Brooks 1988; Navas et al. 1999; Gomes et al. 2002).

Communication and Sensory Systems

Any communication signals of amphibians that are produced by muscular action are likely to be strongly temperature dependent. For example, the frequency of tail beating and other courtship displays by alpine newts (*Triturus alpestris*) are strongly influenced by water temperature (Denoël 1998; Denoël, Mathieu, and Poncin 2005). The best-studied communication signals in relation to temperature are the vocalizations of anurans (see chapter 7). Different features of signals are affected to varying degrees by changes in temperature. Features affected by active muscle contraction, such as calling rate and pulse-repetition rate, are highly temperature dependent (fig 3.5), whereas features not involving active muscle contraction, such as dominant frequency, are much less affected by temperature (Zweifel 1968a; Schneider 1977, 1988; B. K. Sullivan 1982c, 1992; Gayou 1984; Wong et al. 2004).

Temperature also affects both the peripheral and central parts of the nervous system involved in call perception. In general, hearing sensitivity in anurans decreases at cold temperatures (Hubl, Mohneke, and Schneider 1977; Hubl and Schneider 1979; Mohneke and Schneider 1979; Walkowiak 1980b; Stiebler and Narins 1990; Narins 1995c). In addition, auditory fibers leading to the amphibian papilla, which detects low-frequency sounds, become selectively tuned to lower frequencies at low temperatures (fig. 3.6; Narins 2001a). Sometimes this can produce a mismatch between the call frequency preferred by females and the frequency of calls produced by males at the same temperature. For example, Gerhardt and Mudry (1980) reported a shift toward lower-frequency preferences in female *Hyla cinerea* at low temperatures when they were presented with calls differing in frequency, even though the dominant frequency of male calls changed very little with an equivalent change in temperature. In contrast, changes in the sensitivity of the brain of gray tree frogs (*Hyla versicolor*) to calls of different pulse rates shows a response to temperature similar to the pulse rates of the calls themselves (Brenowitz, Rose, and Capranica 1985; Rose, Brenowitz, and Capranica 1985). This results in females preferring calls with pulse rates similar to those produced by males at the same body temperature (Gerhardt 1978a).

Ecological Effects of Temperature

Adult Thermal Tolerance and Latitudinal Distribution

Amphibians are primarily inhabitants of tropical regions, although some groups, including several salamander families, have distributions centered in the temperate zone. About

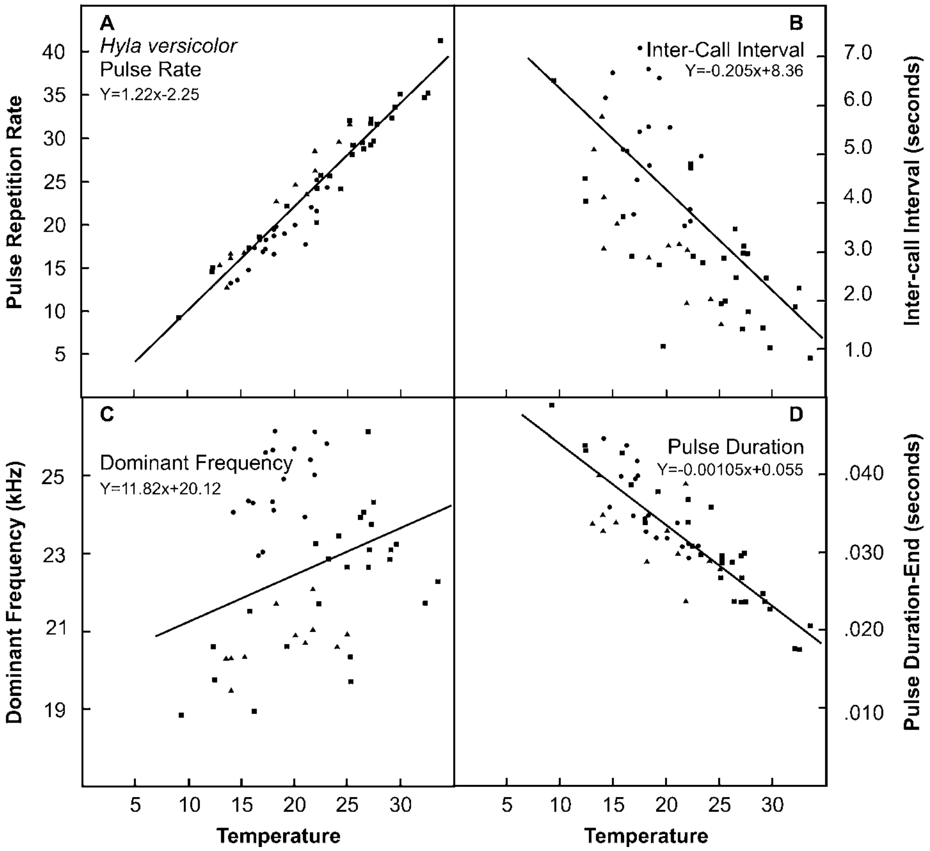

Fig. 3.5. Effect of temperature on various features of the calls of the gray treefrog (*Hyla versicolor*). (A) Pulse rate. (B) Intercall interval. (C) Dominant frequency. (D) Pulse duration. Circles are for 19 males recorded in the field. Squares are for 28 males recorded in a temperature-controlled chamber in the laboratory. Triangles are data for a single individual recorded in the laboratory at different temperatures. After Gayou (1984).

80–90% of all anuran species are found in the tropics. A single site in Amazonian Ecuador studied by Duellman (1978) had more species of anurans than do all of the United States and Canada. There are many possible reasons for these patterns of distribution, including past historical events, such as periodic glaciation of high-latitude regions, which undoubtedly reduced amphibian diversity in those areas. Nevertheless, it seems clear that these ectothermic animals do best in warm climates, and the latitudinal distribution of many species probably is limited by their ability to function or survive at low temperatures.

Latitudinal trends in thermal adaptation usually are studied by measuring thermal tolerance limits. The critical thermal maximum (CT_{Max}) is most frequently used as an index of high-temperature tolerance. CT_{Max} has been measured in different ways in different studies. Many investigators have slowly heated animals in water until they list over and are no longer able to right themselves. Other investigators have used the onset of spasms as a more accurate measure of the point at which the animal would die if not removed from the high temperature (Hutchison 1961; Hutchison and Maness

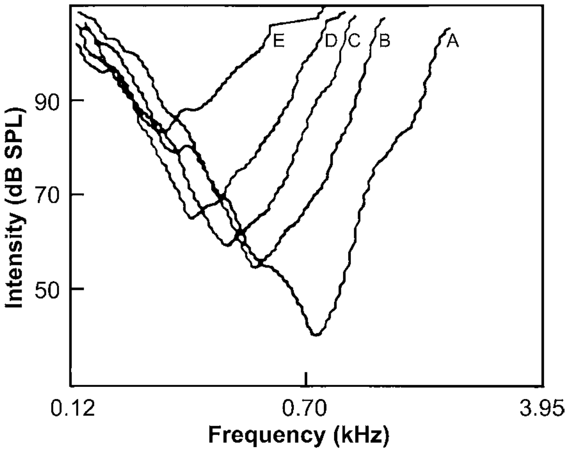

Fig. 3.6. Displacement of the tuning curve of an auditory nerve neuron with changing temperature in *Eleutherodactylus coqui*. The Y-axis shows the intensity of sound required to elicit a response from the neuron as a function of frequency. Decreasing temperature decreases the sensitivity of the ear and shifts the tuning curve toward lower frequencies. (A) 25° C, (B) 21° C, (C) 18° C, (D) 15° C, (E) 13° C. After Stiebler and Narins (1990).

1979). The onset of spasms usually occurs at temperatures 0.5–1.5° C above the temperatures at which loss of righting response occurs (V. H. Hutchison, personal communication). Unfortunately, the lack of standardization in measurement techniques makes comparisons among studies difficult. Measurement of critical thermal minima (CT_{Min}) is difficult because amphibians simply become more and more sluggish until no longer able to move at very low temperatures. Some authors have used lower lethal temperatures as a measure of cold tolerance. In comparisons of 53 species of anurans from seven families (Bufonidae, Ranidae, Hylidae, Leptodactylidae, Dendrobatidae, Pelobatidae, and Microhylidae), Brattstrom (1968) and Snyder and Weathers (1975) found a significant decline in critical thermal maximum (CT_{Max}) with increasing latitude, and an even greater decrease in lower lethal temperatures (fig. 3.7). The result is that tropical species typically tolerate a narrower range of temperatures than temperate-zone species and are particularly intolerant of low temperatures (fig. 3.8). Unfortunately, this comparison was not controlled for phylogenetic effects, so different families were represented in the tropical and temperate-zone samples. When these comparisons are made within families (hylids and bufonids) to control for phylogeny, there is some evidence for greater cold tolerance in temperate-zone species, but the data are limited. For example, a comparison of *Bufo regularis* and *Bufo viridis* from Egypt revealed that *B. viridis* is more tolerant of cold than is *B. regularis*. *Bufo viridis* has a largely temperate distribution, whereas *B. regularis* is a more tropical African species (Katz and Gil 1997).

The possible role of low temperature in limiting latitudinal distributions of some anurans is evident from the distributions of species that barely enter the southern United States. For example, several species of leptodactylid frogs are limited to southern Texas and Florida; all represent northern extensions of genera found mostly in the tropics (Stebbins 1985; Conant and Collins 1991). The introduced marine toad (*Bufo marinus*) is now common in southern Florida, but is limited in its ability to disperse northward because it cannot survive prolonged exposure to temperatures below 10° C (Krakauer 1970). In Guatemala and Texas, this toad is not found in regions with a mean minimum temperature below 15° C (L. C. Stuart 1951; Zug and Zug 1979). Even brief exposure to cold can be lethal for tropical frogs. Heyer et al. (1988) documented a precipitous decline in several species of frogs in the Atlantic coastal forest of southeastern Brazil that was attributed to an unusually severe frost.

The number of amphibian species decreases dramatically at high northern latitudes. In North America, most species of salamanders are not found farther north than southern Canada, although *Ambystoma laterale* reaches Labrador and *Taricha granulosa* is found along the coast in southern Alaska. Many North American anurans also have their northernmost limits in southern Canada, but *Bufo americanus* reaches Labrador, and both *Bufo boreas* and *Rana sylvatica* are found in Alaska. *Rana sylvatica* is the only North American frog found north of the Arctic Circle (Conant and Collins 1991; Pinder, Storey, and Ultsch 1992). In Europe, *Triturus cristatus, T. vulgaris, Bufo bufo,* and *Rana*

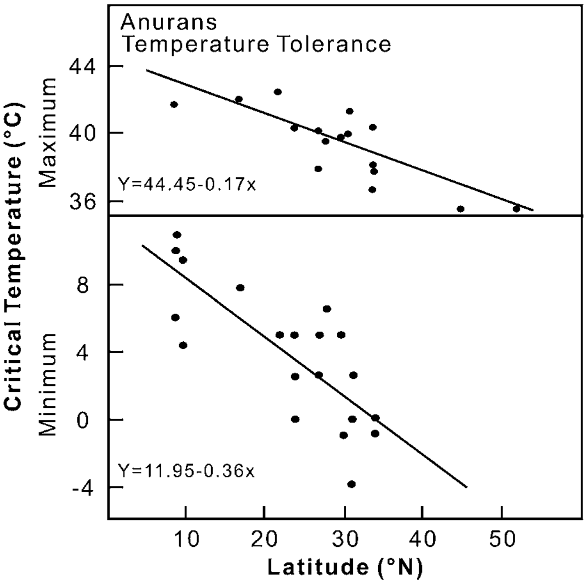

Fig. 3.7. Relationship of critical maximum temperature (top) and critical minimum temperature (bottom) to latitude for various species of anurans. The relationships have not been corrected for phylogeny and include tropical and temperate zone species from different families. After Snyder and Weathers (1975).

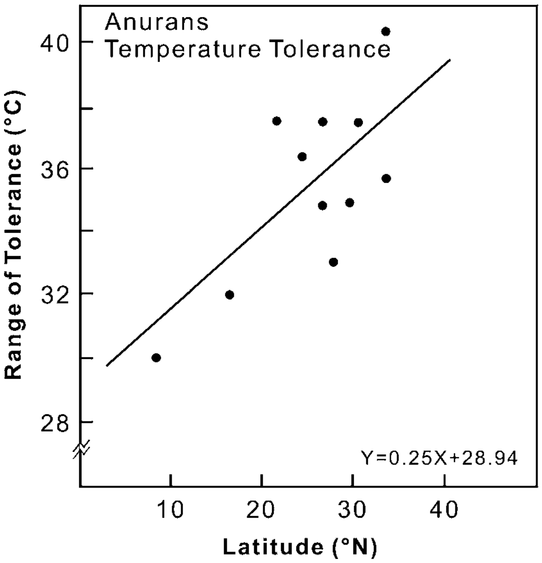

Fig. 3.8. Range of temperature tolerance (the difference between critical maximum and minimum temperatures) in anurans as a function of latitude. The data have not been corrected for phylogeny. The increased range of temperature tolerance at high latitudes is due mainly to increased tolerance for cold temperatures. After Snyder and Weathers (1975).

arvalis reach the central parts of Scandinavia, while *R. temporaria* lives north of the Arctic Circle. Only one urodele, the Siberian salamander (*Salamandrella keyserlingii*), is found north of the Arctic Circle (Arnold and Burton 1978; Pinder, Storey, and Ultsch 1992).

These far-northern amphibians not only must tolerate or avoid extreme cold in winter, but they also have short activity seasons and often are active at relatively low temperatures even in summer. These conditions can constrain feeding, growth, and reproduction (Forselius 1963; Koskela and Pasanen 1974, 1975; Bider and Morrison 1981; Sjögren, Elmberg, and Berglind 1988; Elmberg 1990). Indeed, several authors have suggested that the northern distribution of amphibians is limited not by low winter temperatures, but by the availability of a sufficient number of warm days during the summer activity period to allow for reproduction, feeding, and larval development (Wynne-Edwards 1952; Darlington 1957).

Among North American hylids, northern species that breed in early spring appear to have undergone adaptation to low temperature that allows them to be active at temperatures that would incapacitate their southern relatives, thereby prolonging their activity seasons (fig. 3.9; John-Alder, Morin, and Lawler 1988). In fact, most of the *Pseudacris* clade consists of species that breed in winter and early spring, a pattern that appears to be phylogenetically derived within North American hylids (Hedges 1986). Within-species comparisons of locomotion in northern and southern populations of *Pseudacris crucifer* did not reveal any difference in temperature sensitivity, however (John-Alder, Barnhart, and Bennett 1989). In contrast, R. S. Wilson (2001) reported that the jumping performance of *Limnodynastes peronii* from lowland tropical rainforests in northern Australia exhibited greater thermal sensitivity at low temperatures than did those from cooler temperate habitats in southern Australia.

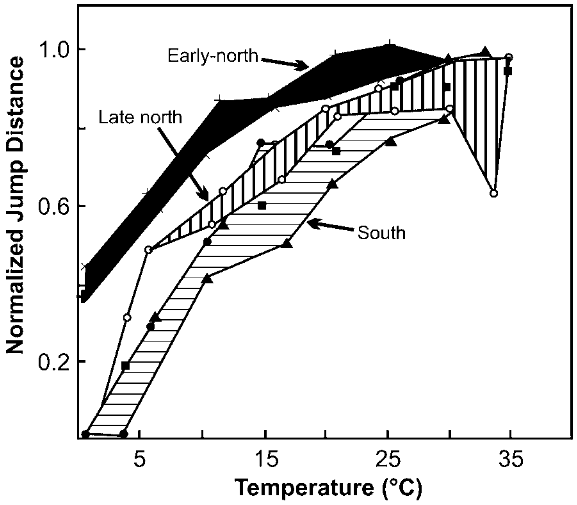

Fig. 3.9. Normalized jump distance as a function of temperature for early- and late-breeding northern populations and for southern populations of North American hylid frogs. Black area indicates northern species that breed in early spring (*Pseudacris crucifer* and *P. triseriata*). Vertical striping indicates northern species that breed in late spring and summer (*Hyla andersonii* and *H. versicolor*). Horizontal striping indicates southern species that breed at warm temperatures (*Acris gryllus, Hyla cinerea,* and *H. squirella*). Northern hylids exhibit greater jumping performance at low temperatures than do southern hylids, especially species of *Pseudacris* that breed at low temperatures. Jumping performance is similar for all species at warm temperatures. After John-Alder, Morin, and Lawler (1988).

Embryonic Thermal Tolerance and Latitudinal Distribution

While the latitudinal distribution of some amphibians is limited by thermal tolerance, or by thermal sensitivity of adults, the effects of temperature on embryos probably is even more important. Early work by J. A. Moore (1939, 1942, 1944, 1949a, b) showed that embryos of species of *Rana* that breed in early spring, such as wood frogs (*R. sylvatica*), are less tolerant of high temperature, and more tolerant of low temperature, than are the embryos of warm-weather breeders such as green frogs (*R. clamitans*) and bullfrogs (*R. catesbeiana*). Differences in lower thermal tolerance are most pronounced, so wood frogs can breed at temperatures that are lethal to green frog or bullfrog embryos. Indeed, wood frog embryos can tolerate brief periods of supercooling to temperatures as low as –2°C, but prolonged exposure to freezing tempertures kills most embryos (Frisbie, Constanzo, and Lee 2000). Among anurans in general, thermal tolerance of embryos tends to be positively correlated with breeding-pond temperature, but thermal tolerance is not necessarily related to latitude in a simple way (R. Douglas 1948; Volpe 1953, 1957; Ballinger and McKinney 1966; L. Licht 1971; H. A. Brown 1967, 1975a, b; Zweifel 1968b, 1977; Bachmann 1969; McLaren and Cooley 1972; Kuramoto 1975, 1978).

In general, intraspecific geographic variation in embryonic thermal tolerance is small relative to interspecific variation (J. A. Moore 1939, 1942, 1949b; Volpe 1953, 1957; Herreid and Kinney 1967; H. Brown 1975b). J. A. Moore (1949a) and others documented geographic variation in embryonic thermal tolerance in *Rana pipiens,* but later taxonomic work showed that these populations comprise a complex of closely related species (Hillis 1988). The same is true for the differences in embryonic thermal tolerance reported by H. A. Brown (1967) for populations of spadefoot toads. In California, *Spea hammondii* breeds after cool winter rains and embryos cannot tolerate high temperatures. In Arizona, populations once thought to be members of the same species breed after warm summer rains, and their embryos can tolerate higher temperatures. This population is now considered to represent a separate species, *Spea multiplicata* (H. A. Brown 1976b). The small differences among populations of the same species, even over wide geographic areas, suggest that evolutionary changes in embryonic thermal tolerance occur slowly compared to the rate at which populations disperse into new habitats. Consequently, it is not unusual for cold-adapted amphibians to breed at temperatures close to their lower thermal limits, while warm-adapted species often breed at temperatures near their upper thermal limits (Bachmann 1969). This means that embryonic thermal tolerance probably limits the latitudinal distributions of some species.

Altitudinal Distribution

Amphibians at high altitudes face the same problems encountered by those at high latitudes, including long, cold winters and short activity seasons with relatively cool temperatures. In addition, high-altitude environments are subject to wide fluctuations in temperature on a daily basis and often are relatively dry during summer activity seasons (Navas 1997, 2002, 2006). For aquatic breeders, altitudinal distribution also often is limited by the availability of ice-free ponds for larval development, especially for species with prolonged larval periods (Vences, Grossenbacher et al. 2003). Zschokke (1900) reported that anurans in the Alps with relatively short larval periods reach higher altitudes than do those with longer larval periods. All of these factors make high altitudes generally inhospitable to amphibians, and relatively few species live there (Hock 1964). Nevertheless, some amphibians manage to thrive even in these harsh conditions. In the western United States, three pond-breeding salamanders, *Ambystoma tigrinum, A. macrodactylum,* and *A. gracile,* live at elevations of up to 3,000 m. Three species of plethodontid salamanders are found above 2,400 m (*Aneides hardii, Hydromantes platycephalus,* and *Plethodon neomexicanus*). Anurans in this region are somewhat more successful at high altitudes. All five western species of *Pseudacris* and *Hyla* reach elevations of at least 2,300 m, and one, *P. triseriata,* is found above 3,600 m. At least five species of toads (*Bufo*) are found above 2,300 m, and two, *B. canorus* and *B. boreas,* above 3,600 m. Ten species of ranid frogs reach elevations of at least 2,400 m, and four (*Rana sylvatica, R. pretiosa, R. muscosa,* and *R. pipiens*) are found above 3,000 m (Stebbins 1985).

European amphibians generally are found at somewhat lower maximum elevations than are those in North America. In the Pyrenees, the limit appears to be about 2,500 m, whereas in the Alps, some species may live as high as 2,742 m (Vences, Grossenbacher et al. 2003). In Asia, the Himalayas support a rich and diverse amphibian fauna, including hynobiid salamanders and anurans in several families. Although fewer species are found at extreme altitudes than at lower elevations, some Himalayan amphibians are commonly found above 3,700 m, including hynobiid salamanders in the genus *Batrachuperus* and several bufonid, megophryid, rhacophorid, and ranid frogs (Liu 1950; Dubois 1974a, b). One megophryid frog, *Scutiger boulengeri* (= *S. alticola*), is reported to live at nearly 5,200 m, probably the highest elevation for any amphibian in the world (Hock 1964). Tropical mountains also tend to have fewer amphibian species at high elevations than at lower levels, although some groups actually are more diverse at mid-elevations than in the lowlands (Navas 2003 , 2006). Often the faunas of high elevations in the tropics are small subsets of faunas found at lower elevations. For example, one area in Colombia at 3,500 m has one species each of *Atelopus, Colostethus, Eleutherodactylus,* and *Hyla,* genera that are much more diverse at lower elevations (Lüddecke 1997; Navas 1997). Other high-elevation sites in the region have similar small amphibian faunas (J. D. Lynch 2001).

There has been relatively little work on the thermal physiology and ecology of high-altitude amphibians, although there is some work on thermoregulatory behavior (see discussion that follows). A number of authors have reported both interspecific and intraspecific differences in CT_{Max} for amphibians at different altitudes. Low-elevation species or populations generally tolerate slightly higher temperatures than do high-elevation forms (Brattstrom 1968; Delson and Whitford 1973b; K. Miller and Packard 1977; Hoppe 1978; Christian et al. 1988). Rome, Stevens, and John-Alder (1992) argued that amphibians rarely experience temperatures in the field that approach their critical thermal maxima and questioned the significance of these small differences in CT_{Max}. For example, J. H. Howard, Wallace, and Stauffer (1983) found that maximum water temperatures in ponds inhabited by *Ambystoma macrodactylum* did not exceed 25° C, but CT_{Max} of several populations was between 33° C and 34° C. Similarly, air temperature in the Puerto Rican lowland forest does not exceed 31° C, considerably lower than the CT_{Max} of *Eleutherodactylus coqui* from low-elevation sites (37.2° C) or *E. portoricensis* from higher elevations (36.3° C; Christian et al. 1988). Nevertheless, individual frogs might be exposed to higher temperatures for short periods of time when sitting in direct sunlight, and it is during these rare but dangerous events that they would benefit from a higher CT_{Max} (V. H. Hutchison, personal communication).

Studies of activities such as calling and locomotion provide a better indicator of how temperature affects the performance of amphibians under natural conditions. Navas (1996c, d) investigated the temperature dependence of swimming in four species of frogs from the high Andes of Colombia and compared their performance with that of congenerics from tropical-lowland populations in Panama. He found

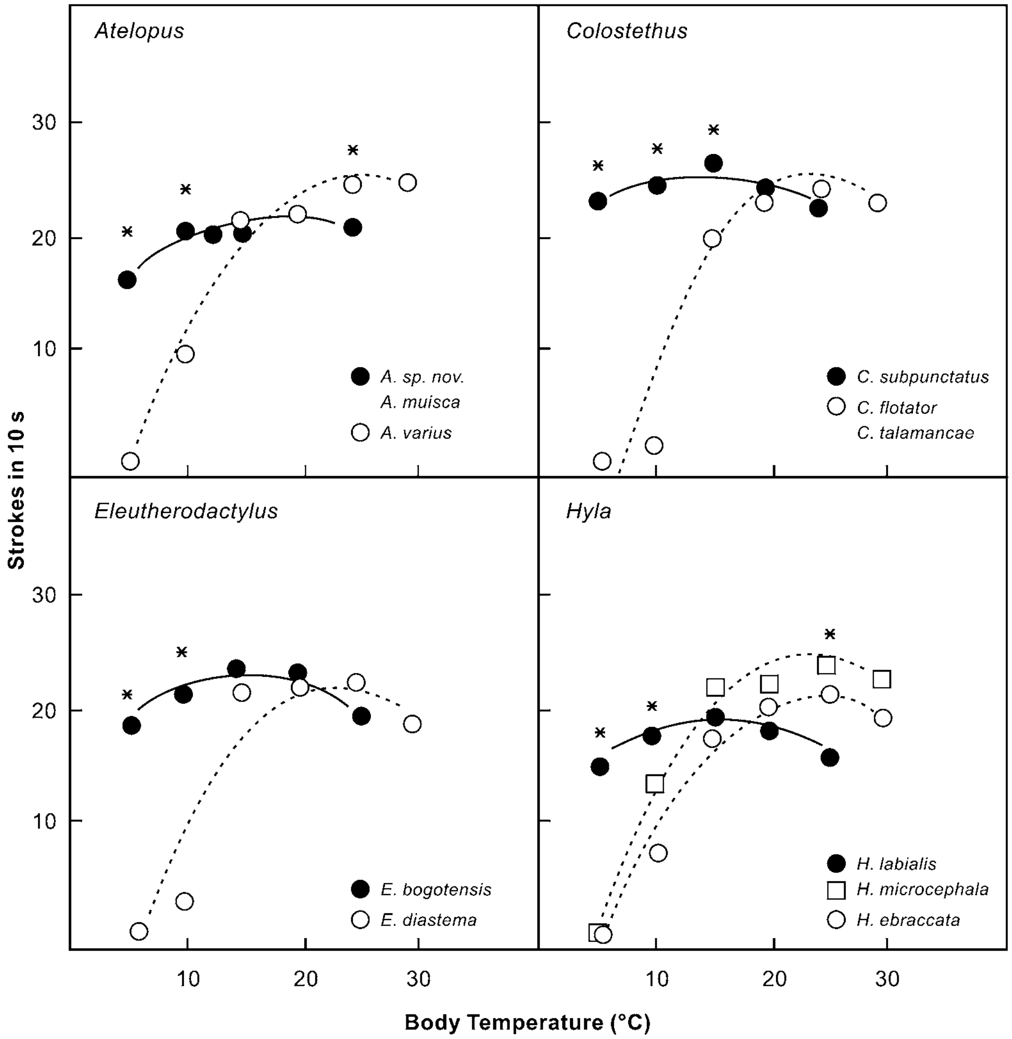

Fig. 3.10. Swimming performance as a function of temperature for high-elevation frogs from the Colombian Andes (dark circles) and for low-elevation congeneric species from Panama (open circles). Asterisks indicate temperatures at which significant differences were found between high- and low-elevation species. Data were pooled for *Atelopus muisca* and an undescribed species from the Andes, because they were not significantly different. Data also were pooled for *Colostethus flotator* and *C. talamancae* from Panama. High-elevation species in all four genera exhibit a much greater capacity for locomotion at low temperatures than do low-elevation congenerics. After Navas (1996c).

that populations of all four genera (*Atelopus, Colostethus, Eleutherodactylus,* and *Hyla*) from high-elevation sites could swim at temperatures as low as 5° C, whereas frogs from Panama were largely incapacitated at temperatures below 15° C (fig. 3.10). The enhanced swimming performance of high-elevation frogs was correlated with much higher metabolic scopes at low temperatures. Because the high-elevation species must have had low-elevation ancestors, their enhanced swimming and metabolic performance at low temperatures are derived physiological traits that have evolved independently in the four genera. Calling rates were more difficult to compare because of differences in call structure, but in general, high-elevation frogs called at lower rates than did low-elevation congenerics (Navas 1996a, d). The same was true for different populations of *Hyla labialis,* a tree frog found at a wide range of altitudes in Colombia. There was evidence in this species, however, for reduced thermal sensititivity in pulse-repetition rate at high altitudes (Lüddecke and Sánchez 2002). Daily patterns of calling activity are similar in high- and low-elevation species within genera (largely diurnal in *Colostethus,* nocturnal in *Eleutherodactylus* and *Hyla*). However, males in a population of *Eleutherodactylus bogotensis* from 3,500 m called for only about 1 hour after sunset, because temperatures dropped to 5° C or lower after that. In contrast, males in a low-elevation population of *Eleutherodactylus diastema* in Panama experienced little change in temperature and called from sunset to sunrise.

Emergence and Timing of Breeding

For many species of amphibians, emergence from hibernation and the beginning of breeding activity are closely tied to rising temperatures, although rainfall can be an important cue as well (Eibl-Eibesfeldt 1950; Rühmekorf 1958a; W. F. Blair 1960, 1961; Heusser 1960; Packer 1960; Forselius 1963; Hock 1967; L. Licht 1969b; Oldham 1969; Geisselmann, Flindt, and Hemmer 1971; van Gelder and Hoedemaekers 1971; Koskela and Pasanen 1974; Salthe and Mecham 1974; Obert 1975; Uwa et al. 1981; Wisniewski, Paull, and Slater 1981; Sofianidou and Kyriakopoulou-Sklavounou 1983; Bea, Rodriguez-Teijeiro, and Jover 1986; Beneski, Zalisko, and Larsen 1986; Radwan and Schneider 1988; Schneider, Sofianidou, and Kyriakopoulou-Sklavounou 1988; Kusano and Fukuyama 1989; Asimakopoulos, Sofianidou, and Schneider 1990; Elmberg 1990; Kyriakopoulou-Sklavounou and Kattoulas 1990; Le Garff 1998; Reading 2003). There is little evidence for geographic variation in thermal sensitivity within populations of the same species. Consequently, species found over a wide range of latitudes or altitudes usually exhibit marked geographic or altitudinal variation in the timing of breeding activity. For example, spring peepers (*Pseudacris crucifer*) and other members of the genus *Pseudacris* typically start breeding during the winter in southern parts of their ranges, but breed later in the spring in the north (John-Alder, Barnhart, and Bennett 1989). High-altitude populations of *Pseudacris* breed later than do lowland populations (Pettus and Angleton 1967). Wood frogs (*Rana sylvatica*) are winter breeders in the south, but are late spring or summer breeders in the north (Martof and Humphries 1959; Herreid and Kinney 1967). High-altitude populations breed later than do lowland populations at the same latitude (Berven 1982a).

Similar patterns are found in Old World anurans. The Japanese toad (*Bufo japonicus*) is found throughout Japan from about 30° N latitude to 42° N latitude. In southern Japan, this species breeds in winter (November and December), but in northern Japan, some populations do not breed until June (Matsui 1989). Breeding date is significantly correlated with mean annual temperature (fig. 3.11). In Britain, common frogs (*Rana temporaria*) are found over a wide range of altitudes (Beattie 1985). Breeding date is positively correlated with altitude (fig. 3.12 A) and negatively correlated with mean winter temperature (fig. 3.12 B). Common frogs also are found over a wide range of latitudes, from southern Europe—where they live mostly in the mountains—to northern Finland (64° N latitude). Frogs in southern Europe breed much earlier in the year than do those from northern parts of their range (Koskela and Pasanen 1975). In a study based on 140 years of breeding records, Terhivuo (1988) showed that common frogs in southern Finland begin breeding in late April, whereas those in the far north breed at the end of May (fig. 3.13). Similarly, *Rana dalmatina* begins breeding in late January or early February in Greece, late February or early March in Romania, and early April in Sweden (Hartel 2003). Local thermal conditions unrelated to latitude or altitude can affect breeding phenology as well. A population of the rhacophorid frog *Buergeria japonica* from a geothermal hot spring in Taiwan breeds throughout the year, whereas stream-breeding populations do not breed in the winter months (T. Chen, Kam, and Lin 2001). Tadpoles in this population exhibit greater tolerance of higher temperature than do those from cooler habitats (Wu and Kam 2005).

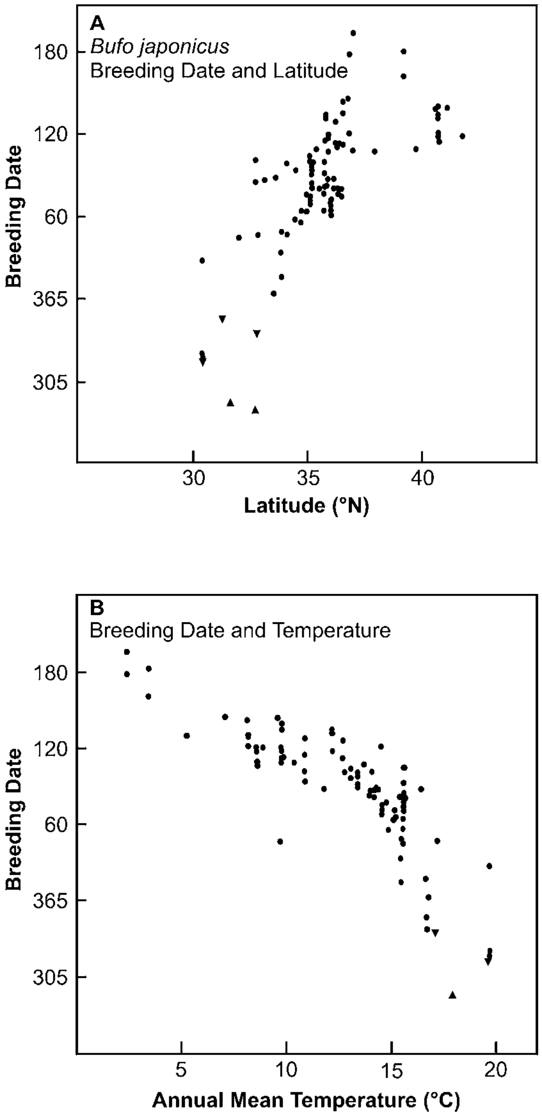

Fig. 3.11. Relationship of first breeding date to latitude (A) and temperature (B) for populations of the Japanese toad (*Bufo japonicus*). Toads begin breeding in late winter at low latitudes, but do not breed until early summer at high latitudes (A), presumably because of much lower average temperatures (B). Date 1 = January 1. After Matsui (1989).

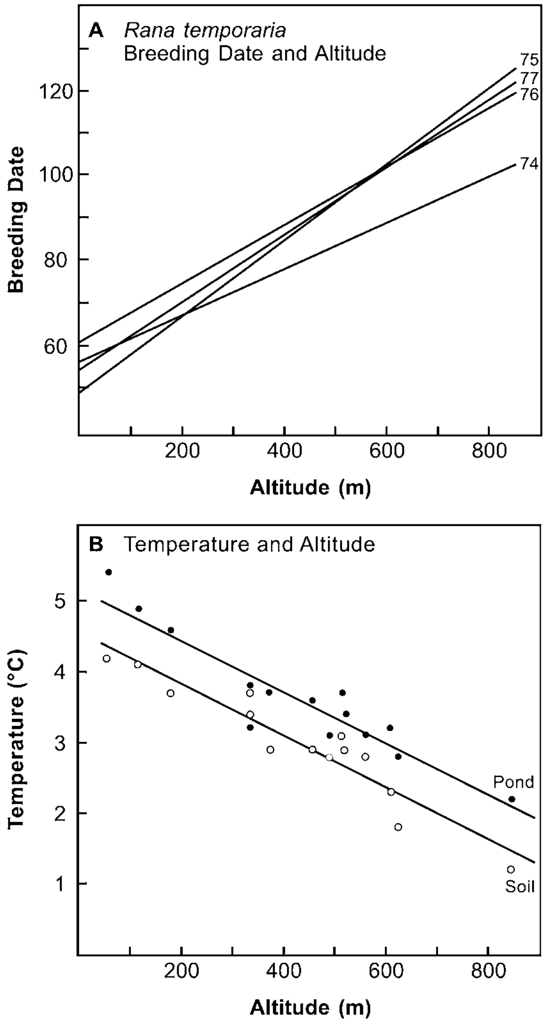

Fig. 3.12. (A) Relationship of breeding date to altitude for populations of the common frog (*Rana temporaria*) in Britain. (B) Relationship of average soil and water temperature to altitude. Data in (A) are shown for four different years (1974–1977). Average temperatures decrease with increasing altitude, and this is correlated with much later breeding. After Beattie (1985).

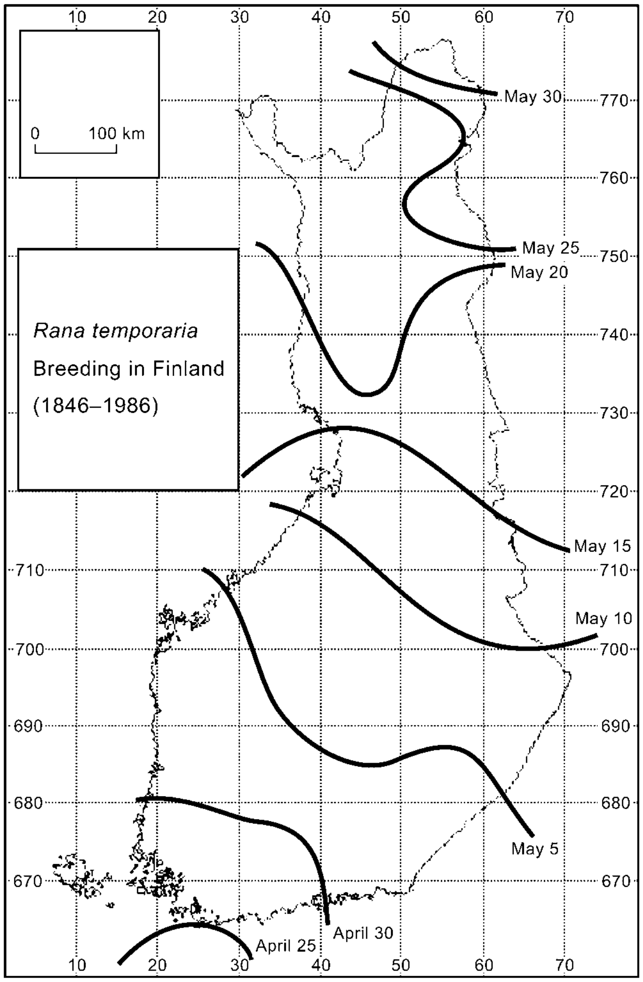

Fig. 3.13. Map showing changes in breeding dates for common frogs (*Rana temporaria*) in Finland as a function of latitude. Isobar lines show average first breeding date for a 140-year period (1846–1986). Breeding in northern Finland is delayed by about a month compared to populations in southern Finland. Breeding in most regions of Finland has started earlier in recent decades because of climate warming. After Terhivuo (1988).

With the general warming of the world's climate in recent decades, there is some evidence that the onset of breeding for some temperate-zone amphibians has shifted to earlier dates. For example, Terhivuo (1988) found that breeding of *Rana temporaria* in all parts of Finland has become progressively earlier over the past 140 years due to gradual warming of the climate. Similar trends toward earlier breeding were observed in two species of anurans and three newts over a 17-year period in England, but not for *Rana temporaria* (Beebee 1995a; Forchhammer, Post, and Stenseth 1998). A 19-year study of a population of *Bufo bufo* in southern England showed that year-to-year variation in timing of breeding was correlated with mean winter temperature in the 40 days immediately before breeding began. This study did not find a clear trend toward earlier breeding over the course of the study, although five of the earliest breeding events occurred in the last 10 years (Reading 1998). Other studies have found that some species appear to be breeding earlier, while others are not (Blaustein et al. 2001; Gibbs and Breisch 2001; Tryjanowski, Rybacki, and Sparks 2003).

For many anuran species, the level of calling activity and the number of pairs laying eggs also are affected by daily fluctuations in temperature. Most species appear to have a low-temperature threshold below which they become inactive. This can result in breeding seasons that otherwise would be continuous being divided into a series of short episodes of breeding activity when temperatures are favorable, separated by periods of inactivity in cold weather (Wahl 1969; Obert 1975). This is most likely to occur in early spring breeders, which tend to experience considerable variation in temperature (Sofianidou and Kyriakopoulou-Sklavounou 1983; Schneider, Sofianidou, and Kyriakopoulou-Sklavounou 1988; Kusano and Fukuyama 1989; Asimakopoulos, Sofianidou, and Schneider 1990). It also can occur in the summer, but periods of inactivity tend to be shorter (R. D. Howard 1978a; Radwan and Schneider 1988; Sjögren, Elmberg, and Berglind 1988; Kyriakopoulou-Sklavounou and Kattoulas 1990).

Choice of Calling and Oviposition Sites

Within breeding ponds, water temperature can have a considerable influence on where males call and where females lay their eggs. For example, *Rana dalmatina* breeds in late January or early February in Greece. Males call mostly underwater early in the breeding season, but move to the surface as air temperature rises (Schneider, Sofianidou, and Kyriakopoulou-Sklavounou 1988). In a population of *Rana lessonae* in Sweden, males consistently chose the warmest locations in the breeding pond to call, and eggs were deposited in the same areas. Males moved from one part of the pond to another depending on the prevailing wind direction and local changes in water temperature (Sjögren, Elmberg, and Berglind 1988). Adams and Frissell (2001) found some clutches of eggs of *Ascaphus montanus,* a cold-adapted stream-breeding frog, in locations near cold groundwater seeps that reduced the temperature of the surrounding water, suggesting active selection of cooler sites for reproduction. In a population of bullfrogs (*Rana catesbeiana*) in Michigan, choruses moved to successively cooler locations as the season progressed; those in early June were in the warmest part of the pond, whereas late-July choruses were in the coolest part (R. D. Howard 1978a). Female bullfrogs avoid depositing eggs in very warm water (above 32° C) that can produce developmental abnormalities in the embryos (R. D. Howard 1978b).

Male bullfrogs are territorial, so choice of calling and oviposition sites are closely linked. In some winter- or spring-breeding ranids, pairs in amplexus move away from calling sites before depositing eggs. They often clump egg clutches together in large communal masses, a behavior generally not seen in warm-weather breeders (Bragg 1953, 1954a; Heusser 1961; Savage 1961; Guyétant 1966; Herreid and Kinney 1967; Zweifel 1968a; L. Licht 1969b, 1971; Hassinger 1970; Beattie 1980). Communal egg masses appear to provide a thermal advantage to the eggs by retaining heat longer than isolated masses as temperatures drop (Seale 1982b; Waldman 1982a; Waldman and Ryan 1983). Communal egg masses often are deposited in very shallow water, exposing them directly to the warmth of the sun during the day (see fig. 10.4 A in chapter 10). Wood frogs (*Rana sylvatica*) consistently place their egg masses in locations where growth and development of tadpoles is enhanced compared to other sites available in the same ponds (Freidenburg 2003). In some species, oviposition behavior changes in response to changes in ambient temperature. For example, J. Caldwell (1986b) found that southern leopard frogs (*R. utricularia*) breeding in warm weather usually deposited egg masses individually, whereas those breeding in cold weather often deposited eggs in communal masses.

Behavioral Thermoregulation

Ectotherms must rely mainly on behavioral adjustments to regulate their body temperatures. This is particularly true of amphibians, which have very limited abilities to alter rates of heat loss and gain physiologically. Following the publication of the classic paper of Cowles and Bogert (1944) on thermoregulation in desert reptiles, studies of behavioral thermoregulation became a major focus of herpetological research (Avery 1982; Huey 1982). Studies on amphibians have lagged behind those on reptiles, perhaps because overt thermoregulatory behavior is less obvious in amphibians than in reptiles such as desert lizards. In fact, there has been some controversy over whether amphibians engage in active thermoregulation in the field. In part, this results from different definitions of the term thermoregulation. Some workers have defined thermoregulation as an ability to maintain body temperatures above that of the surrounding environment, but probably the best definition is an ability to maintain body temperatures within a range that is narrower than the range of environmental temperatures available to the animal (Hutchison and Dupré 1992).

The precision of thermoregulation varies considerably among species, depending on the ecological circumstances in which they find themselves. Behavioral thermoregulation not only has obvious benefits in enabling an animal to select temperatures that are most favorable for feeding, digestion, growth, locomotion, or reproduction, but it also has costs, such as increased exposure to predation, increased energy expenditure, and decreased time available for other activities. The degree to which a given species engages in active thermoregulation represents a balance between these costs and benefits (Huey and Slatkin 1976; Huey 1982). For example, most desert lizards thermoregulate very precisely. The cost of not doing so can be high, because these animals often are exposed to near-lethal environmental temperatures. In contrast, some tropical rainforest lizards are effectively thermoconformers, allowing their body temperatures to vary with environmental temperature. For these animals, the cost of moving between widely spaced sunspots is greater than the benefit of maintaining temperature within a very narrow range, especially when they can function reasonably well over the entire range of temperatures to which they are normally exposed. The same probably is true for many amphibians. Species that choose a relatively narrow range of temperatures in laboratory thermal gradients often exhibit a much wider range of body temperatures in the field, either because the preferred temperature is not available, or because the cost of shuttling between microhabitats is too great (Hutchison and Dupré 1992).

Thermoregulation in Water

Because the thermal conductivity of water is much greater than that of air, amphibians that are completely immersed in water seldom have body temperatures that differ significantly from that of the surrounding environment (Spotila, O'Connor, and Bakken 1992). Furthermore, heating and cooling rates tend to be very rapid, especially for small-bodied species. While some reptiles can make physiological adjustments that alter heating and cooling rates (Bartholomew 1982), this does not appear to be true for most amphibians. For example, two relatively large-bodied salamanders, *Amphiuma means* and *Necturus maculosus,* and two frogs, *Rana catesbeiana* and *R. pipiens,* all heat and cool at similar rates in water (Tripp and Lustick 1974; K. A. Anderson and Beitinger 1979; Bohlin and Beitinger 1979; Tracy, Tracy, and Turner 1992). Consequently, the only way that an aquatic amphibian can alter its body temperature is to move between microhabitats in response to local differences in water temperature.

Tadpoles often exhibit clear preferences for certain temperatures when tested in laboratory thermal gradients (Workman and Fisher 1941; Rühmekorf 1958b; Herreid and Kinney 1967; Lucas and Reynolds 1967; de Vlaming and Bury 1970; Casterlin and Reynolds 1978; Hutchison and Hill 1978; Dupré and Petranka 1985; Wollmuth et al. 1987; Wollmuth and Crawshaw 1988; see summary of data in table 9.2 of Hutchison and Dupré 1992). Studies of larval newts and ambystomatid salamanders have produced similar results (P. Licht and Brown 1967; Heath 1975; Keen and Schroeder 1975; Stauffer, Gates, and Goodfellow 1983; Dupré and Petranka 1985). In most laboratory studies tadpoles or salamander larvae were presented with a choice of temperatures from near freezing to between 25° and 35° C. The animals generally chose a range of temperatures somewhere in the middle (between 15° and 25° C), avoiding both very cold and very warm temperatures. However, tadpoles of the tailed frog (*Ascaphus truei*) from cold streams of the northwestern United States selected much lower temperatures (5–9° C) than did the other species tested. Tadpoles confronted with very high temperatures, such as those found in thermal springs, are capable of avoiding near-lethal temperatures (Wu and Kam 2005).

Both acclimation temperature and stage of development can affect the range of temperatures selected by amphibian larvae (Hutchison and Dupré 1992). In bullfrog tadpoles, for example, preferred temperature tends to increase both with increasing acclimation temperature and with stage of development, although the latter trend is not consistent at all acclimation temperatures (Hutchison and Hill 1978; Wollmuth and Crawshaw 1988). Preferred temperature has been reported to increase with stage of development in several other species of amphibian larvae, including *Rana cascadae, R. utricularia, Bufo marinus, B. americanus, Pseudacris triseriata,* and *Ambystoma texanum* (Floyd 1984; Keen and Schroeder 1975; Dupré and Petranka 1985; Wollmuth et al. 1987). This pattern was not seen in *Taricha rivularis,* however (P. Licht and Brown 1967). In some species, preferred temperature increases during most of development, but then drops significantly at metamorphic climax. As a result, the larvae select the warmest temperatures just before metamorphosis, thereby ensuring rapid development when larvae are racing to reach metamorphosis before temporary ponds dry up (see chapter 13) and when they are particularly vulnerable to predators (see chapter 14; Dupré and Petranka 1985; Hutchison and Dupré 1992).

How closely do the temperatures selected by amphibian larvae in laboratory gradients reflect normal activity temperatures and the precision of thermoregulation in the field? Unfortunately, this question is hard to answer, because reliable data on thermoregulation of larvae in the field are scarce. Since these animals generally are too small for temperature to be monitored by implanted thermocouples or temperature-sensitive transmitters, it has been nearly impossible to collect data on changes in body temperature of individual animals over time. Most field data consist of single measurements of body temperatures, or measurements of water temperature in areas where aggregations of larvae were observed (e.g., Rühmekorf 1958b; Brattstrom 1962c, 1963; P. Licht and Brown 1967; J. D. Anderson 1968b; Heath 1975; Wollmuth et al. 1987). Often such measurements reveal a rather wide range of temperatures over which larvae are active, but provide little information on the precision of thermoregulation. The best field evidence for active thermoregulation in aquatic larvae comes from studies showing a tendency for larvae to aggregate in the warmest available parts of the habitat. Nearly all such examples are species that breed at high altitudes in relatively cool environments, or in shallow, temporary ponds (Brattstrom 1962c; Heath 1975; Wollmuth et al. 1987). In either case, rapid growth and development would be advantageous and would be promoted by selection of warm microhabitats.

Information on thermoregulation by adults of aquatic amphibians is meager. There has not been a single detailed study of thermoregulation in a fully aquatic frog, and only a handful of such studies on salamanders and newts. P. Licht and Brown (1967) found little evidence of precise temperature selection by *Taricha rivularis* breeding in a stream, although they did avoid very warm temperatures near hot springs feeding into the stream. Body temperatures of newts in an aquatic gradient in the laboratory were monitored with implanted thermocouples and exhibited rapid fluctuations as the animals moved through the gradient. Although they did not show a strong preference for a narrow range of temperatures, they did avoid raising their body temperatures above 20° C. The newts did not show a clear avoidance of very low temperatures and sometimes climbed onto ice at the cold end of the gradient. In contrast, adult *Ambystoma tigrinum* from high-altitude ponds in Colorado tended to avoid cold water in the field and were consistently found in the warmest sections of the ponds, moving into shallow water during the day and into deeper water at night (Heath 1975). In a laboratory gradient, adults selected a rather wide range of temperatures between about 12° and 26° C and were somewhat less precise thermoregulators than were larvae.

Hutchison and Hill (1976) studied temperature selection by two large aquatic salamander species, *Cryptobranchus alleganiensis* and *Necturus maculosus,* in a laboratory thermal gradient. In both species, acclimation temperature had a significant effect on preferred temperatures. Salamanders acclimated to 5° C tended to select the lowest temperatures available in the gradient (down to about 4° C) and almost always avoided temperatures above 18° C. Those acclimated to 15° C and 25° C selected somewhat higher temperatures, but also were less precise in their thermoregulation. *Necturus* also exhibited a daily shift in preferred temperature, becoming more active and selecting higher temperatures at night than they did during the day. This suggests that when these salamanders are relatively inactive during daylight hours, they retreat to deeper, cooler water and allow their body temperatures to fluctuate with that of the environment (Hutchison and Spriestersbach 1986). Unfortunately, we have little detailed information on temperature selection in the field for either of these species, but both are found mainly in cool environments. Adams and Frissell (2001) found evidence of seasonal movements of *Ascaphus montanus* adults into cool water in streams where summer temperatures exceeded 16° C, but not in streams that remained cool all year.

Thermoregulation on Land

Thermoregulation on land is considerably more complex than thermoregulation in water because there are more avenues of heat loss and heat gain to be considered (fig. 3.14). Of particular importance is the interaction between temperature and evaporative water loss in animals with a highly permeable skin (Tracy 1975, 1976; Spotila, O'Connor, and Bakken 1992; Tracy, Tracy, and Turner 1992; Bartelt and Peterson 2005). A terrestrial amphibian often is severely constrained in its choice of activity temperatures because preferred temperatures are not available in suitably moist microhabitats. For example, terrestrial salamanders often choose relatively narrow ranges of temperatures in laboratory gradients, but choices can be modified by the availability of cover and hydration state. They choose temperatures higher than those normally preferred if suitable cover is available only at the warm end of the gradient. Dehydrated animals prefer cooler temperatures than those chosen by fully hydrated individuals, thereby reducing rates of evaporative water loss (P. Licht and Brown 1967; Spotila 1972; Feder and Pough 1975).

Terrestrial salamanders have perhaps the simplest form of thermoregulation in the field because they do not engage in overt thermoregulatory behavior such as basking. Moisture probably is more important than temperature preference in selection of microhabitats, but in general, the wet microhabitats favored by salamanders also are relatively cool. Consequently, it is unusual for terrestrial salamanders to be found at temperatures exceeding 25° C, even in the tropics, and typical activity temperatures for most species are below 15° C (Brattstrom 1963; Spotila 1972; Feder 1982b; Feder and Lynch 1982; Feder et al. 1982). Nevertheless, there is limited evidence for active selection of temperatures in the field. For example, Feder (1982b) reported finding individuals of a small Neotropical salamander, *Thorius narisovalis,* under the bark of logs at temperatures up to 6° C warmer than the coolest available temperatures. Even so, the warmest temperature recorded for one of these salamanders was only about 21° C. In contrast, it is not unusual for tropical frogs to have body temperatures above 30° C, and average activity temperatures for many anurans are around 25° C (Hutchison and Dupré 1992). Because of their low activity temperatures and generally slow-moving way of life, terrestrial salamanders, especially plethodontids, have extremely low metabolic rates and the lowest energy requirements of any terrestrial vertebrates (Feder 1983a; see also chapter 5).

Like terrestrial salamanders, many frogs and toads exhibit clear preferences for relatively narrow ranges of temperature when tested in laboratory thermal gradients (Strübing 1954; Cabanac and Jeddi 1971; Lillywhite 1971a; Claussen 1973a; Carey 1978; Gatten and Hill 1984; Smits 1984; Shoemaker et al. 1987; Shoemaker, Baker, and Loveridge 1989; Wollmuth et al. 1987; Malvin and Wood 1991; Tracy et al. 1993; Lüddecke 1995b; Katz, Hoffman, and Gil 1997; see data summary in table 9.2 of Hutchison and Dupré 1992). Preferred temperatures in laboratory thermal gradients

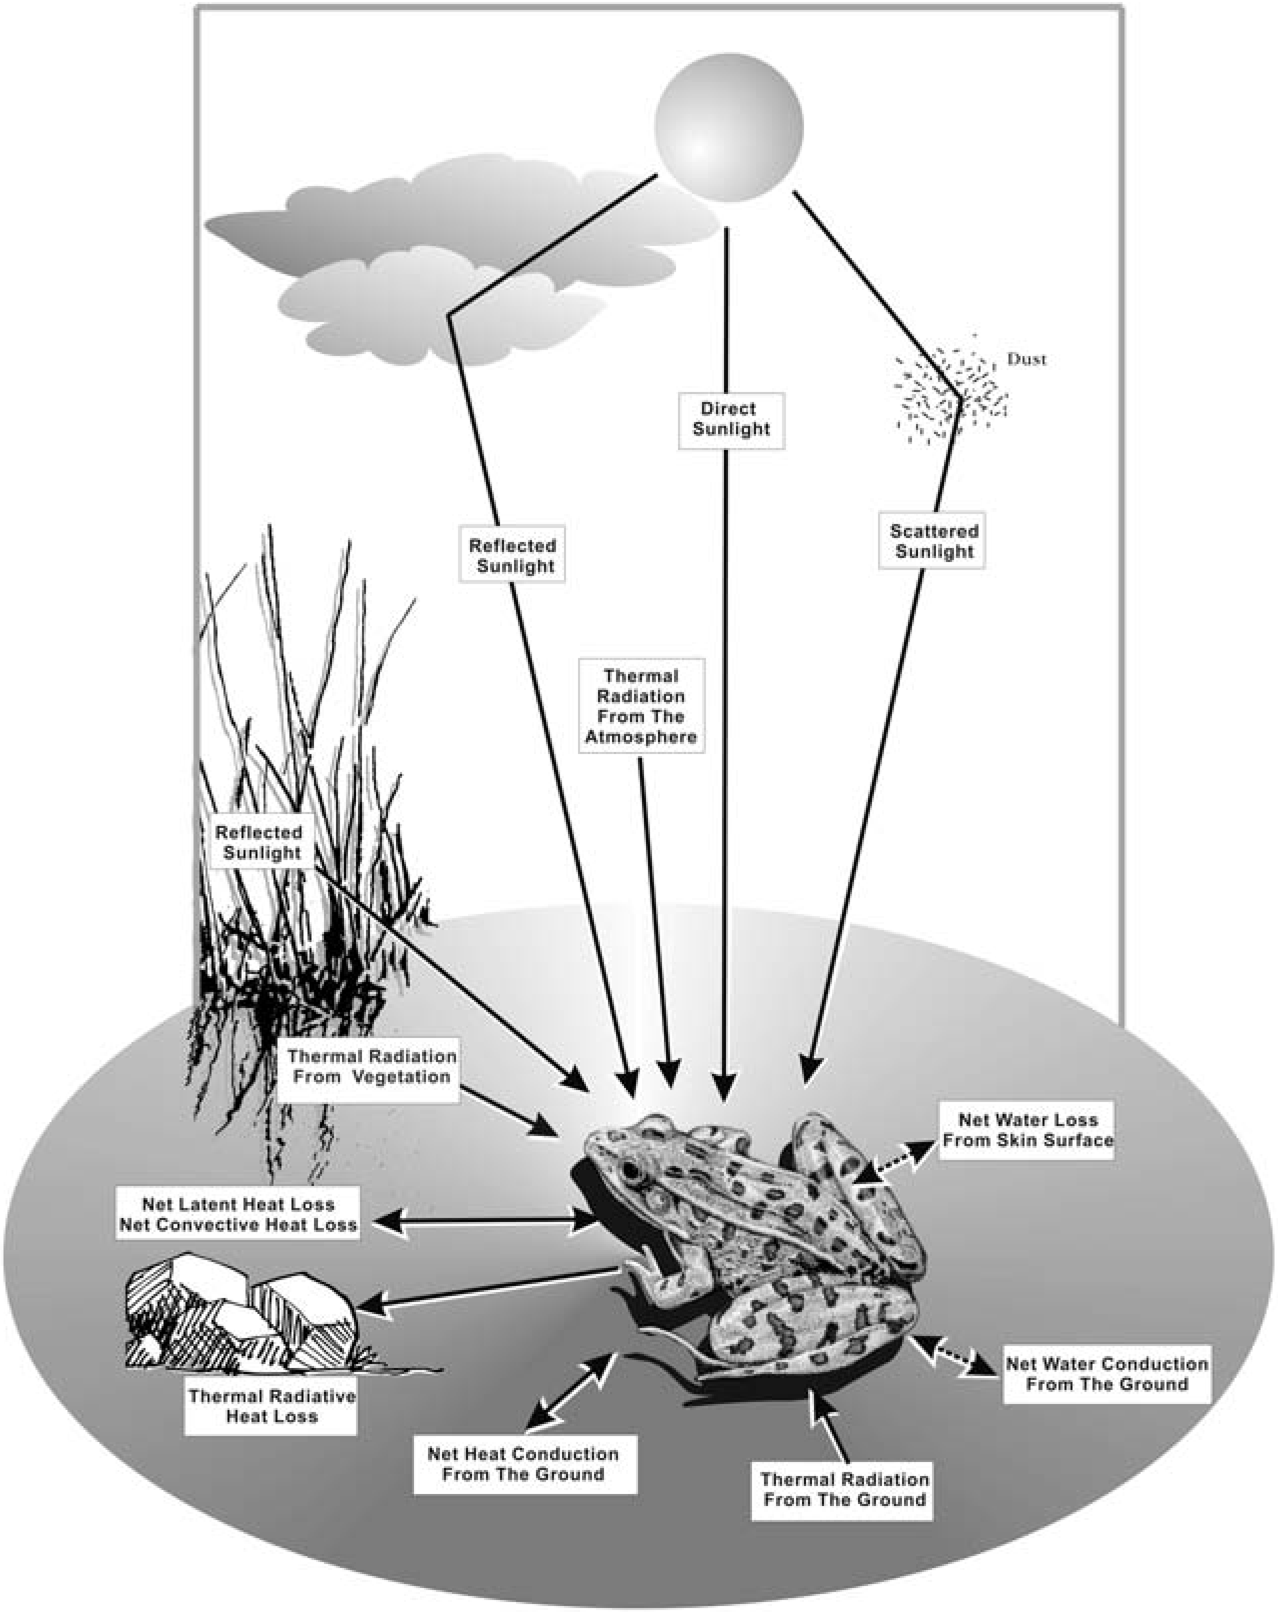

Fig. 3.14. Avenues of heat loss and gain (solid arrows) and water loss and gain (dashed arrows) for a leopard frog (*Rana pipiens*) in a meadow. Drawing by Mary Jane Spring after Tracy (1976).

sometimes are correlated with activity temperatures in the field, but often the range of activity temperatures in the field is wider. For example, many anurans select temperatures in laboratory gradients between 26° and 30° C, regardless of the actual temperatures available to these animals in the field (Hutchison and Dupré 1992; Lüddecke 1995b; Katz, Hoffman, and Gil 1997). Most anurans are less secretive than are terrestrial salamanders, which tend to venture from thermally buffered retreat sites only at night or during rainy weather. Consequently, anurans frequently are exposed to major fluctuations in environmental temperature on both a daily and seasonal basis (Carey 1978). Often the body temperatures of these animals simply track ambient temperatures, but many anurans engage in more obvious thermoregulatory behavior than do terrestrial salamanders.

Some anurans regulate their body temperatures by moving between microhabitats that differ in temperature. Sinsch (1984) investigated this type of behavior in three species of European ranid frogs. He put the frogs in a large aquarium with shallow water at one end and soil at the other. The terrestrial section was covered with grass and other plants and provided with boxes for shade. He tested animals during the day and at night. During the day, a light bulb suspended over the soil provided a thermal gradient of about 8° C between the cool aquatic end and the warmer terrestrial end of the tank. The responses of frogs were tested at four different ranges of temperatures (coolest 8–16° C; warmest: 24–31° C).

Sinsch found that *Rana temporaria,* the species with the northernmost distribution, generally preferred the coolest temperatures and could not tolerate the highest range of test temperatures for an extended period. These frogs shifted activity periods from mostly nocturnal at warm temperatures to mostly diurnal at cool temperatures. This is the most terrestrial of the three species outside of the breeding season, and these frogs spent most of their time on land except when retreating to the cooler water at very warm temperatures. The other two species, *R. lessonae* and *R. ridibunda,* have a more southern distribution and both tolerate and prefer higher temperatures than does *R. temporaria. Rana lessonae,* which inhabits the shorelines of ponds, remained on land most of the time, but moved to the water at cool temperatures. While on land, they often sat directly exposed to heat from a lamp. In contrast, *R. ridibunda,* the most aquatic of the three species, spent considerably more time in the water, especially at warmer temperatures, but retreated to terrestrial hiding places at the coolest temperatures. Thus, both the microhabitats and general range of temperatures chosen by these species are correlated with their geographic ranges and habitat associations in nature.

The first detailed fieldwork on thermoregulation in anurans was Lillywhite's (1970) study of bullfrogs (*Rana catesbeiana*) in California. In a pond that lacked vegetation along the shore, the frogs maintained body temperatures within a relatively narrow range by shuttling back and forth between the water and the land. On cool evenings, the frogs were found mainly near the warm water at the center of the pond, but gradually moved closer to shore during the day. As water temperatures rose as high as 35–40° C in the shallow water, close to the critical thermal maximum of 38° C, the frogs emerged onto the shore, where they remained exposed to direct sunlight. On particularly hot days, the frogs adopted an upright posture, with their legs extended, a posture that Lillywhite interpreted as facilitating evaporative cooling. However, in contrast to some lizards, the frogs did not appear to alter their orientation relative to the sun as body temperature changed. At very high temperatures, the bullfrogs periodically discharged mucus onto the surface of the skin, resulting in enhanced evaporative cooling and a temporary reduction in body temperature (Lillywhite 1971b, 1975). These frogs could sit all day in direct sunlight only if a source of moisture (the pond or damp soil) was available to compensate for evaporative water losses. The frogs inhabiting this very exposed pond probably experienced temperatures higher than they would normally prefer, and when artificial shelters were provided, the frogs often moved into the shade.

Although the bullfrogs studied by Lillywhite moved frequently between land and water, such movements are not always necessary to keep body temperatures within a relatively narrow range. Tracy (1976) studied the water and temperature relations of leopard frogs, *Rana pipiens,* using biophysical models to predict the effects of environmental variables such as wind speed, air temperature, substrate temperature, relative humidity, and absorbed solar radiation. During the summer, leopard frogs disperse away from breeding ponds into damp meadows, where individuals are quite sedentary for long periods of time. In an earlier study, Dole (1965a) reported that some frogs spent several days at a time sitting in the same spot in damp soil. Tracy found that frogs sitting in such positions in direct sunlight could maintain body temperatures within a range of less than 5° C, even without extensive movements between microhabitats. He also found that the amount of cover in a frog's immediate surroundings had very little effect on core body temperature, which was more strongly influenced by substrate temperature.

Amount of cover did have a significant effect on rates of evaporative water loss, with frogs in shaded environments losing water at a much slower rate than frogs in direct sunlight. Hence, the shade-seeking behavior observed in bullfrogs and other species probably has more to do with reducing evaporative water loss than with regulating core body temperature. However, even in shaded environments, a frog exposed to relatively high temperatures will desiccate unless it can rehydrate periodically (Tracy 1975, 1976). Therefore, the key to a frog being able to maintain an elevated body temperature is the availability of substrates wet enough to allow the frog to compensate for losses through evaporation. This is consistent with field observations that leopard frogs in meadows are invariably found on wet soil (Dole 1967; Tracy 1976). In contrast to bullfrogs, leopard frogs often are far from standing water during the summer, so shuttling between microhabitats to maintain body temperatures within a narrow range could be costly because movement would increase evaporative water loss. Since these frogs do not heat up excessively as long as they have a source of moisture available, most individuals probably are better off remaining in one spot, even when exposed to bright sunlight, rather than moving through patches of dry, inhospitable habitat.

Thermoregulation at High Altitudes

Anurans living at high altitudes face particularly difficult problems of thermoregulation. High-altitude environments generally have cooler average temperatures than low-altitude environments, but perhaps more important, they often have much greater fluctuations of temperature during a single day. This is because of the low density and high transparency of air at high altitudes, which produces intense solar radiation during the day, followed by rapid radiative cooling at night. Hence, it is not unusual for anurans living at high altitudes to experience temperature changes of 25° to 30° C in a 24-hour period, and changes of more than 10° C can occur within a few minutes (Carey 1978; Navas 1997, 2003, 2006). Further complicating problems of thermoregulation is the relatively low humidity of many mountain environments during the day, resulting in high rates of evaporative water loss from the exposed skin of amphibians (Bradford 1984b). Anurans at high altitudes have several options for dealing with the combination of low average temperature and high temperature variation. These include (1) being active at a wider range of temperatures than are anurans at lower elevations, (2) shifting activity periods to daylight hours to maximize activity temperatures, and (3) being active in particularly warm microhabitats, provided that suitably moist substrates are available.

The boreal toad, *Bufo boreas boreas,* studied by Carey (1978) in the mountains of Colorado, is one species exposed to such extremes of temperature. Although these toads select a relatively narrow range of temperatures in a laboratory thermal gradient, they are active at a wider range of temperatures in the field, from near freezing to almost 34° C. Toads in her high-elevation population (2,900 m) were active during the day and at night. On very cold nights, they took shelter under logs or in water, but did not use burrows. Carey used implanted radio transmitters to monitor changes in body temperature of several toads released into an enclosure with access to sun, shade, and water. Even in summer, body temperatures of these toads often were only a few degrees above freezing in early morning, but rose rapidly as the sun came out. In direct sunlight, the toads maintained body temperatures between about 27° and 32° C for up to 6 hours in the middle of the day, although extended periods of cloud cover could drop body temperatures by 10° C in an hour. This species has been observed basking on warm rocks around breeding pools, enabling basking individuals to attain body temperatures that were 8° C above those of non-basking toads in the water (Muths and Corn 1997).

In contrast to high-altitude populations, populations of *B. boreas* studied at low altitudes in California by Carey (1978) and Smits (1984) were primarily nocturnal during the summer, spending hot daylight hours in burrows. Smits found that activity periods changed throughout the year, with toads being much more active during the day in the spring and fall, when air temperatures were cooler. During these cool periods, emergence from burrows was regulated mainly by the time when temperatures at the burrow entrance exceeded that inside the burrow. In contrast, evening emergence was governed mainly by sunset time, although temperature also had an effect (Smits and Crawford 1984). Toads in these populations were active at a narrower range of temperatures (about 10–28°C) than was the high-altitude population, generally avoiding both hot and cold extremes. However, the preferred body temperatures of the high-altitude toads and the two low-altitude populations measured in laboratory gradients were not different, averaging about 24° C in all cases. Thus, it appears that high-altitude populations are active over a wider range of temperatures because that is the only way for them to have enough time to acquire the food they need, not because of inherent differences in preferred body temperature. The increased diurnal activity of high-altitude toads probably is a response to the activity periods of their insect prey rather than a direct physiological response to temperature (Carey 1978).

Physiological differences between high- and low-altitude populations of North American toads are similar to those observed in studies of toads in the Andes of South America. Sinsch (1989a) found that populations of *Bufo spinulosus* at 3,200 m in the Peruvian Andes were active day and night. On sunny days, they warmed up quickly in the morning sun and then remained in the open for several hours. Substrate temperature was more important than air temperature in determining body temperature, so by sitting on warm substrates, the toads could maintain body temperatures above that of the surrounding air, even at night. However, on very sunny days, toads in the open always had body temperatures below air temperature because of evaporative cooling (fig. 3.15).

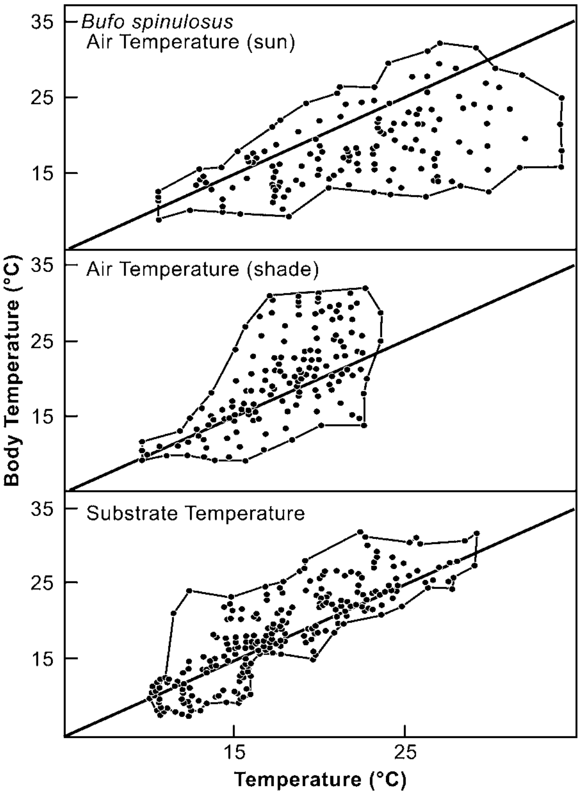

Fig. 3.15. Relationship of body temperature to air and substrate temperature in a toad from the high Andes of Peru (*Bufo spinulosus*). Body temperatures of toads typically are lower than air temperature in the sun, but not in the shade, because of increased evaporative water loss in the sun. Body temperatures usually are slightly higher than substrate temperature. After Sinsch (1989a).

Bladder water was gradually depleted on sunny days, so by afternoon, the toads usually retreated to shady sites.

A study of the same species at a higher elevation (4,300 m) by Pearson and Bradford (1976) revealed that adult toads were active only during the day, probably because nighttime temperatures were too low. Lambrinos and Kleier (2003) reported that juveniles at the same altitude also were diurnal, but were active only around midday. Both juveniles and adults were most active on sunny days and had a limited capacity to increase body temperatures by basking. The toads did not reach maximum temperatures as high as those achieved by lizards (*Liolaemus multiformis*) living in the same habitat because evaporation of water from the skin had a cooling effect (fig. 3.16). However, adult toads were active for more hours per day than the lizards and accepted a wider range of activity temperatures.

Navas (1996b) studied the temperature relations of four high Andean frogs in Colombia. He compared microhabitat selection and variation in body temperature in an undescribed species of *Atelopus*, *Colostethus subpunctatus*, *Eleutherodactylus bogotensis*, and *Hyla labialis* at 3,500 m. Each of these species used somewhat different microhabitats and consequently had different thermal strategies (fig. 3.17). *Atelopus* was active during the day in relatively exposed locations that received direct solar radiation, but spent the cold nights sheltered in thermally buffered retreat sites under rocks or in dense vegetation. *Colostethus subpunctatus* also was diurnal, but used more sheltered locations and retreated to protected sites at night. *Eleutherodactylus bogotensis* and *Hyla labialis* were nocturnal and therefore exposed to low temperatures for much of their

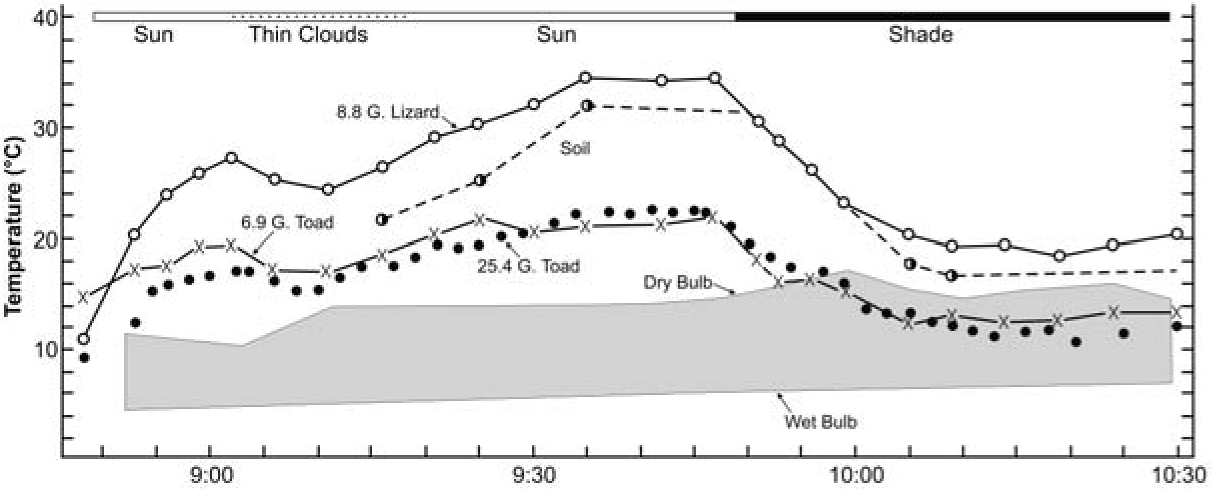

Fig. 3.16. Comparison of body temperatures of toads (*Bufo spinulosus*) and a lizard (*Liolaemus multiformis*) for one morning in March at 4,300 m in the Peruvian Andes. Bars at top show sun and cloud conditions. Data are shown for one free-ranging lizard (8.8 g) and a large (25.4 g) and small (6.9 g) toad. Temperatures measured at the soil surface also are shown. The shaded area at the bottom shows the range of air temperatures encompassed by dry bulb (top) and wet bulb (bottom) measurements. The lizard consistently maintained a body temperature significantly above that of the toads and above ambient air temperature in both sun and shade conditions. After Pearson and Bradford (1976).

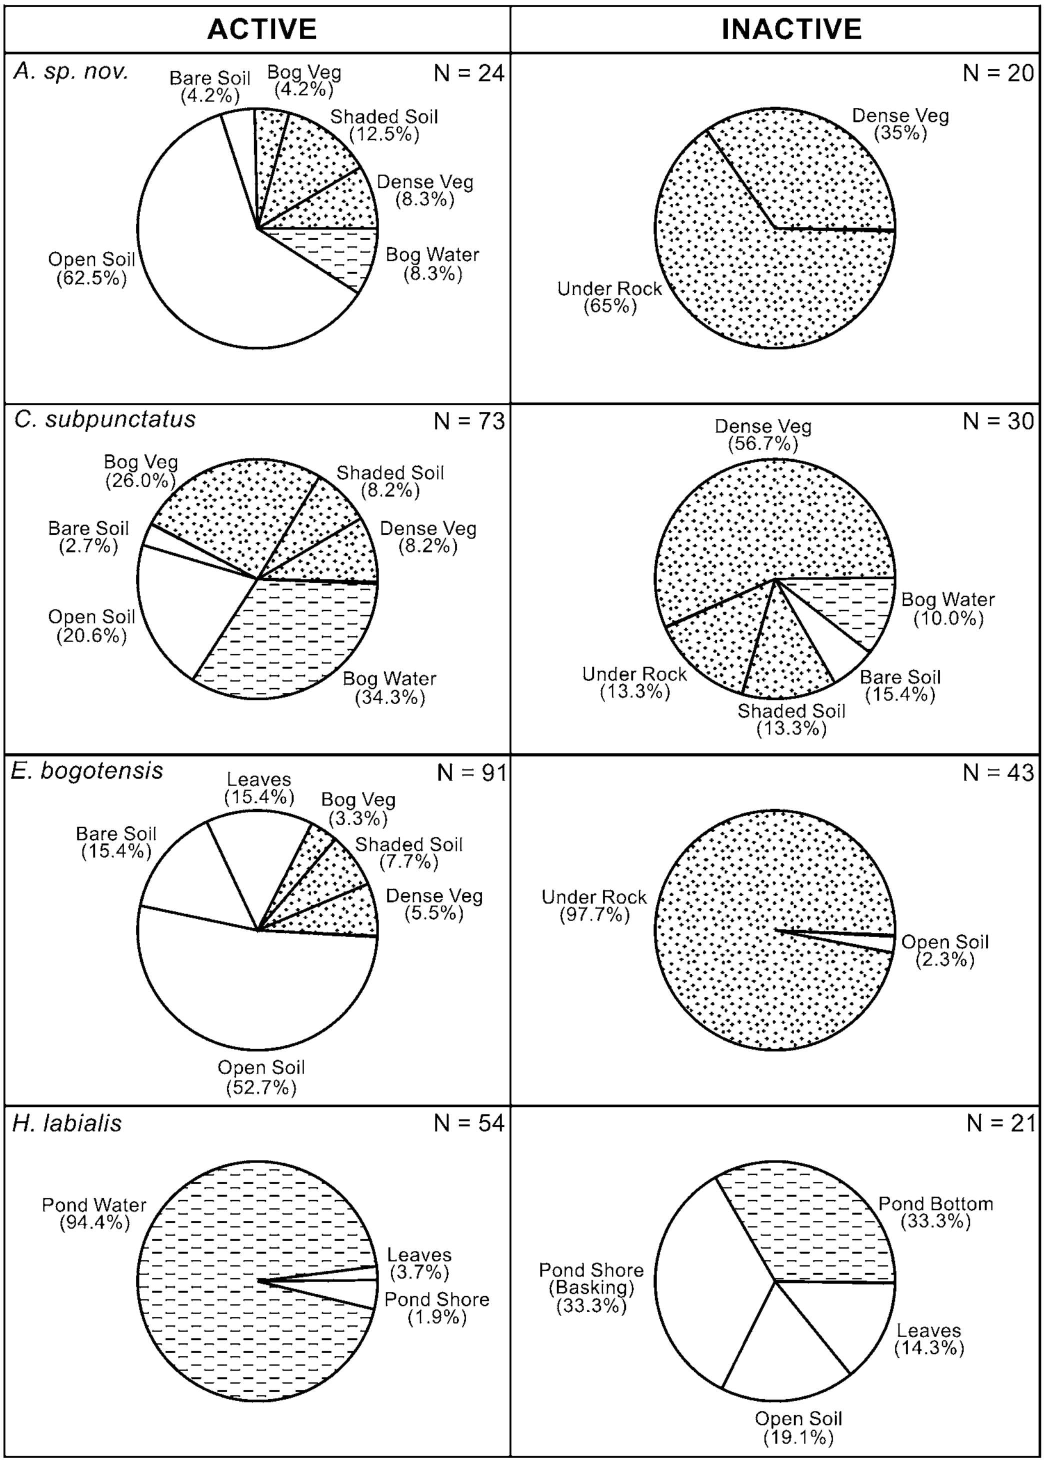

Fig. 3.17. Microhabitats selected by active and inactive frogs of four species from the paramo of Colombia. Symbols indicate the thermal stability of the microhabitats. White sections are exposed terrestrial microhabitats with low thermal stability. Dotted sections are sheltered terrestrial habitats with moderate thermal stability. Dashed sections are aquatic habitats with high thermal stability. Genera: *A* = *Atelopus, C* = *Colostethus, E* = *Eleutherodactylus, H* = *Hyla.* After Navas (1996d).

activity periods. However, *E. bogotensis* was terrestrial and often active in exposed locations that experienced the lowest temperatures and the greatest range of temperatures. *Hyla labialis* was found mainly around permanent ponds, where temperatures were much more stable. This species has greater resistance to water loss than the other frogs and can bask in the sun during the day to raise its body temperature above that of the air, especially at lower temperatures. The other three species are thermoconformers, with body temperatures very similar to substrate temperatures. Average activity temperature was lowest for the nocturnal *E. bogotensis* (6.5° C) and highest for the diurnal *C. subpunctatus* (12.5° C). The other two species were intermediate (about 11° C).

Another high-altitude amphibian, *Rana muscosa,* was studied by Bradford (1984b). This species reaches altitudes of more than 3,600 m in the Sierra Nevada of California, as high as any amphibian in North America. These frogs were always in or near water, but spent most of the day exposed to direct sunlight, where body temperatures often exceeded both air and water temperatures by more than 10° C. The frogs moved between microhabitats during the day, consistently selecting the warmest available locations. The frogs sometimes formed dense aggregations at midday, clustering on wet rock surfaces warmed by the sun (fig. 3.18). This allowed the frogs to warm up through contact with a warm substrate, but at the same time minimize evaporative water loss. At night, the frogs were largely inactive, submerging in deep water as temperatures dropped. In a laboratory thermal gradient, frogs tested during the day had a mean selected temperature of about 24° C, almost exactly the same as the toads studied by Carey (1978) and Smits (1984). However, in the field, environmental temperatures were so cool that the frogs seldom reached this temperature except for a few hours on particularly warm afternoons. Thus, these frogs are forced to be active at temperatures well below their preferred body temperature (average daytime activity temperature = 17° C).

Thermoregulation in Arboreal Frogs

In all of the ranids and bufonids discussed so far, the skin offers little or no resistance to water loss (see chapter 2). Hence, heating the skin through increased absorption of solar radiation results in increased evaporation of water across the skin surface, thereby reducing core body temperature. The highly permeable skin of these species therefore limits their ability to use basking as a means of increasing body temperature. This was shown by the inability of *Bufo spinulosus* to achieve body temperatures as high as those of dry-skinned lizards exposed to the same conditions (Pearson and Bradford 1976; see also Tracy, Tracy, and Turner 1992 for a comparison *of Rana pipiens* with a desert lizard, *Sauromalus obesus*). Elevations of body temperature of 2–3° C above air temperature have been reported in mink frogs (*Rana septentrionalis*) sitting partially submerged at the edge of a pond in direct sunlight, but body temperatures were closer to the temperature of the surrounding water (Hedeen 1971). In general, body temperatures of ranids and bufonids sitting in direct sunlight probably track substrate temperature more closely than air temperature (Tracy 1975, 1976; Carey 1978; Sinsch 1989a; Tracy et al. 1993; Vences, Galán et al. 2002). Therefore, these anurans might be more accurately characterized as thigmothermic (thigm [G.] = touch) rather than heliothermic (heli [G.] = sun), since sitting in direct sunlight normally will be correlated with selection of warm substrates.

In contrast to these species, many arboreal frogs have much higher cutaneous resistance to evaporative water loss. This is especially true of the so-called waterproof frogs, including some species of *Phyllomedusa, Chiromantis,* and *Hyperolius* (see chapter 2 for details of water relations). Even some North American tree frogs have resistances to water loss that are several times greater than those of ranids or bufonids (Wygoda 1984). One would expect the temperature relations of arboreal frogs to be different from those of other anurans. Lower rates of evaporative water loss should allow these frogs to make more effective use of basking to raise body temperatures above that of the surrounding environment, but reduced evaporative cooling could lead to heat stress at high temperatures. Furthermore, tree frogs often spend daylight hours perched on dry leaves or branches, making it impossible for them to replace water lost through evaporation without moving to a moist microhabitat.

There are many reports of tree frogs sitting for extended periods of time in direct sunlight (Brattstrom 1979; Hutchison and Dupré 1992). Examples include hylids from North America (*Hyla cinerea*), South America (*Hyla labialis*), and Australia (*Litoria caerulea, L. chloris, L. xanthomera;* C. R. Johnson 1970; Valdivieso and Tamsitt 1974; Freed 1980; Buttemer 1990; Buttemer and Thomas 2003). Wygoda (1984) reported that several arboreal hylids had body temperatures higher than those of nonarboreal frogs (*Acris, Rana, Bufo, Atelopus, Gastrophryne*) under identical conditions in the laboratory, a difference he attributed to lower rates of evaporative water loss and reduced evaporative cooling. In the field, green tree frogs (*Hyla cinerea*) sitting in direct sunlight have body temperatures as high as 36° C, higher than typical activity temperatures for most frogs (Freed 1980). When water-soaked plaster models of frogs were placed in the same microenvironments as living green tree frogs, the frogs had body temperatures up to 7° C higher than did the models (Wygoda and Williams 1991). In the laboratory, this species heated more rapidly and cooled more slowly than individuals of *Rana sphenocephala* subjected to the same conditions, resulting in higher body temperatures (Wygoda 1988, 1989).

Three Australian tree frogs, *Litoria caerulea, L. chloris,* and *L. xanthomera,* have considerably greater skin resistance to water loss than the North American hylids, but less than the waterproof frogs (see chapter 2). These frogs can tolerate environmental temperatures as high as 50° C and body temperatures up to 38° C. Resistance to water loss is higher in *L. chloris* than in *L. caerulea,* and at any given ambient temperature, *L. chloris* had a somewhat higher body temperature. In both species, there was a linear relationship between air temperature and body temperature at temperatures between 25° C and 40° C, but body temperature was always below air temperature. However, further increases in temperature did not result in a linear increase in body temperature, particularly in *L. chloris* (fig. 3.19). Body temperature leveled off at about 38° C at air temperatures between 43° and 47° C, probably because of increased discharge of mucus onto the skin, resulting in increased evaporative cooling. At these high temperatures, resistance to water loss dropped to a level similar to that of North American hylids (Buttemer 1990). Similarly, cutaneous resistance to evaporative water loss decreased at temperatures above 37° C in *L. xanthomera* (Buttemer and Thomas 2003).

The ability of these frogs to thermoregulate by evaporative cooling is limited by their water storage capacity and the availability of water sources for rehydration (see also chapter 2). A rhacophorid tree frog, *Polypedates maculatus,* exhibits responses to increasing temperature similar to those observed in the Australian species, but this species has a lower temperature threshold for discharge of mucus onto the skin (about 30° C; Lillywhite et al. 1997a, b). *Polypedates maculatus* can tolerate body temperatures as high as 38° C when fully hydrated, but generally avoids high temperatures by seeking shelter in banana plants and other retreat sites.

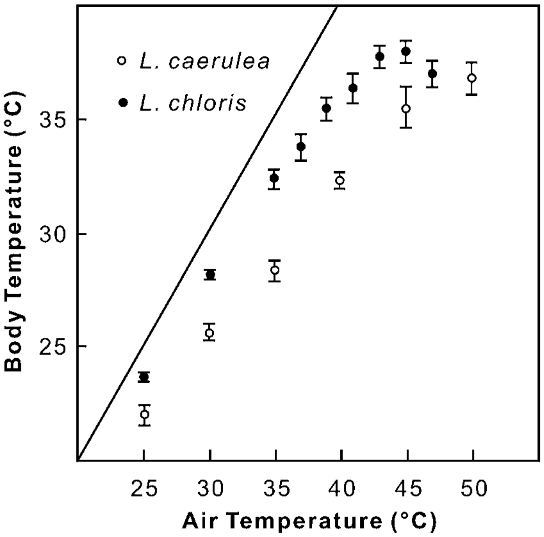

Fig. 3.19. Relationship of body temperature to air temperature in two treefrogs from Australia, *Litoria caerulea* and *Litoria chloris.* Symbols and lines indicate means ± 95% confidence intervals. The diagonal line shows body temperature equal to air temperature. After Buttemer (1990).

Waterproof frogs (*Chiromantis* and some species of *Phyllomedusa* and *Hyperolius*) have cutaneous resistance to water loss approaching that of some reptiles (see chapter 2). All of these frogs can sit for days, weeks, or even months at a time in exposed locations during the dry season without rehydrating. Environmental temperatures often exceed 40° C, and all of these frogs can tolerate body temperatures that would be lethal to most semiaquatic and terrestrial anurans: about 40° C in *Chiromantis* and *Phyllomedusa;* up to 43° C in *Hyperolius viridiflavus* (Shoemaker et al. 1987; Geise and Linsenmair 1988). The highest field body temperature ever recorded for an amphibian is 41° C, from *Phyllomedusa sauvagii* in Argentina (McClanahan and Shoemaker 1987; Hutchison and Dupré 1992). The low rates of evaporative water loss in these frogs allows them to maintain body temperatures above that of the surrounding air even after dark. This has been documented in *Hyperolius marmoratus,* which had nocturnal body temperatures averaging about 3° C above air temperature even several hours after sunset (Passmore and Malherbe 1985). This elevation in nocturnal body temperature is considerably greater than the 0.8° C reported for the less waterproof green tree frog (*Hyla cinerea;* Wygoda and Williams 1991).

In all three genera of waterproof frogs, diurnal body temperatures track ambient temperatures rather closely until they approach the critical thermal maximum (fig. 3.20); the frogs then increase evaporative cooling by increasing the

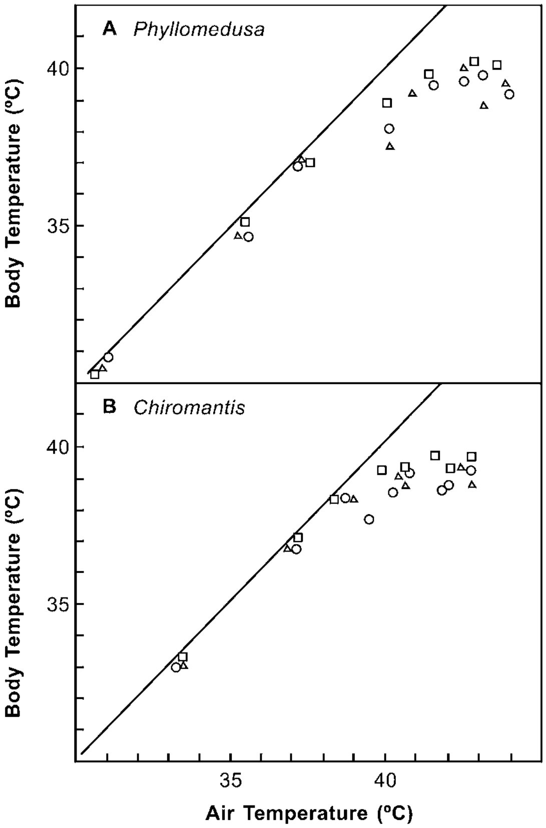

Fig. 3.20. Relationship of body temperature to air temperature in two species of "waterproof frogs," *Phyllomedusa sauvagii* and *Chiromantis xerampelina.* The diagonal line shows body temperature equal to air temperature. Symbols show data collected at different air speeds (squares = 160 cm/s, circles = 30 cm/s, triangles = 8 cm/s). After Shoemaker et al. (1987).

discharge of fluid and mucus onto the skin surface (Shoemaker et al. 1987; Geise and Linsenmair 1988). This allows the frogs to maintain a stable body temperature several degrees below ambient temperature. In *Phyllomedusa,* the lipid secretions responsible for very low rates of evaporative water loss begin to lose their effectiveness at temperatures above 35° C, a point at which problems of thermal stress outweigh problems caused by loss of water reserves (McClanahan, Stinner, and Shoemaker 1978). Both *Chiromantis* and juvenile *Hyperolius viridiflavus* further reduce heat loads by increasing the reflectance of their skin, a response that is absent in *Phyllomedusa.* In juvenile *Hyperolius,* changes in skin reflectance occur gradually at the beginning of the dry season through the accumulation of reflective irridophores in the skin (Kobelt and Linsenmair 1986, 1992; Schmuck, Kobelt, and Linsenmair 1988). In *Chiromantis,* individuals undergo a rapid color change from brown to white only at high body temperatures (Shoemaker, Baker, and Loveridge 1989).

Some other tree frogs, such as *Agalychnis callidryas,* assume a chalky white color when exposed to direct sunlight, and this helps reduce radiant heat loads. *Agalychnis* and some other hylid and centrolenid tree frogs also have skin pigments that reflect near-infrared radiation (Schwalm, Starrett, and McDiarmid 1977). This could provide a thermoregulatory advantage to animals sitting in direct sunlight, but the effect of infrared reflectance on body temperature has not been investigated. In nonarboreal frogs that do not have high cutaneous resistance to water loss, changes in skin reflectance are expected to have a minimal effect on body temperature. Higher reflectance could reduce radiant heat gains, but any increased heat gained through darkening of the skin will lead to increased evaporation of water and lowering of body temperature (Tracy 1976, 1979). For example, dark-skinned toads (*Bufo boreas*) sitting in direct sun absorb about 4% more solar radiation than do light-skinned toads, but this is not expected to raise core body temperature by more than about 0.34° C (Carey 1978).

Adaptive Significance of Basking Behavior

The widespread occurrence of basking in anurans, and the use of warm substrates to raise body temperatures, suggests an adaptive advantage to such behavior, but any benefits must be balanced against potential costs, such as increased risk of desiccation. Only a few studies have examined possible benefits of maintaining elevated body temperatures. At present, the most convincing evidence is that basking is beneficial because it increases rates of digestion and growth, particularly in juvenile anurans. Several studies of toads have shown that newly emerged juveniles often bask on the exposed banks of ponds, while adults in the same populations tend to be active mainly at night (Black and Black 1969; Seymour 1972; Lillywhite, Licht, and Chelgren 1973; Lillywhite and Wassersug 1974). Toad tadpoles generally develop very rapidly and emerge from the water in a relatively underdeveloped state. For example, newly emerged juveniles have a low aerobic capacity for locomotion, but aerobic capacity increases steadily as they grow (Taigen and Pough 1981). Consequently, any increase in growth rate would decrease the time required to reach adult aerobic capacity. Lillywhite, Licht, and Chelgren (1973) demonstrated that juvenile toads (*Bufo boreas*) had a preferred body temperature both in the field and laboratory of about 27° C. Toads that were maintained at 27° C had faster growth rates than did those maintained at either 20° or 33° C, suggesting that the toads preferred a temperature that optimizes growth rate. Furthermore, the toads engaged in basking behavior after feeding, but not after going several days without food. Basking also would be advantageous to juvenile toads in allowing them to attain higher metabolic rates during activity because of the temperature dependence of aerobic metabolism (see chapter 4). Consequently, juvenile toads active at 27° C would have mass-specific metabolic rates approximately equal to those of adults active at 20° C (Taigen and Pough 1981).

The benefits of basking for adult anurans are less obvious. Many adult anurans grow relatively little after reaching sexual maturity, although long-lived species such as *Rana catesbeiana, R. clamitans,* or *R. virgatipes* grow more as adults than do short-lived species, such as many hylids (R. D. Howard 1984; E. Werner 1986; Given 1988a). Freed (1980) found that basking resulted in increased growth rates for juvenile *Hyla cinerea,* but not for adults. However, higher body temperatures produced increased rates of digestion in frogs of all sizes, resulting in more rapid food passage time for both juveniles and adults. Freed suggested that this in turn might make more energy available for activities such as reproduction. Indeed, adult males allowed to bask in the laboratory called in the evening approximately five times more often than nonbasking males. Although these results are intriguing, sample sizes were small, and the experiments need to be repeated. Increased digestion rates and more rapid food passage times also could be important in accelerating accumulation of fat reserves for the winter, particularly in high-altitude populations with short activity seasons (Carey 1978). However, for many anurans, especially arboreal species that sit for long periods exposed to direct sunlight, elevated body temperatures probably are tolerated rather than preferred.

Thermal Acclimation

Ectotherms typically compensate for seasonal or even shorter-term changes in environmental temperature by acclimation. For example, if a salamander living at 10° C is exposed to a temperature of 20° C, its metabolic rate will rapidly increase, but if the exposure to the warmer temperature lasts for several days, the animal experiences a compensating decrease in metabolic rate. Although such compensation often is not complete (Rome, Stevens, and John-Alder 1992), the result is reduced thermal dependence of metabolism. Other physiological processes undergo acclimation as well. For example, some fish can compensate for reduced muscle performance at low temperatures through physiological and morphological changes in locomotor muscles. This allows cold-acclimated animals to make greater use of their aerobic muscle fibers at low temperatures than warm-acclimated animals (Rome, Loughna, and Goldspink 1985). Many ectotherms also exhibit acclimation of temperature tolerance, with individuals acclimated to high temperatures being able to tolerate higher temperatures than those exposed only to low temperatures. Acclimation of metabolic rate is discussed in more detail in chapter 5, so I will focus on acclimation of locomotor performance and thermal tolerance here.

Data from a limited number of species suggest that most adult amphibians lack a capacity for thermal acclimation of locomotor performance like that seen in many fish, especially compensation for cold temperatures (Rome 1983; Renaud and Stevens 1983b, 1984; Else and Bennett 1987; Whitehead et al. 1989; Knowles and Weigl 1990; Rome, Stevens, and John-Alder 1992; R. Wilson and Franklin 2000b). For example, leopard frogs (*Rana pipiens*) acclimated to 5° C could not jump any farther at temperatures between 5° and 15° C than frogs acclimated to 25° C, and their performance at higher temperatures was worse than that of warm-acclimated frogs (Renaud and Stevens 1983b). Indeed, the only example of acclimation of locomotor performance to cold temperatures is for *Xenopus laevis,* a strictly aquatic frog (R. Wilson, James, and Johnston 2000). In this species, individuals acclimated to 10° C swam 67% faster when tested at 10° C than did those acclimated to 25° C. Individuals acclimated to the higher temperature did not exhibit enhanced performance at that temperature, however. Tadpoles of *X. laevis* also showed acclimation to cold temperatures, but locomotor performance of cold-acclimated tadpoles declined when they were tested at 30° C. Tadpoles of an Australian myobatrachid frog, *Limnodynastes peronii,* exhibited a similar capacity to compensate for cold temperatures (R. Wilson and Franklin 1999), but adults do not. R. Wilson, James, and Johnston (2000) argued that cold acclimation of locomotor performance is limited to aquatic amphibians because aquatic environments are more thermally buffered than are terrestrial environments. The latter can undergo such rapid fluctuations in temperature that acclimation is not possible. Unfortunately, the limited number of species tested for acclimation responses to date makes any such conclusion premature.

Many studies of thermal acclimation in amphibians have focused on acclimation of thermal tolerance (for reviews, see Brattstrom 1970; Hutchison and Maness 1979; Rome, Stevens, and John-Alder 1992). Most temperate-zone amphibians exhibit an increase in CT_{Max} with increasing acclimation temperature, but the magnitude of change varies considerably. For example, in many salamanders, a 20° C change in acclimation temperature (from 5 to 25° C) raises CT_{Max} by only about 1.5–4.5° C. In frogs, a change of similar magnitude (18–20° C) raises CT_{Max} by about 2–8° C. Rates of acclimation vary among species, but generally several days to several weeks are required for acclimation to be complete (Hutchison 1961; Brattstrom 1968; Claussen 1977; Layne and Claussen 1982). Exposure to cold temperatures results in lowered CT_{Max}, but the rate of acclimation to cold generally is slower than acclimation to warm temperatures (Rome, Stevens, and John-Alder 1992).

One might expect tropical amphibians that live in relatively equable thermal environments to show less capacity for thermal acclimation, but the limited data available for tropical species are not consistent. For example, some tropical ranids and bufonids tested by Brattstrom (1968) have a capacity for acclimation to warm temperatures similar to that of North American ranids and bufonids, but the tropical species are much less cold tolerant. On the other hand, some tropical hylids showed relatively little acclimation of CT_{Max} (Brattstrom 1968), and the tropical frog *Eleutherodactylus coqui* showed no acclimation, even though this species experiences greater seasonal temperature fluctuation than do many tropical anurans (Christian et al. 1988). Tropical anurans often are killed by low temperatures, so most species have been acclimated over a relatively narrow range of temperatures, making direct comparison with temperate-zone species difficult. Furthermore, comparisons of species in different families often confound latitudinal differences with phylogenetic history. For example, it is possible that *Eleutherodactylus,* a genus largely confined to the Neotropics, lacks a capacity for thermal acclimation, but this is not necessarily true for tropical species in more widespread genera. We need considerably more information on tropical species from a variety of thermal environments, with careful controls for phylogenetic history, before valid comparisons can be made with temperate-zone forms.

Most authors have used CT_{Max} as an index of thermal tolerance, assuming that an increase in CT_{Max} with prolonged exposure to warm temperatures (for example, during summer months) provides added protection from potentially lethal temperatures. Rome, Stevens, and John-Alder (1992) argued that the benefit of the small changes in CT_{Max} seen in many species has yet to be demonstrated. One trivial reason for this is the rarity of observations of amphibians exposed to extreme temperatures in the field (V. H. Hutchison, personal communication). CT_{Max} for most amphibians is 5–15° C higher than their normal activity temperatures. For example, frogs with average activity temperatures around 25° C often have a summertime CT_{Max} approaching or even exceeding 40° C (Brattstrom 1968). Many of the salamander species studied by Hutchison (1961) had a CT_{Max} exceeding 35° C after acclimation to 20° C, and some species, such as *Notophthalmus viridescens,* had a CT_{Max} above 40° C when acclimated to temperatures above 25° C. Both temperate-zone and tropical salamanders typically avoid temperatures above 25° C (Feder 1982b; Feder and Lynch 1982). Nevertheless, amphibians sometimes can be exposed to near-lethal temperatures when trapped in drying pools in hot weather or when exposed to extreme temperatures on land during hot, dry periods. V. H. Hutchison (personal communication) observed a hellbender (*Cryptobranchus alleganiensis*) trapped in a shallow pool that reached 41° C, far above the normal activity temperature of this species. The animal went into spasms, indicating it had reached its CT_{Max}. Seasonal acclimation of CT_{Max} could be essential in providing protection against this type of exposure to extreme temperatures, even though such incidents are rare.

Some amphibians appear to adjust thermal tolerance on a daily basis after only brief exposure to unusually high temperatures. For example, Pough and Wilson (1970) studied newly metamorphosed *Ambystoma maculatum* hiding under rocks on the exposed shore of a pond in late summer. In the morning, temperatures under the rocks were between 17° and 21° C, but by afternoon, they were 27–39° C. Salamanders avoided rocks with temperatures above 32° C, and deserted rocks that were heated to this temperature in the laboratory. Nevertheless, many individuals were exposed to unusually high temperatures for several hours each day. The salamanders became dehydrated, but were able to survive. Laboratory studies of animals collected in the field revealed that CT_{Max} increased from about 38.5° to 39.7° C from morning to afternoon. Although the salamanders generally avoided temperatures approaching the CT_{Max}, the highest temperature they tolerated in the afternoon (32° C) was high enough to induce some loss of coordination in salamanders collected in the morning. Hence, Pough and Wilson argued that the daily increase in CT_{Max}, although small, is correlated with increased resistance to potentially dangerous temperatures. Pough (1974b) reported a similar short-term increase in CT_{Max} in red efts (*Notophthalmus viridescens*) exposed to high temperatures in the field. In both of these studies, changes in thermal tolerance were attributed to rapid thermal acclimation. Other workers have suggested the phenomenon is more accurately described as heat hardening, defined as a rapid increase in thermal tolerance in animals exposed to temperatures close to their CT_{Max} (Hutchison and Maness 1979; Rutledge, Spotila, and Easton 1987a; Rome, Stevens, and John-Alder 1992). One hypothesis to explain increased thermal tolerance in amphibians exposed to short-term increases in temperature is that the animals initially undergo rapid heat hardening that depends on the presence of a heat shock protein (hsp-70) that provides some protection to cells. This is followed by a longer-lasting response that depends on production of new hsp-70 in response to heat shock (Easton, Rutledge, and Spotila 1987; Rutledge, Spotila, and Easton 1987a, b; Near et al. 1990; Yu, Magee, and Spotila 1994; Yu et al. 1998).

Overwintering and Hibernation

Most studies of amphibian thermal biology have focused on responses to high temperatures, but amphibians living at high latitudes or high altitudes also must contend with periodic exposure to cold. Amphibians generally respond to short-term exposure to low temperatures by retreating to warmer microhabitats and remaining inactive until warm temperatures return. For example, anurans at high altitudes typically seek shelter in burrows or under logs in cold weather (Pearson and Bradford 1976; Carey 1978). However, dealing with many months of cold weather is a different matter. No amphibian can remain active at subfreezing temperatures, and many species spend the winter months in a relatively inactive state, depending on stored energy reserves for survival. Stores of glycogen and lipids accumulate during periods of feeding in the summer and fall and are deposited in fat bodies and the liver to support metabolism, and in some cases, egg development, during the winter (see chapter 5 for additional discussion of overwintering energetics). Because metabolic rates decrease rapidly with falling temperatures, overwintering amphibians often can survive for many months without food (8–9 months for some frogs in northern latitudes or high altitudes; Koskela and Pasanen 1974; Morton 1981; Kuzmin and Maslova 2003). In general, amphibians that are aquatic as adults tend to overwinter in water, whereas terrestrial species usually overwinter on land (Pinder, Storey, and Ultsch 1992). However, there are exceptions, and many species exhibit considerable plasticity in overwintering behavior.

Urodeles

Fully aquatic salamanders such as *Necturus* and *Cryptobranchus,* which never leave the water even as adults, have no choice but to spend the winter underwater, where they continue to feed, but at a slower rate than in the summer. In the relatively equable climate of the North Carolina mountains, stream-dwelling plethodontids, including species of *Gyrinophilus, Pseudotriton, Eurycea,* and *Desmognathus,* remain active throughout the winter, even when nearby slopes are covered with snow. These species tend to have prolonged larval periods, with larvae spending several winters in streams before metamorphosing (Bruce 1972a, b, 1974, 1978a, b, 1982a, b, 1985a, b, 1988a, b).

Farther north, the semiaquatic plethodontids *Desmognathus fuscus, D. ochrophaeus,* and *Eurycea bislineata* sometimes hibernate on land near streams as adults, but remain active and even feed during warm periods (Bishop 1941b; Ashton 1975; Ashton and Ashton 1978). The more aquatic species *Gyrinophilus porphyriticus* and *Pseudotriton ruber* apparently remain underwater during the winter (Bishop 1941b). Larvae of all of these species spend at least one winter in streams before metamorphosing, but show little growth in winter months (Wilder 1913, 1924; Bishop 1941b; Juterbock 1990). Terrestrial plethodontids always hibernate on land, using root holes and other natural cavities in the soil (Blanchard 1933a; Vernberg 1953; Stebbins 1954a), and they sometimes eat insects underground (R. Caldwell and Jones 1973; R. Caldwell 1975). Adult ambystomatids also hibernate on land and usually are seen above ground only during the breeding season. Spotted salamanders (*Ambystoma maculatum*), for example, typically overwinter in burrows of white-footed mice (*Peromyscus*) and other rodents (Madison 1997). However, in some populations, larval ambystomatids remain in the water throughout the winter (Bleakney 1952; Whitford and Vinegar 1966; Brandon and Bremer 1967), and must do so in *Ambystoma opacum,* which lays eggs in the fall (Noble and Brady 1933; Bishop 1941b).

The natural history of most hynobiid salamanders is so poorly known that little can be said about their winter behavior. In southern Japan (35° N latitude), *Hynobius nebulosus* actually breeds in streams and ditches in midwinter (Tanaka 1989). *Onychodactylus fischeri* apparently hibernates mainly in flowing water that does not freeze in winter (Kuzmin and Maslova 2003). The Siberian hynobiid salamander *Salamandrella keyserlingii,* the only urodele found north of the Arctic Circle, hibernates on land in rotting logs and holes and often forms aggregations of up to 25 individuals (Kuzmin and Maslova 2003). In northern parts of its range, hibernation begins as early as August and lasts until April. This is the only salamander known to be freeze-tolerant (Berman, Leirkh, and Mikhailova 1984; see the following). Hibernation sites are relatively shallow, no more than 7 cm below the surface, where temperatures can be as low as –20° C, but daily fluctuations in temperature are small (Berman 1992; Kuzmin and Maslova 2003).

Adult red-spotted newts (*Notophthalmus viridescens*) in eastern North America spend the winter either on land or in the water. Morgan and Grierson (1932) reported that newts in Massachusetts were active in permanent ponds all winter and continued to feed, mostly on mayfly nymphs, even in the coldest months. In populations of newts from North Carolina to New York, some adults migrate in the fall to breeding ponds, where they spend the winter, while others remain in terrestrial hibernation sites and move to breeding ponds in the spring (Bishop 1941b; Chadwick 1944; Hurlbert 1969). In other populations, such as those studied by Gill (1978a) in the mountains of Virginia, all individuals leave the breeding ponds in the fall and hibernate on land, probably because some ponds freeze all the way to the bottom in very cold winters.

Most species of European newts (*Triturus*) leave their breeding ponds in winter and hibernate on land, and species in the genus *Salamandra* hibernate on land as well. These salamanders use a variety of hibernation sites, including natural cavities in clay deposits and gravel piles; spaces under mats of vegetation, large stones, logs, and piles of timber; and in drain pipes, cellars, and mines (Hecht 1931; M. Smith

1969; Feldmann 1967a, b, 1977; Steward 1969; Kabisch 1971a, b; Kowalewski 1974; Dolmen 1983a; Frazer 1983; Sinsch 1989c; Baumgartner 1999). In regions with mild climates or where permanent water is available, some newts remain in the water all winter. For example, Bell (1977) observed fall migrations of adult *Triturus vulgaris* to permanent breeding ponds, where they spent the winter, a phenomenon not observed in populations that use shallow or temporary ponds for breeding (Griffiths 1984). Van Gelder (1973) reported that a substantial proportion of a population of *Triturus helveticus* in the Netherlands spent the winter in a fen, where breeding also occurred. Some larvae wintered there as well, but metamorphosed juveniles left the water and hibernated on land, returning to the water only when they were sexually mature. Hibernation of newts in ponds and tarns has been reported in other parts of Europe as well (Wolterstorff 1923; Steward 1969; Hagström 1970, 1982).

Anurans

Most anurans living in cold regions probably hibernate on land, particularly bufonids, pelobatids, bombinatorids, discoglossids, and hylids. Burrowing forms such as toads (*Bufo*) and spadefoot toads (*Scaphiopus, Spea, Pelobates*) often bury themselves in sand or loose soil a meter or more below the surface. They also use natural cavities beneath large stones, cellars, mouse holes, mole tunnels, and other mammal burrows (Breckenridge and Tester 1961; Tester and Breckenridge 1964; M. Smith 1969; J. B. Campbell 1970; Kabisch 1971a; Kowalewski 1974; Frazer 1983; Nöllert 1984; van Gelder, Aarts, and Staal 1986; Sinsch 1989c; Kuyt 1991; Denton and Beebee 1993b; Bosman, van Gelder, and Strijbosch 1996; Kuzmin 1999; Kuzmin and Maslova 2003). European spadefoot toads (*Pelobates fuscus*) and natterjack toads (*Bufo calamita*) hibernate in the nest holes of sand martins (Smith 1969; Frazer 1983; Nöllert 1984), although one account (Thompson 1843) suggested that the martins actually use holes previously constructed by toads. Midwife toads (*Alytes obstetricans*) and common toads (*Bufo bufo*) sometimes hibernate in mine tunnels (Feldmann 1977). There are a few reports of both juvenile and adult *B. bufo* hibernating in water (Waddington 1952; Hagström 1982; Juszczyk et al. 1984; Kwet 1996b), but this appears to be unusual. This species is able to withstand up to a month of flooding of terrestrial hibernation sites, whereas natterjack toads (*Bufo calamita*) suffer high mortality if their burrows are flooded (Bosman, van Gelder, and Strijbosch 1997). In the Russian Far East, *B. gargarizans,* a close relative of *B. bufo,* normally hibernates on land, sometimes in aggregations of more than 60 individuals. Nevertheless, some populations hibernate in shallow rivers and lakes (Kuzmin and Maslova 2003). The Asian toad *B. raddei* hibernates in sandy soil at depths of about 2 m, sometimes in groups of up to 60 individuals (Kuzmin and Maslova 2003).

Fire-bellied toads (*Bombina*) hibernate both on land and in the water, sometimes in aggregations of dozens of individuals. In the Primorye Region of eastern Siberia, *Bombina orientalis* hibernates from September to April or May in rotting logs, leaf litter, rock piles, and occasionally in streams. Frogs in one population were observed hibernating near geothermal springs, where water temperatures in winter can be as high as 24° C, with some individuals remaining active in the warm water (Kuzmin 1999; Kuzmin and Maslova 2003).

North American cricket frogs (*Acris*) have been found hibernating in cracks in soil near breeding ponds, crayfish burrows, cavities under rocks, and gravel banks near streams (W. T. Neill 1948a; A. P. Blair 1951; R. H. Gray 1971; Irwin, Costanzo, and Lee 1999; McCallum and Trauth 2003). Cricket frogs prefer moist sites near water that do not freeze, but are intolerant of prolonged submersion in hypoxic or anoxic pond water. Hibernation sites of the Japanese tree frog *Rhacophorus schlegelii* also appear to be chosen to minimize the chances of freezing and desiccation, with moist sites near the edges of ponds and streams being preferred (Ihara 1999). European tree frogs (*Hyla arborea*) usually hibernate on land in a variety of sites under rocks or clumps of vegetation, in cellars or crevices in brick walls, or buried in piles of leaves or manure (Stumpel 1990). In some regions, these tree frogs also hibernate in mud at the bottom of ponds (Berger and Michalowski 1963; Kowalewski 1974). The closely related *H. japonica* has been found hibernating in leaf litter, cracks in soil, rodent burrows, rock piles, tree holes, and under logs, but not in water (Kuzmin and Maslova 2003). Hibernation sites of most North American tree frogs have not been reported, but *Hyla chrysoscelis,* a freeze-tolerant species (see the following), has been found hibernating in loose soil at the bases of trees (Burkholder 1998) and in tree holes (Ritke and Babb 1991).

The most aquatic North American ranid frogs, such as *Rana catesbeiana, R. clamitans, R. septentrionalis,* and *R. muscosa,* all hibernate in ponds, lakes, swamps, and rivers (Martof 1956a; Willis, Moyle, and Baskett 1956; Bradford 1983; Stinner, Zarlinga, and Orcutt 1994; Matthews and Pope 1999), although occasional terrestrial hibernation has been reported (Bohnsack 1951, 1952; Jenssen 1968). Green frogs (*Rana clamitans*) in upstate New York moved from summer home ranges in ponds to hibernation sites in flowing water, including streams and seeps. These areas remained unfrozen throughout the winter and also were well oxygenated (Lamoureux and Madison 1999). Juveniles of these large ranids appear to be somewhat more tolerant of cold than adults and usually enter hibernation later in the fall and emerge earlier in the spring than adults (Martof 1956a; Willis, Moyle, and Baskett 1956; Jenssen 1968). Juvenile green frogs have been seen active and even feeding in the winter as far north as Illinois (Jenssen and Klimstra 1966). Leopard frogs (*Rana pipiens* complex) are somewhat more terrestrial than the larger North American ranids. They hibernate mainly in ponds and streams (Breckenridge 1944; Manion and Cory 1952; Emery, Berst, and Kodaira 1972; Cunjak 1986; L. Licht 1991). Leopard frogs in Vermont were found hibernating in a well-oxygenated river in the company of map turtles (*Graptemys geographica;* Ultsch, Graham, and Crocker 2000). Leopard frogs also have been found overwintering in caves and rock crevices (Rand 1950; A. P. Blair 1951), as have pickerel frogs (*Rana palustris;* Resetarits 1986). Tadpoles of ranids that breed in permanent ponds often spend one or more winters in the water before metamorphosis (Wright and Wright 1949; Martof 1956b; Collins 1979a; Collins and Lewis 1979; Bradford 1983). Wood frogs (*Rana sylvatica*), among the most terrestrial of North American ranids, generally use shallow ponds for breeding and hibernate in upland forested habitats where the soil is not saturated in winter (Storey and Storey 1986a; L. Licht 1991; Regosin, Windmiller, and Reed 2003b). This is the only North American ranid frog known to tolerate freezing (see following).

In Europe, common frogs (*R. temporaria*)—which resemble wood frogs in morphology, ecology, and behavior—differ from the North American species in that they hibernate mostly underwater (Bannikov 1940; Savage 1961; Ashby 1969; Hazelwood 1969; Kabisch and Engelmann 1971; Koskela and Pasanen 1974; Kowalewski 1974; Feldmann 1977; Frazer 1983; Juszczyk et al. 1984; Verrell and Halliday 1985a; D. Weber 1989b; Pasanen and Sorjonen 1994; Kwet 1996b). Like some North American ranids, such as *Rana clamitans, R. temporaria* often shows a preference for hibernating in sites with running water, including rivers, streams, springs, and ditches (Kuzmin 1999). However, some individuals spend the winter on land, buried in soil or in caves and mine tunnels. Common frogs have even been found hibernating in the dens of poisonous adders (*Vipera berus*) in Finland (Vitanen 1967).

The European moor frog (*Rana arvalis*), which is largely terrestrial outside the breeding season, is mainly a terrestrial hibernator, but some individuals spend the winter in streams or at the bottom of breeding ponds (Juszczyk et al. 1984; Büchs 1987; Hellbernd 1987). Moor frogs have been seen moving about in mild weather during winter (Henle 1999), perhaps shifting between hibernation sites. Another European frog that usually hibernates on land, *Rana lessonae,* sometimes moves between hibernation sites in the winter as well (Holenweg and Reyer 2000). Many other Eurasian ranid frogs, including *Rana dalmatina, R. macrocnemis, R. amurensis, R. asiatica, R. pirica,* and *R. dybowskii,* hibernate either on land or in water, with the latter being the rule in colder regions (Kuzmin 1999). Many of these species hibernate underwater in large groups, with aggregations of 1,000–2,000 being reported for *Rana amurensis,* up to 1,500 for *R. pirica,* and thousands of individuals for *R. dybowskii* (Kuzmin and Maslova 2003). *Rana nigromaculata,* which occurs mostly in warmer climates, usually hibernates in ponds, but sometimes in holes in streams (Kuzmin and Maslova 2003).

Species of water frogs in the *Rana esculenta* complex differ in their hibernation behavior according to their habitat preferences. *Rana ridibunda,* the largest and most aquatic species, hibernates mostly under water (Kowalewski 1974; Berger 1982; Lutschinger 1988; Voituron, Eugene, and Barre 2003). In some populations individuals leave the ponds where they spend most of the year and move to rivers for hibernation, perhaps to take advantage of higher levels of oxygen in the water (Heym 1974). Some *R. ridibunda,* particularly juveniles, spend the winter on land, but this is relatively rare. In contrast, *R. lessonae,* a smaller, more terrestrial species that breeds mainly in temporary ponds, is mainly a terrestrial hibernator. These frogs usually dig individual burrows in the soil or can be found under moss and leaf litter 3–7 cm below the surface (Holenweg and Reyer 2000). Small aggregations under boards and logs also have been observed (Berger 1982). A third "species," *R. esculenta,* is a hybrid between *R. ridibunda* and *R. lessonae* that is perpetuated by hybridogenetic reproduction (Berger 1977; Graf and Polls Pelaz 1989; see chapter 7). Berger (1982) found that populations of *R. esculenta* associated with *R. lessonae* (the most common situation) hibernated on land with the parent species, but populations living in permanent water with *R. ridibunda* hibernated mostly under water. Holenweg and Reyer (2000) also found that *R. esculenta* associated with *R. lessonae* mostly hibernated on land, but they tended to move shorter distances from a pond, and a few individuals were found hibernating underwater. Tunner (1992) reported that thousands of individuals in a mixed population of *R. lessonae* and *R. esculenta* moved up to 15 km from a lake to a terrestrial hibernation site. Some *R. esculenta* spent the winter in a canal running into the lake, but this site was not used by *R. lessonae.* In a study in Switzerland, overwinter survival of mixed populations of *R. lessonae* and *R. esculenta* was negatively correlated with an index of the severity of the winter. This was not due simply to low temperatures, but to variable temperatures. Possibly frogs emerged from retreat sites and moved around during warm periods, thereby depleting some of their stored energy reserves and risking being trapped when freezing winter returns (Anholt et al. 2003).

Costs and Benefits of Hibernation in Water

For amphibians hibernating in water, there is no danger of desiccation, and little chance of freezing to death unless the water is very shallow. For the most part, spending the winter underwater is simply a matter of slowing metabolism and other physiological processes to very low rates in response to cold temperatures. However, the animals are not in a truly dormant state and sometimes move around under the ice of frozen ponds and lakes. Because of their very low metabolic rates, amphibians wintering underwater generally can take up sufficient oxygen through the skin to supply their metabolic needs. However, in contrast to many freshwater turtles that also hibernate underwater, aquatic amphibians have a poor capacity for anaerobic metabolism in winter. This means that frogs hibernating underwater typically do not bury themselves in mud on the bottom of ponds, which can become anoxic (E. Stewart, Reese, and Ultsch 2004). Some frogs are capable of moving around under the ice (Emery, Berst, and Kodaira 1972) and following oxygen gradients to maintain a capacity for aerobic metabolism. They also can select colder microhabitats, which results in reduced oxygen demands (Boutilier et al. 1997; Tattersall and Boutilier 1997, 1999). The preference of many aquatic hibernators for flowing water enhances survival by ensuring a steady supply of oxygen throughout the winter. Frogs submerged in cold water (3° C) undergo a variety of physiological changes that suppress their metabolic rates by as much as 70% below those measured in air at the same temperature, thereby reducing both energy costs and oxygen demands (Donohoe and Boutilier 1998, 1999; Donohoe, West, and Boutilier 1998, 2000; Ultsch, Reese, and Stewart 2004).

Despite the ability of frogs to lower metabolic rates and seek out microhabitats that provide sufficient oxygen, the chief danger for most aquatic hibernators probably is anoxia caused by freezing over of shallow ponds and lakes and heavy snow cover that blocks sunlight needed for photosynthesis by aquatic plants (Ultsch 1989; Pinder, Storey, and Ultsch 1992; E. Stewart, Reese, and Ultsch 2004; Ultsch, Reese, and Stewart 2004). Mass mortality due to anoxic conditions has been reported in many species of ranid frogs in cold, northern climates, where aggregations of more than 1,000 frogs at a single site have been reported. These include *Rana pipiens* (Manion and Cory 1952), *R. muscosa* (Bradford 1983), *R. temporaria* (Bannikov 1948; Smith 1969; Pasanen and Sorjonen 1994), *R. ridibunda* (Berger 1982; Kuzmin 1999), and the Asian frogs *R. amurensis, R. dybowskii, R.pirica,* and *R. nigromaculata* (Kuzmin and Maslova 2003). More than 3,000 dead *R. dybowskii* were found in one hole in a Russian stream (Maslova 2000). R. D. Howard (1981a) reported that many large adults in a population of bullfrogs (*R. catesbeiana*) overwintering in a shallow marsh died during two especially cold winters, probably having frozen to death because of meager snow cover. Some ranid frogs are better able to tolerate hypoxic conditions than are others. For example, *R. esculenta* is more tolerant of low oxygen levels than is *R. lessonae* (Tunner and Nopp 1979), which might explain its somewhat greater tendency to hibernate underwater.

Predation also can be a significant source of mortality for hibernating frogs, which are particularly susceptible to capture when cold and sluggish, or when they aggregate in large numbers (see chapter 14). European otters (*Lutra lutra*) and water shrews (*Neomys fodiens*) frequently capture hibernating frogs (*Rana temporaria*) in ditches, ponds, and streams (Erlinge 1967; Wolk 1976; J.-M. Weber 1990), and frogs comprise up to 45% of the winter diet of these animals. In the Russian Far East, hibernating *R. dybowskii* are a major component of otter diets as well (Kuzmin and Maslova 2003). European polecats (*Mustela putorius*) also feed heavily on frogs in winter, capturing them while hibernating in ditches or on land (D. Weber 1989a, b). Frogs hibernating in ponds are subject to predation by trout and perhaps other fish as well (Kabisch and Weiss 1968). Breckenridge (1944, p. 85) described a huge aggregation of hibernating leopard frogs (*Rana pipiens*) in Minnesota that "literally paved" the bottom of a sandy stream. Mergansers (*Mergus*) in the area were feeding mainly on hibernating frogs.

Costs and Benefits of Hibernation on Land

Amphibians hibernating on land do not face a shortage of oxygen, but are susceptible to predation, desiccation, and freezing. Predation on amphibians that hibernate on land is not as well documented as predation on aquatic hibernators. In Finland, however, pine martens (*Martes martes*) were observed feeding on common frogs (*Rana temporaria*) after searching under moss, logs, and stones and in root cavities (Pulliainen and Ollinmäki 1996a). It was not clear, however, whether the frogs were captured during hibernation or killed before hibernation and stored by the martens.

Terrestrial hibernators have only two options available to them to survive freezing temperatures: find microhabitats that remain above freezing throughout the winter, or tolerate freezing of body tissues (Pinder, Storey, and Ultsch 1992). Most species do the former, constructing burrows in deep soil or seeking out natural cavities with sufficient insulation to keep them from freezing. Usually such sites protect the animals throughout the winter, but unusually cold winters can result in significant mortality in terrestrial hibernators. For example, Petranka (1979) found that several populations of terrestrial salamanders (*Plethodon dorsalis* and *P. richmondi*) virtually disappeared from sites in Kentucky after an exceptionally cold winter. Populations of salamanders survived only in rocky areas with extensive networks of underground tunnels. M. Smith (1969) observed mass mortality in a population of *Triturus vulgaris* hibernating under piles of timber, and Berger (1982) found many European water frogs (*Rana esculenta*) dead in their terrestrial hibernation sites. Mass mortality also has been reported at terrestrial hibernation sites of *Hyla arborea* and *Rana arvalis* in very cold winters or years with little snow cover (Kuzmin 1999).

Freeze Tolerance

Some amphibians have evolved the ability to remain frozen for extended periods of time at temperatures as low as –8° C (Storey 1990). Similar freeze tolerance also is found in many insects, as well as garter snakes (*Thamnophis sirtalis*), and box turtles (*Terrapene carolina;* Storey and Storey 1988; Storey et al. 1988; Costanzo and Claussen 1990; Lee 1990; Storey 1990; Costanzo, Lee, and Wright 1993). There has been some controversy over whether hatchling painted turtles (*Chrysemys picta*) are freeze tolerant. These turtles apparently can survive some freezing at relatively high temperatures (–4° C), but survive lower nest temperatures by supercooling and avoiding freezing (Storey et al. 1988; Churchill and Storey 1992; Costanzo, Iverson, Wright, and Lee 1995; Packard and Packard 1995; Costanzo, Litzgus, Iverson, and Lee 1998; Packard et al., 1997, 1999). The European lizard *Zootoca* (= *Lacerta*) *vivipara* also employs both freeze tolerance and supercooling to survive the winter (Costanzo, Grenot, and Lee 1995; Grenot et al. 2000; Voituron et al. 2002).

Seven species of amphibians are known to tolerate prolonged freezing (fig. 3.21). Six of these are North American anurans: *Rana sylvatica, Pseudacris crucifer, P. triseriata, P. regilla, H. versicolor,* and *H. chrysoscelis* (Lotshaw 1977; MacArthur and Dandy 1982; Schmid 1982; Storey 1984, 1986, 1987a; Storey and Storey 1984, 1985a, 1986a, b, 1988, 1992; Layne and Lee 1987, 1989; Lee 1988; Costanzo, Wright, and Lee 1992; Lee and Costanzo 1993; Swanson, Graves, and Koster 1996; Packard, Tucker, and Lohmiller 1998; Croes and Thomas 2000; Edwards, Koster, and Swanson 2000). The seventh is a Siberian salamander, *Salamandrella keyserlingii,* a species found well above tree line and farther north than any other salamander (Berman, Leirkh, and Mikhailova 1984; Berman 1992). This species is the most freeze tolerant of all amphibians and can survive temperatures down to –40° C. There are reports of individuals being excavated from depths of 10 m or more in Russian permafrost that appeared from radiocarbon dating to be up to 90 years old (Kuzmin and Maslova 2003). Freeze tolerance is absent in terrestrial hibernators such as *Bufo americanus, B. boreas, B. cognatus, B. woodhousii, Pseudacris streckeri, Rana aurora, Plethodon cinereus,* and *Ambystoma laterale,* as well as the aquatic hibernators *Rana pipiens* and *R. septentrionalis* (Storey and Storey 1986a; Swanson, Graves, and Koster 1996; Packard, Tucker, and Lohmiller 1998). The aquatic hibernator *Rana ridibunda* can tolerate having up to 55% of its body water frozen, but freezing of more than 58% is fatal. This species does not accumulate cryoprotectants like those found in terrestrial freeze-tolerant frogs (Voituron, Eugene, and Barre 2003). Juvenile spadefoot toads (*Spea bombifrons*) can tolerate body temperatures as low as –4° C, but they cannot survive freezing (Swanson and Graves 1995).

Fig. 3.21. A frozen wood frog (*Rana sylvatica*), a freeze-tolerant species that hibernates under shallow cover such as moss or leaf litter. Photo by Jon Costanzo.

Physiology of Freeze Tolerance

Freeze-tolerant amphibians use cryoprotectants to depress the freezing point of their intracellular fluids, much as antifreeze decreases the freezing point of water. In most species, the main cryoprotectant is glucose (Storey 1997; Croes and Thomas 2000), but both glucose and glycerol are produced by *Hyla versicolor* (Schmid 1982; Storey and Storey 1985a; Layne 1999) and the closely related *Hyla chrysoscelis* (Irwin and Lee 2003), and glycerol has been found in *Salamandrella keyserlingii* (Kuzmin and Maslova 2003). *Hyla versicolor* is a tetraploid frog that evolved from ancestral diploid *Hyla chrysoscelis* populations, and one might expect them to have similar physiology. There is a possibility, however, that freeze tolerance has evolved independently several times in this complex of tree frogs, because recent studies of mitochondrial DNA have shown that frogs currently called *H. versicolor* evolved more than once from different lineages of frogs currently called *H. chrysoscelis* (Ptacek, Gerhardt, and Sage 1994). Nevertheless, a study of populations from Missouri, Indiana, and Minnesota failed to reveal any major geographic differences in freeze tolerance or concentrations of cryoprotectants (Irwin and Lee 2003). Frogs from Minnesota did tend to store more glycogen in the liver in preference to storing fat, perhaps as an adaptation to more prolonged periods of cold weather, but this did not translate into higher cryoprotectant concentrations in frozen frogs.

The biochemical and physiological changes that allow amphibians to tolerate subfreezing temperatures are similar in all species studied to date. They have been investigated in most detail for the wood frog (*R. sylvatica*). Frogs can tolerate freezing of extracellular fluids, but not complete freezing of internal organs. As freezing begins, water is drawn out of cells into extracellular spaces, particularly in the abdomen and between the skin and muscles (Storey and Storey 1984; Layne and Lee 1987; Lee et al. 1992). Wood frogs can have more than 60% of their body fluids frozen without ill effect. As a frog cools, internal organs, including the heart, continue to function even after peripheral tissues have started to freeze, allowing cryoprotectant glucose to be distributed to vital organs through the bloodstream (Layne, Lee, and Heil 1989). Thawing occurs throughout the body simultaneously, but organs such as the liver thaw most quickly because they contain high concentrations of cryoprotectant (Rubinsky et al. 1994; Lee and Costanzo 1998).

For frogs to tolerate freezing, it is essential for freezing not to be too rapid and that ice crystal formation occur at a relatively high body temperature. If freezing occurs quickly, it can be fatal (Costanzo, Lee, and Wright 1991) because there is not sufficient time for water to be drawn out of vital organs and for cryoprotectant to accumulate (Costanzo, Lee, and Wright 1992). A frog that has been supercooled (with a body temperature several degrees below 0° C) is at risk of instantaneous freezing (Costanzo, Bayuk, and Lee 1999). Ice formation in the animal generally is initiated by contact with ice crystals in the soil, but also can be promoted by various nucleating agents, such as ice-nucleating bacteria in the gut and skin (Layne, Lee, and Huang 1990; Layne 1995; Costanzo and Lee 1996). Production of cryoprotectant does not begin until ice crystals begin to form in the peripheral tissues (Storey and Storey 1985b).

Conversion of liver glycogen to glucose is supported by anaerobic metabolism facilitated by a rapid increase in the activities of key liver enzymes as soon as ice formation begins (Storey 1987a). Glucose is then rapidly distributed in the blood to vital organs, particularly heart and brain tissue (Storey and Storey 1986b; Storey 1987b). Uptake of glucose by organs is enhanced by a six-fold increase in rates of glucose transport across plasma membranes in frogs collected in the fall, compared to those collected in the spring (P. King, Rosholt, and Storey 1995). A frog's capacity for cryoprotectant production is ultimately limited by the available stores of glycogen in the liver, so frogs that enter hibernation with low glycogen stores should be less capable of surviving subfreezing temperatures (Costanzo and Lee 1993; Jenkins and Swanson 2005).

Freeze-tolerant wood frogs generally do not remain frozen all winter, but undergo repeated cycles of freezing and thawing, with glucose being rapidly reconverted to glycogen and stored in the liver after thawing (Storey and Storey 1986b; Storey 1987b). In fact, these frogs cannot survive prolonged freezing (3–4 weeks), but survival can be improved by injection of supplemental glucose prior to freezing (Layne, Costanzo, and Lee 1998). Wood frogs cannot tolerate freezing at very low temperatures (–7.5° C). Such low temperatures can result in extensive tissue damage, including damage to nerve cells (Costanzo, Allenspach, and Lee 1999) and sperm (Costanzo, Mugnano, Wehrheim, and Lee 1998).

Wood frogs and other freeze-tolerant species retain their capacity to survive subfreezing temperatures even after emerging from hibernation in spring, but low glycogen reserves limit their capacity to produce cryoprotectant. Frogs that have previously thawed lose considerable quantities of glucose through excretion of urine, but some glucose can be recovered by resorption of glucose across the bladder wall (Costanzo, Callahan, Lee, and Wright 1997). Freeze tolerance rapidly declines once the frogs begin to feed (Storey and Storey 1987). Recovery of organ system function is relatively rapid after the frog thaws, with the heart recovering first and peripheral nerves and limb muscles taking somewhat longer (Layne and First 1991; Kling, Costanzo, and Lee 1994). Late freezing does carry some cost, however, because previously frozen males exhibit reduced mate-searching behavior in breeding aggregations for a day or so after freezing (Costanzo, Irwin, and Lee 1997), as well as reduced muscle performance (Irwin, Costanzo, and Lee 2003).

The rapid increase in transport of glucose into cells in freeze-tolerant frogs resembles the physiological responses of many frogs to desiccation. For example, leopard frogs (*Rana pipiens*), which cannot tolerate freezing, can endure losses of up to 50% of total body water content. As desiccation proceeds, a frog maintains the water content of its tissues by greatly increasing intracellular concentrations of glucose, which in turn increase the osmotic concentration of the cells. The glucose is derived from glycogen stored in the liver. Freeze-tolerant wood frogs (*Rana sylvatica*) and spring peepers (*Pseudacris crucifer*) are slightly more tolerant of desiccation than are leopard frogs and have a much greater capacity for transporting glucose into vital organs. Freeze-tolerant chorus frogs (*Pseudacris triseriata*) showed elevated mobilization of liver glycogen in response to desiccation during the winter, whereas freeze-intolerant toads (*Bufo cognatus* and *B. woodhousii*) did not (Edwards, Jenkins, and Swanson 2004). Dehydrated anurans also tend to accumulate urea (see chapter 2), and urea has been shown to have cryoprotectant properties similar to that of glucose. In contrast to glucose, however, urea concentrations do not increase with freezing (Costanzo and Lee 2005). The similarity in responses to desiccation and freezing suggest that the physiological responses of freeze-tolerant frogs are modifications of preexisting physiological responses that are widespread in frogs, although these responses may not be present in all anurans (Churchill and Storey 1993, 1995; Costanzo, Lee, and Lortz 1993).

Evolution of Freeze Tolerance

Although a detailed phylogenetic analysis of the evolution of freeze tolerance is not yet possible, the distribution of freeze tolerance among ranids and hylids suggests that this adaptation has evolved independently at least three times and possibly more. *Rana sylvatica* is one of the few terrestrial hibernators among North American ranids, and so far is the only member of its family known to tolerate freezing. The European common frog, *R. temporaria,* can survive at –2° C for 24 hours, but it lacks the prolonged freeze tolerance of *R. sylvatica* (Pasanen and Karhapää 1997). Recent phylogenetic analyses suggest that these frogs are not closely related, despite a general similarity in appearance and breeding ecology (Hillis and Wilcox 2005). The two freeze-tolerant species of *Pseudacris* are closely related (Hedges 1986) and could represent a single origin of freeze tolerance that clearly is independent of wood frogs. *Pseudacris streckeri,* a burrowing species with a more southern distribution, is not freeze tolerant (Packard, Tucker, and Lohmiller 1998). *Pseudacris regilla,* was previously considered not to be freeze tolerant (Storey and Storey 1988), but a recent study demonstrated that individuals from a high-altitude population in northern California have at least a limited capacity for freeze tolerance (Croes and Thomas 2000). Freeze tolerance in *Hyla chrysoscelis* and *Hyla versicolor* could be a single evolutionary event, or several independent events, depending on how many lineages of this complex are freeze tolerant. At least limited freeze tolerance eventually may be found in other amphibians from North America and Eurasia. For example, Berger (1982) found two adult *Rana lessonae* frozen in a block of ice where water had collected in their terrestrial hibernation site. Both individuals were alive when the ice thawed, but six adult *R. esculenta* frozen with them were dead. He also found evidence that *R. lessonae* was more tolerant of cold temperatures in more typical terrestrial hibernation sites than was *R. esculenta.*

Summary and Conclusions

In addition to their highly permeable skin, no feature of amphibian physiology has a greater impact on their ecology and behavior than ectothermy. Virtually every physiological process in amphibians is temperature dependent, including metabolic rate, the rate at which food can be processed, growth and development, reproductive cycles, locomotion, and sensory biology. This high degree of temperature dependence in turn affects the latitudinal and altitudinal distribution of amphibians, their activity cycles, the timing of breeding and the structure of their mating systems, choice of calling and oviposition sites, and life history strategies. Temperature also can affect the interactions of amphibians with their predators and with other amphibian species in the community.

Because they lack the capacity to generate their own body heat, amphibians are dependent on behavioral thermoregulation to keep their body temperatures within a suitable range. In contrast to many reptiles, however, amphibians are constrained in how precisely they can regulate body temperature by the permeability of their skin. Amphibians can reduce heat loads through evaporative cooling, but only if they have access to sufficient moisture to replace that lost through evaporation. Their ability to increase body temperatures through basking is severely limited, because radiation absorbed by the skin tends to increase evaporative water loss, which in turn lowers body temperature. The only amphibians capable of raising body temperatures significantly through basking are arboreal species that have evolved increased cutaneous resistance to evaporative water loss. Precise thermoregulation is virtually impossible for amphibians in water, because the small size of most amphibians ensures that heat will be conducted away from the body very rapidly. Consequently, amphibians in water are essentially thermoconformers, relying on selection of warm or cool microhabitats to regulate body temperature.

Amphibians at high altitudes face particular severe problems of thermoregulation. Many high-altitude environments undergo major daily temperature fluctuations, with intense solar radiation during the day and rapid cooling at night. High-altitude environments also tend to be relatively dry, which exacerbates problems of evaporative water loss. Some high-altitude populations of amphibians cope with these problems mainly through behavioral adjustments, including being active mainly during the day and at a wider range of temperatures than low-elevation populations. There also is evidence for some tropical frogs that high-elevation populations have evolved physiological traits that enable them to be active at temperatures that would incapacitate their low-elevation relatives.

Temperate-zone amphibians have some capacity to adjust physiologically to seasonal changes in temperature through acclimation of metabolic rate and thermal tolerance, but such acclimation responses appear to be absent in tropical species. Most amphibians exhibit little or no capacity for acclimation of locomotor performance. There have been many experimental studies of acclimation of thermal tolerance, as measured by the critical thermal maximum (CT_{Max}), but the adaptive significance of such acclimation is unclear. In many species, a difference of acclimation temperature of as much as 20° C produces change in CT_{Max} of only a few degrees. Because the CT_{Max} typically is well above the upper limit of normal activity temperatures, the benefit of a slight increase in CT_{Max} has yet to be demonstrated. Possibly such acclimation provides survival benefits on rare occasions when amphibians are exposed to unusually high and near-lethal temperatures. Typical acclimation requires a period of days or weeks of exposure to a new temperature regime to produce measurable responses. Such long-term acclimation is unlikely to be beneficial when amphibians are exposed to sudden changes in temperature. Some species exhibit short-term physiological adjustments to elevated temperature in a matter of hours. This type of heat hardening is beneficial in allowing amphibians to survive daily fluctuations in temperature during summer months.

Amphibians are limited in their ability to remain active at very high temperatures, but they are completely incapacitated by very low temperatures. This means that amphibians in winter must seek out microhabitats that remain above freezing, or they must be able to tolerate being frozen on at least a short-term basis. Aquatic hibernators are not freeze tolerant, but often seek out hibernation sites that remain unfrozen and well oxygenated throughout the winter. Most terrestrial hibernators also are not freeze tolerant and must burrow into the ground to a sufficient depth to avoid freezing or seek out caves, rock crevices, and other sheltered sites. A limited number of amphibians have been shown to tolerate freezing for periods of days or weeks. They do so by removing most of the water from their cells, protecting the cells with a cryoprotectant that prevents freezing (glucose or glycerol), and allowing the extracellular spaces to freeze. The phylogenetic distribution of freeze tolerance is poorly understood. At present, all examples of freeze tolerance among anurans are North American hylids (*Pseudacris* and *Hyla*) and one ranid (*Rana sylvatica*). Species that are closely related to these in North America, Europe, and Asia appear not to be freeze tolerant, but most species have not been thoroughly tested.

Another question that remains to be answered is whether freeze tolerance is widespread within species, such as *Pseudacris crucifer, Hyla versicolor,* and *Rana sylvatica,* or is population specific. There was not much geographic variation in freeze tolerance among populations of gray tree frogs from relatively cold regions, but more southern populations have not been studied. It is clear that freeze tolerance has evolved several times independently in North American anurans, possibly multiple times even within widespread species. The question is of particular interest for the gray tree frogs. Both the diploid species, *Hyla chrysoscelis,* and the tetraploid species, *H. versicolor,* have been shown to be freeze tolerant. Recent molecular evidence indicates that tetraploid gray tree frogs have arisen several times independently from different lineages of *H. chrysoscelis.* This raises the question of whether freeze tolerance evolved in all lineages of *H. chrysoscelis* and subsequently was passed on to populations of *H. versicolor,* or arose independently several times within the complex.

Chapter 4 Respiration

The toads, Bufo, *have a thick-set body, covered with warts or papillae, from which exudes a viscid humor. . . . These hideous and disgusting reptiles ordinarily conceal themselves in shady, humid places, from which they do not go out, except at night, or immediately after warm and abundant rains of summer. . . . In countries where the winter is cold, they pass the season benumbed in holes. Their respiration then becomes extremely limited, and the contact of a very small quantity of air with the skin is sufficient to maintain their existence.*
—W. S. W. Ruschenberger, MD, *Elements of Herpetology and Ichthyology* (1856)

It has long been obvious to biologists that there is something unusual about the respiration of amphibians. Not only do they often appear to need very little oxygen to stay alive, but they also can take up most of it through the skin, bypassing the respiratory organs used by other terrestrial vertebrates. These unusual characteristics of amphibians have made them popular subjects for investigations of respiratory physiology since the earliest days of experimental biology. The nineteenth-century anatomist Alexander Ecker stated that the frog "enjoys the doubtful honour of being the physiological domestic animal," being "daily sacrificed upon the altar of science." He added, "the history of the most important physiological discoveries is closely related with the employment of the frog in physiological research" (Ecker 1889, 1). Indeed, studies of frogs were important in the development of modern ideas on animal respiration (for a detailed historical review, see C. B. Jørgensen 2000). In the 17th century, Robert Boyle placed frogs and other animals in chambers evacuated with his newly designed vacuum pump to test the effects of reduced air pressure on living organisms; needless to say, most of these animals died (Boyle 1670). Boyle's interest in respiration was incidental to his research on pneumatics and the chemistry of air, however. At the end of the next century, after the discovery of oxygen by the French chemist Antoine Lavosier, the Italian physiologist Lazzaro Spallanzani performed a number of experiments on frogs in his attempt to understand the nature of respiration. He removed the lungs of frogs and showed that these animals used oxygen and produced carbon dioxide as did intact frogs; he concluded that the skin must be an important avenue of gas exchange (Spallanzani 1803). Spallanzani also was one of the first scientists to suggest that respiration occurs in the tissues and not just in the lungs, as many others had assumed (Perkins 1964; Dolman 1975; Castellani 1984).

In the nineteenth century, the French physiologist William Frederic Edwards (1817) studied the influence of environmental variables on living organisms, including the effects of heat and cold on animals, the role of light in the development of amphibians, and the responses of frogs and other animals to a lack of oxygen. His results were later published in a book (Edwards 1824) that could be considered the first major work on physiological ecology (Allee et al. 1949; Kauta 1971; C. B. Jørgensen 2000). Edwards repeated Spallanzani's experiment of removing the lungs of frogs and confirmed his findings that respiration continued, apparently through the skin. He also showed that frogs without lungs could survive for more than a month in cold water saturated with air. He blocked cutaneous respiration by various means including coating frogs with paint and submerging them in oil. Since many frogs subjected to these treatments died, he concluded that the skin is essential for respiration (Dolk and Postma 1927).

In the 1840s, two French chemists, Victor Henri Regnault and Jules Reiset, developed the first closed respirometer for making quantitative measurements of oxygen consumption and carbon dioxide production in animals. They undertook a detailed comparative study of respiration in "warm-blooded" and "cold-blooded" vertebrates and, in the process, made the first accurate measurements of respiratory quotients in animals (the ratio of CO_2 produced to O_2 consumed). In experiments with both frogs (probably *Rana esculenta*) and salamanders (most likely *Salamandra salamandra*), they obtained values for O_2 consumption that are remarkably close to those reported by later workers (see table 1 in Gatten, Miller, and Full 1992, for comparative data). Their data showed that O_2 consumption of frogs increases with temperature, although they did not comment on this point, and they demonstrated that amphibians and reptiles have much lower metabolic rates than do birds and mammals. They followed the example of Spallanzani and Edwards in removing lungs from frogs and found only a slight reduction in the amount of O_2 consumed, supporting previous conclusions that most gas exchange takes place through the skin (Regnault and Reiset 1849).

The modern era of amphibian respiration studies was initiated by the Danish physiologist Christian Bohr and his student August Krogh. The former was the first to describe the change in O_2 affinity of blood brought about by a change in acidity, now known as the Bohr Effect (Astrup 1972). In his studies of frog respiration, Bohr found that metabolic rates were higher in summer than in winter and that removal of the lungs therefore had a much greater effect on O_2 consumption in the summer. He also proposed that the skin of a frog is much more permeable to CO_2 than to O_2 (Bohr 1900). In 1903, Krogh completed his PhD dissertation on pulmonary and cutaneous respiration in frogs, greatly expanding on Bohr's work. His study was the first to actually quantify the uptake of O_2 and release of CO_2 through both skin and lungs. He found that most CO_2 was eliminated through the skin, while the lungs were more important for uptake of O_2. He also confirmed Bohr's finding of seasonal variation in metabolic rates (Krogh 1904). Much of this work was repeated by two Dutch workers, H. E. Dolk and N. Postma (1927), who confirmed Krogh's major results and provided additional evidence for seasonal variation in metabolism. Because all of these early researchers used artificial means to ventilate the lungs, their work provided little information on the relative importance of pulmonary and cutaneous respiration in freely breathing amphibians, and more than 35 years passed before accurate measurements of this type were made on both salamanders and frogs (Whitford and Hutchison 1963; Vinegar and Hutchison 1965).

Much of the subsequent work on amphibian respiration has focused on comparisons of aquatic and terrestrial species. Major research themes have included the relative importance of pulmonary and cutaneous respiration, aspects of acid-base balance as it is affected by gas exchange in the two environments, and chemical influences on the control of respiration (Boutilier, Stiffler, and Toews 1992; Shoemaker et al. 1992; Booth 1994; Malvin 1994). There also has been a revival of interest in the neuromuscular control of lung ventilation (Brainerd 1994), a field that traces back to the work of Robert Townson (1799) in the late eighteenth century (C. B. Jørgensen 2000). Much of this work has been in the tradition of comparative physiology established by Krogh. Hence, most of our knowledge of the details of respiration in amphibians comes from studies of a few species chosen primarily for their usefulness as laboratory animals (e.g., *Rana catesbeiana, Bufo marinus, Xenopus laevis, Ambystoma tigrinum*). Exceptions are a few studies relating respiratory adaptations to environments differing in the availability of oxygen (e.g., Guimond and Hutchison 1976; Ultsch 1976). While the emphasis of most studies has been more on physiological mechanisms than on ecological adaptations, they do provide insights into ways in which amphibians cope with a variety of habitats.

Environmental Aspects of Gas Exchange

The Availability of Oxygen

Oxygen is seldom a limiting factor for amphibians in the terrestrial environment. The atmosphere is approximately 21% O_2, and its O_2 content is not greatly affected by the respiration of animals. While the percentage of O_2 in the atmosphere remains constant, the partial pressure of O_2 (PO_2) declines with increasing altitude, and it is PO_2 that determines the availability of O_2 to respiring organisms. However, because of their low metabolic rates, terrestrial amphibians do not appear to be limited by low PO_2 at high altitudes. In North America, terrestrial salamanders are found as high as 3,300 m (11,000 ft; Hock 1964), while a toad, *Bufo spinulosus,* occurs as high as 4,500 m (14,760 ft.) in the Andes of South America (Pearson and Bradford 1976; Sinsch 1989a). More than a quarter of the anuran fauna of Sichuan Province, China, is found only above 2,200 m (7,200 ft), and some pelobatid frogs in the genus *Scutiger* are regularly found at altitudes over 4,200 m (14,000 ft; Liu 1950; Hock 1964; Zhao, Wu, and Inger 1989). Anurans can easily survive PO_2 levels equivalent to those at altitudes of over 20,000 m (Hock 1964), although metabolic rates are depressed under hypoxic conditions (Hou and Huang 1999). Perhaps more pertinent is a study by Withers and Hillman (1983), who demonstrated that maximal O_2 consumption during forced exercise in both *Bufo cognatus* and *Rana pipiens* was independent of PO_2 down to values as low as 80 Torr (1 Torr = 1 mm Hg). This is equivalent to PO_2 at about 4,500 m (14,760 ft). Hence, terrestrial amphibians should be capable of carrying out their normal activities throughout the altitudinal range of all living species.

One situation that might expose terrestrial amphibians to low levels of O_2 is burrowing. Indeed, many experimental studies of physiological responses of amphibians to hypoxic conditions (Armentrout and Rose 1971; Boutilier and Toews 1977; D'Eon, Boutilier, and Toews 1978; Boutilier et al. 1979c; Portner, MacLatchy, and Toews 1991) or O_2 affinity of the blood (Wood et al. 1975) have been based on the assumption that O_2 is depleted inside burrows. The only careful measurements of O_2 concentration in soil adjacent to burrowing amphibians are those made by Seymour (1973c) on spadefoot toads (*Scaphiopus couchii*). He found that O_2 concentration in soil next to winter burrows (55–80 cm deep) was not significantly different from that at the soil surface. Oxygen concentration in soil adjacent to shallow (8 cm) summer burrows of *S. couchii* was slightly lower than that at the surface, but not enough to have any effect on the animal's metabolism. Hence, one cannot assume that burrowing amphibians are normally exposed to severe hypoxia. Oxygen content of soil decreases with increasing water content, and is lowest in soils with fine particle size, such as those composed mostly of clay. Hypoxic conditions in burrows are most likely to occur in the tropics, where water-logged soils inhibit diffusion of gases. Nevertheless, wet tropical soils can be surprisingly well oxygenated. On Barro Colorado Island in Panama, soil O_2 content rarely dropped below 15% during the rainy season, even at depths of 80 cm, and usually was above 17%—much higher than the O_2 content of aquatic habitats (Kursar, Wright, and Radulovich 1995).

Aquatic environments can present less favorable conditions for O_2 uptake and are more variable in oxygen availability than are terrestrial environments. The O_2 content of fully saturated water is only about 1/30th that of air and is strongly influenced by temperature (O_2 capacity decreases with increasing temperature; Krogh 1941; Dejours 1976; Randall et al. 1981). In addition, the O_2 content of closed bodies of water is affected by the respiration of aquatic organisms, so seasonal and even daily fluctuations in respiration can result in major changes in the availability of O_2. Oxygen content also is governed by the degree of mixing in the water column. In the absence of wind-driven or thermally driven mixing in lakes and ponds, deep waters tend to become hypoxic or even anoxic because diffusion of O_2 from air into water is exceedingly slow. This problem is less severe in flowing water, where movement of the water usually keeps it well aerated. Hence, amphibians that inhabit rapidly flowing streams or rivers, particularly in cool environments, are less likely to encounter stressful hypoxic conditions than those found in still water.

With the exception of Gordon Ultsch's work on the respiration of sirens (Ultsch 1971, 1973a, b, 1974, 1976), there have been few detailed studies of aquatic O_2 availability in relation to amphibian ecology. Scattered data on habitats with low levels of dissolved O_2 are summarized in table 4.1. Some of these come from studies of amphibian ecology, while others are taken as representative of conditions in habitats often used by amphibians. In most cases, the values shown are among the lowest recorded and are not necessarily typical of the habitat throughout the year. Open aquatic habitats with exposure to sunlight often have higher O_2 levels during the day, when photosynthesizing plants are producing O_2, than at night, when photosynthesis stops and the plants and other organisms deplete the O_2 through respiration. Some investigators have reported measurements from several depths or different locations within a habitat, but only a few have attempted to document daily or seasonal variation in O_2 availability (e.g., Laessle 1961; W. Moore and Burn 1968; Ultsch 1971, 1973a, 1976; Bradford 1983; Wong and Booth 1994; Nie, Crim, and Ultsch 1999).

Low levels of O_2 are particularly characteristic of swampy habitats, both in the tropics and the temperate zone (table 4.1). In many areas, such as the "floating meadows" of the Amazon, papyrus swamps of Africa, and lakes invaded by water hyacinths, O_2 can be totally depleted in warm weather. This is due to respiration of bacteria breaking down vast amounts of organic material and to a lack of light for photosynthesis resulting from dense mats of vegetation covering the water. Temporary ponds often have very low O_2 content as well, but vary considerably depending on depth, density of vegetation, shading from surrounding trees, and so on. Hutchinson, Pickford, and Schnurman (1932) found that shallow pans and vlies in South Africa, the principal breeding sites of many anurans in that region, varied from severely hypoxic to nearly saturated with O_2. Consistently low levels were found in shallow seasonal pans with large amounts of decaying organic matter and few photosynthesizing plants.

Hypoxia can be particularly severe in very small bodies of water, where respiration of organisms can quickly deplete the available O_2 supply. For example, Kluge (1981) found very low O_2 concentrations in the mud basins used by *Hyla rosenbergi* for oviposition (table 4.1), and eggs could survive only if they remained suspended at the surface. Laessle (1961) and Janetsky and Vareschi (1993) made detailed studies of variation in O_2 content of water-filled bromeliads in Jamaica. Oxygen levels usually were low, particularly in

Notes: Most measurements were made at 20–30°C. Water saturated with air at these temperatures would have a dissolved oxygen content of 8–9 mg/l. Species marked with an asterisk (*) are representative of the habitat type but were not necessarily found in the same location in which oxygen measurements were made.

bromeliads filled with organic detritus. When algae were present, water near the surface sometimes was supersaturated in bright sunlight, but the pools became hypoxic, especially deeper in the chamber, when low light prevented photosynthesis by the algae. These bromeliads are inhabited by tadpoles of the hylid frog *Osteopilus brunneus,* which appear to be obligate air-breathers from an early age (Lannoo, Townsend, and Wassersug 1987). Many other species of frogs, including some hylids, microhylids, rhacophorids, and dendrobatids, either breed or deposit their tadpoles in bromeliads or tree holes. The latter are likely to be even more hypoxic because they often are filled with organic detritus and have little exposure to light, but I have been unable to find quantitative measurements of O_2 concentrations. Tadpoles in such habitats generally must breathe air to survive and often have specialized morphological adaptations for aerial respiration (Noble 1929a; Wassersug, Frogner, and Inger 1981; Lannoo, Townsend, and Wassersug 1987; Krügel and Richter 1995; see also chapter 12).

Although warm, swampy waters often have low levels of dissolved O_2, the same also can be true of cold, clear ponds and lakes when such environments are covered by ice in winter. In shallow lakes with thick ice cover, O_2 depletion can be severe enough to cause mass mortality of fish (Greenbank

1945; Barica and Mathias 1979). High winter mortality among predatory fish can actually benefit some amphibians (Eaton et al. 2005), but amphibians that overwinter at the bottom of ice-covered ponds and lakes (Emery, Berst, and Kodaira 1972) sometimes suffer high mortality as well (see chapter 3). One such species, *Rana muscosa,* lives in high-elevation lakes in the western United States (Bradford 1983). Adult frogs were less tolerant of low O_2 tensions than were tadpoles and therefore were more susceptible to being eliminated from shallow lakes because of O_2 depletion. However, in many lakes, severe O_2 depletion probably occurs only in years with exceptional ice cover. Consequently, even if adult frogs are periodically eliminated from the population by winter mortality, the population of most lakes is maintained because overwintering tadpoles are able to survive long enough to reach sexual maturity and reproduce.

Environmental Carbon Dioxide

In addition to supplying O_2 to the tissues, animals also must eliminate CO_2 produced as a by-product of metabolism. Carbon dioxide itself is not especially toxic to animals; its main detrimental effects are manifested as changes in the organism's acid-base balance. Terrestrial amphibians have little difficulty eliminating CO_2, which readily diffuses into the atmosphere. Probably the only circumstances in which terrestrial species are likely to encounter elevated levels of CO_2 are in burrows. A buildup of CO_2 inside a burrow could reduce rates of diffusion away from the body, resulting in some respiratory acidosis (Boutilier et al. 1979c). This should be especially true for species that burrow in mud and remain dormant as the mud dries out (e.g., *Siren, Amphiuma*). For species that burrow in loose soil, however, CO_2 concentrations in burrows are not likely to be very high because CO_2 will diffuse rapidly into the soil. In addition, CO_2 released by a burrowing animal will combine with water in the soil, thereby reducing the PCO_2 of the burrow.

Aquatic environments often are subjected to major fluctuations in CO_2 concentrations. Swampy environments that have very low levels of dissolved O_2 usually have high levels of CO_2 as well (fig. 4.1). High CO_2 concentrations will impede elimination of CO_2 through the skin, resulting in severe acidosis. Under some circumstances, CO_2 levels in the water can be so high that CO_2 actually will move across the skin into the animal instead of being eliminated (Ultsch 1976). Most fish cannot tolerate such conditions for long, but sirens thrive in ponds covered with water hyacinths where CO_2 concentrations become very high. Tests of one species, *Siren lacertina,* showed that individuals of all sizes were capable of surviving many days exposure to CO_2 levels well above those normally encountered in such ponds (Ultsch 1976).

Gas Exchange by Adult Amphibians

Amphibians have a number of different avenues of gas exchange in both air and water. Air-breathing amphibians can utilize the lungs, skin, or lining of the mouth and pharynx for gas exchange, while water-breathers use gills or the skin. Some species are biomodal breathers, exchanging gas with

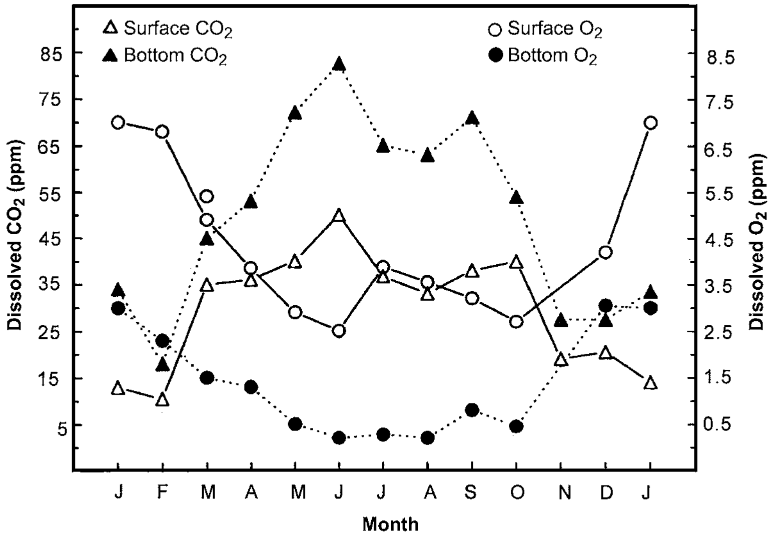

Fig. 4.1. Concentrations of dissolved oxygen and carbon dioxide throughout the year in a water hyacinth community in Florida, measured at the water surface and at the bottom of the pond. Oxygen is depleted during the summer, especially on the bottom, while carbon dioxide levels are at their highest during the summer. After Ultsch (1976).

the surrounding water through the skin while surfacing to breathe air with their lungs. The relative importance of the skin for O_2 uptake varies among species and within species as a function of temperature and metabolic demand. The skin itself is a metabolically active organ that performs a variety of biological functions (see chapter 2). A significant proportion of the O_2 taken up through the skin is used to support the metabolism of the skin itself (Vitalis 1990).

The early work of Krogh (1904) showed that the skin is the major avenue of CO_2 excretion in ranid frogs, and subsequent work has confirmed this pattern for most aquatic and terrestrial amphibians (Mendes 1945; Sawaya 1947; Whitford and Hutchison 1963, 1965b; Hutchison, Whitford, and Kohl 1968; Guimond and Hutchison 1968, 1973a, b, 1974, 1976; Bentley and Shield 1973; Shield and Bentley 1973; Gottlieb and Jackson 1976; Ultsch 1976; Mackenzie and Jackson 1978; Emilio and Shelton 1980; Burggren and West 1982; Burggren and Moalli 1984; Feder and Burggren 1985a; Jared et al. 1999). In many species, at least 75% of CO_2 exchange takes place through the skin.

Oxygen Uptake in Air

In the 1960s, investigators studied partitioning of aerial gas exchange in terrestrial amphibians by fitting frogs and salamanders with plastic masks and placing them in a divided chamber. This procedure separates the air surrounding the head from that surrounding the rest of the body (Whitford and Hutchison 1963, 1965a, b, 1966, 1967; Vinegar and Hutchison 1965; Guimond and Hutchison 1968; Hutchison, Whitford, and Kohl 1968). O_2 uptake through the skin is then measured in the body chamber, while the combined uptake through the lungs and buccopharyngeal region is measured through the mask. In lungless species, of course, only buccopharyngeal and cutaneous gas exchange are measured. The resulting measurements provide an estimate of the relative importance of various gas exchangers. This procedure is subject to considerable error, however, because the presence of a mask often causes an animal to struggle to free itself, thereby elevating its metabolic rate (Feder 1976a, b, 1977). The result would be an overestimate of the importance of lungs in oxygen uptake, since the lungs account for most of the increase in oxygen uptake in active animals (see the following).

Data for a number of terrestrial salamanders and anurans are summarized in figure 4.2. At 15° C, pulmonary respiration predominates for nearly all of the anurans, whereas only a few species of salamanders take up more than half of their O_2 through the lungs. This reflects the more extensive respiratory surface area in the lungs of anurans compared to most salamanders (see further discussion in the following). In plethodontids, the skin is by far the most important av-

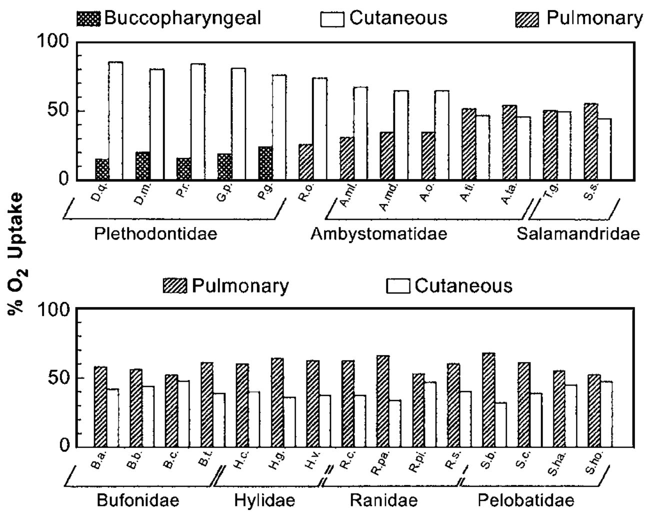

Fig. 4.2. Relative importance of pulmonary, cutaneous, and buccopharyngeal oxygen uptake in air for selected terrestrial urodeles (top) and anurans (bottom). Pulmonary and buccopharyngeal respiration could not be measured separately in species with lungs. Bars indicate mean proportions for several individuals of each species. Species abbreviations: *D.q. = Desmognathus quadramaculatus; D.m. = D. monticola; P.r. = Pseudotriton ruber; G.p. = Gyrinophilus porphyriticus; P.g. = Plethodon glutinosus; R.o. = Rhyacotriton olympicus; A.ml. = Ambystoma maculatum; A.md. = A. macrodactylum; A.o. = A. opacum; A.t. = A. tigrinum; A.ta. = A. talpoideum; T.g. = Taricha granulosa; S.s. = Salamandra salamandra; B.a. = Bufo americanus; B.b. = B. boreas; B.c. = B. cognatus; B.t. = B. terrestris; H.c. = Hyla cinerea; H.g. = H. gratiosa; H.v. = H. versicolor; R.c. = Rana clamitans; R.pa. = R. palustris; R.pi. = R. pipiens; R.s. = R. sylvatica; S.c. = Scaphiopus couchii; S.ho. = Scaphiopus holbrookii; S.b. = Spea bombifrons; S.ha. = Spea hammondii.* Plotted from data in Whitford and Hutchison (1963, 1965b, 1966), Vinegar and Hutchison (1965), and Hutchison, Whitford, and Kohl (1968).

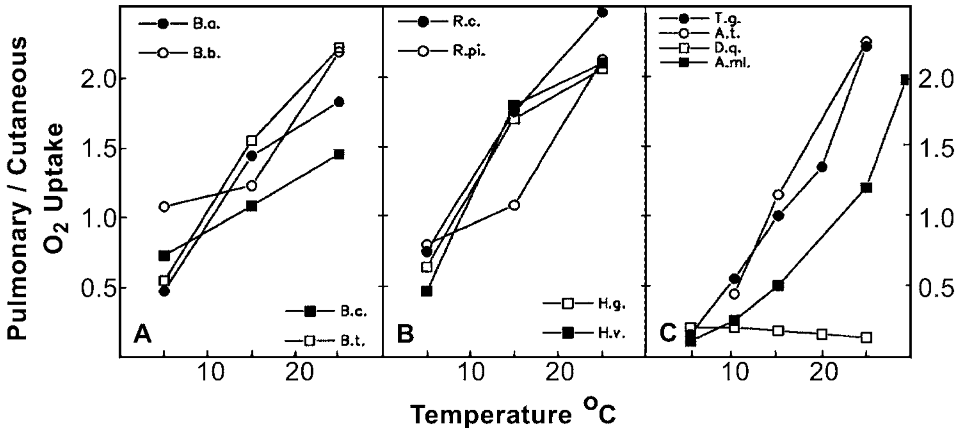

Fig. 4.4. Changes in the relative importance of lungs and skin in the uptake of oxygen as a function of temperature in selected amphibians, as shown by the ratio of pulmonary to cutaneous uptake. A positive slope indicates an increase in the importance of pulmonary gas exchange with increasing temperature. (A) Four species of *Bufo*. (B) Two species of *Rana* and two species of *Hyla*. (C) Four species of urodeles. Species abbreviations as in fig. 4.2. Plotted from data in Whitford and Hutchison (1963, 1965b) and Hutchison, Whitford, and Kohl (1968).

enue of O_2 uptake, with the buccopharyngeal region seldom accounting for more than 20%. Even in the Ambystomatidae, which have relatively large lungs, most O_2 is taken up through the skin. In a few ambystomatids and terrestrial salamandrids, the lungs and skin are about equally important. Data on partitioning of O_2 uptake are not available for terrestrial caecilians at rest, but measurements for two species engaged in moderate levels of activity indicate that the skin accounts for only about 20% of O_2 uptake (Smits and Flanagan 1994). Combined pulmonary and cutaneous uptake of resting animals was slightly lower than cutaneous uptake in active animals (fig. 4.3), so it is possible that the skin could supply all of the animals' O_2 at rest.

The relative importance of different gas exchangers is not fixed, but varies with temperature and level of activity. An increase in temperature leads to a substantial increase in pulmonary O_2 uptake in species with lungs, while cutaneous uptake increases more slowly. The net result is a substantial increase in the relative importance of pulmonary respiration (fig. 4.4). This reflects a large effect of increased ventilation on gas exchange through the lungs (Whitford and Hutchison 1965b; Guimond and Hutchison 1968; Hutchison, Whitford, and Kohl 1968; Kruhoffer et al. 1987). Increased activity also can be expected to increase the importance of pulmonary O_2 uptake. Although amphibians can increase rates of O_2 diffusion through the skin as metabolic demands increase (see Feder and Burggren 1985a and following discussion), the change is less dramatic than the increase in pulmonary gas exchange, and not sufficient to supply all of the needs of an active animal. Lungless salamanders apparently have a limited ability to increase O_2 uptake through the buccopharyngeal region, so cutaneous respiration remains the predominant mode even at high temperatures (e.g., *Desmognathus quadramaculatus* in fig. 4.4c). During vigorous exercise, amphibians with lungs greatly increase ventilation rates, and the importance of pulmonary gas exchange presumably increases as well. Large-bodied species that lack lungs are somewhat limited in their capacity to sustain vigorous activity, but this does not seem to be true for very small lungless species (Full 1986; Feder 1988; Feder, Full, and Piiper 1988; Full et al. 1988; see chapter 5).

Oxygen Uptake in Water

Only a few adult amphibians take up O_2 exclusively from the water. Most species are water-breathers only when metabolic demands are relatively low, or O_2 content of the water is particularly high. For example, some frogs spend the winter at the bottom of ponds or streams (Emery, Berst, and Kodaira 1972; Bradford 1983). At winter temperatures, metabolic rates are so low that O_2 demands can be met through cutaneous respiration (Pinder 1987). However, at other times of year, the same species generally survive only a few days without access to air, even at relatively low temperatures (Holzapfel 1937; Hutchison and Dady 1964; Hutchison and Whitford 1966). A few frogs, such as species of *Telmatobius* from high Andean lakes and *Ascaphus truei* from the streams of western North America, are strictly aquatic throughout their lives and live in cold, O_2-saturated water. They probably meet nearly all of their metabolic demands through cutaneous respiration, although they are capable of breathing air if the O_2 content of the water declines (Hutchison, Haines, and Engbretson 1976).

Highly aquatic salamanders probably take up most of their O_2 through the skin as well. For example, the hellbender (*Cryptobranchus alleganiensis*) is strictly aquatic and is found almost exclusively in relatively cold, well-oxygenated habitats. Its loosely folded skin (fig. 1.31 C in chapter 1) is the primary respiratory organ under most conditions (Guimond and Hutchison 1973a, 1976). The lungs of these salamanders are simple sacs that lack extensive subdivisions. Nevertheless, they are capable of using the lungs to breathe at the surface. They can survive for nearly a week in severely hypoxic water at 20° C by breathing air, but their metabolic rates are greatly reduced under hypoxic conditions and their acid-base balance is disrupted by a buildup of CO_2 (Boutilier, McDonald, and Toews 1980; Ultsch and Duke 1990).

Other salamanders that live in relatively cold, well-oxygenated water probably rely mainly on the skin for respiration. This certainly is true of aquatic plethodontids, which lack lungs, such as *Desmognathus marmoratus, Desmognathus quadramaculatus,* and *Gyrinophilus porphyriticus*. Some hynobiids and salamandrids that live in cold mountain streams also have reduced lungs, as do species of *Rhyacotriton* (see chapter 1). All of these species must be mainly skin breathers. Even ambystomatid salamanders, which have well-developed lungs, can remain submerged for long periods of time at cold temperatures when O_2 content of the water is high (Whitford and Massey 1970), but come to the surface more often as temperatures rise (Whitford and Sherman 1968).

Some paedomorphic salamanders retain gills throughout adult life and are primarily water-breathers. For example, adult *Necturus* generally surface to breathe only if the O_2 content of the water is very low, even though they have fully functional lungs (Lenfant and Johansen 1967; Shield and Bentley 1973; Guimond and Hutchison 1972, 1976; Ultsch and Duke 1990). The gills account for more than half of all O_2 uptake and become increasingly important as water temperature increases (Guimond and Hutchison 1972, 1976). At low O_2 levels, the lungs can be used as supplementary respiratory organs, enabling these salamanders to survive for up to a week in severely hypoxic water, although with considerably reduced metabolic rates (Ultsch and Duke 1990). When branchial respiration is experimentally blocked, *Necturus* can survive when O_2 content of the water is high, but total gas exchange is significantly reduced (Shield and Bentley 1973).

Sirenid salamanders also retain gills as adults, but they are somewhat vestigial and generally account for less than 5% of total O_2 uptake. The lungs are much more important than in *Necturus* and are the major sites of O_2 uptake at warm temperatures (Guimond and Hutchison 1973b, 1976) or low O_2 levels (Duke and Ultsch 1990). These salamanders often live in swampy, oxygen-poor habitats and must rely on aerial respiration to survive under these conditions. Consequently, sirens are essentially air-breathing aquatic salamanders with some capacity for respiration through the skin and gills, in contrast to *Cryptobranchus* and *Necturus,* which are primarily water-breathers that sometimes breathe air.

Amphiumas are even more dependent on their lungs for respiration. These strictly aquatic salamanders lack gills and often live in oxygen-poor habitats. They have the most complex lungs of any of the large aquatic salamanders and cannot survive very low O_2 levels without breathing air. The lungs become increasingly important as water temperature increases, accounting for only 8% of total O_2 uptake at 5° C, but more than 50% at 25° C (Guimond and Hutchison 1974, 1976). They also have a lower capacity for O_2 uptake across the skin than the other "giant" salamanders. Duke and Ultsch (1990) interpreted this as an adaptation for living in hypoxic water or in burrows, where O_2 levels are so low that they might actually lose O_2 across the skin to the surrounding water.

Most aquatic amphibians do not live in swampy, oxygen-poor habitats like those inhabited by amphiumas and sirens. Most species are bimodal breathers, using the lungs to breathe air and the skin for gas exchange with the water. Partitioning of gas exchange in these species generally is measured by placing the animal in a water-filled chamber with access to air at the top. The water is covered with a layer of oil to minimize diffusion of gases between the aerial and aquatic portions of the chamber (Whitford and Sherman 1968; Guimond and Hutchison 1973b, 1974, 1976; Ultsch 1973b, 1974, 1976; Emilio and Shelton 1974; Gottlieb and Jackson 1976; Wakeman and Ultsch 1976; MacKenzie and Jackson 1978; Burggren and Moalli 1984). Relatively few species have been studied in detail, but variation among species is considerable. In general, salamanders tend to more be dependent on aquatic O_2 uptake through the skin than are anurans (see Feder and Burggren 1985a, for summary table). Even a fully aquatic frog such as *Xenopus* takes up about 75% of its O_2 via the lungs at temperatures of 20°–25° C (Emilio and Shelton 1974, 1980). These frogs have well-developed lungs that serve as major reservoirs for O_2 during prolonged voluntary dives (Boutilier and Shelton 1986b). Measurements of O_2 consumption in the aquatic caecilian *Typhlonectes natans* revealed that about 55% of O_2 consumed by resting animals is taken up through the lungs, with about 45% being taken up through the skin (Smits and Flanagan 1994). In bimodal breathers, dependence on lungs for O_2 uptake generally increases with increasing temperature or activity and decreasing O_2 levels, as in amphiumas. In *Typhlonectes* active animals increase O_2 consumption by 13 times over resting levels, and about 96% is taken up through the lungs (fig. 4.5).

Respiratory Surface Area and Capillary Density

A number of workers have made extensive studies of the surface area, capillary density, and thickness of various respira-

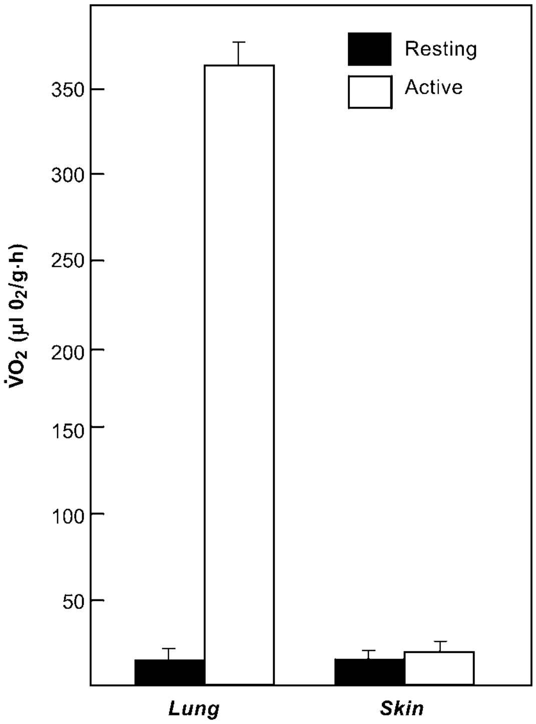

Fig. 4.5. Comparison of cutaneous and pulmonary oxygen uptake by the aquatic caecilian *Typhlonectes natans* at rest and after exercise. After Smits and Flanagin (1994).

tory exchange surfaces in amphibians and have related these morphological variables to the relative importance of each organ in gas exchange (J. Czopek 1955a, b, 1957, 1959a, b, c, 1961, 1962, 1965; G. Czopek and J. Czopek 1955; Szarski 1955, 1964; Strawinski 1956; G. Czopek, J. Czopek, and Szarski 1962; Andrzejewski et al. 1962; Bieniak and Watka 1962; Whitford and Hutchison 1967; Hutchison, Whitford, and Kohl 1968; Ultsch 1973b, 1974). In many of the early studies, data were analyzed as ratios of respiratory surface area or capillary length to body mass, a procedure that can yield misleading interpretations (Packard and Boardman 1986). Therefore, I present the data as allometric regressions. Conclusions drawn from these studies must be treated with some caution because, in many cases, morphological measurements are based on examinations of single specimens of each species. Exceptions are a few studies that examined changes in total respiratory surface area during ontogeny (e.g., Strawinski 1956; Andrzejewski et al. 1962; Ultsch 1973b; Talbot and Feder 1992). There have been few attempts to study intraspecific variation in features such as capillary density or skin thickness, and there has not been a thorough statistical analysis of how morphological features differ among species.

The elongate body form of salamanders often is assumed to favor cutaneous gas exchange more than in anurans because of a more advantageous surface/volume ratio (e.g., Feder 1983b; Duellman and Trueb 1986). However, this assumption is somewhat misleading because anurans generally have much longer legs than salamanders and therefore have considerable skin surface area on the legs and feet that tends to compensate for a reduced surface/volume ratio of the trunk region alone. Data from J. Czopek (1965), Whitford and Hutchison (1967), and Hutchison, Whitford, and Kohl (1968) yield a similar scaling of surface area with body mass in salamanders and anurans (fig. 4.6), with an exponent of about 0.67. There is no clear difference in the intercepts of these regressions, indicating that anurans and salamanders of similar body mass have similar surface areas. A reanalysis of these data by Talbot and Feder (1992) suggests that J. Czopek's (1965) data actually underestimate total skin surface area in anurans because he apparently did not include foot webbing in his measurements.

Some amphibians that are heavily dependent on cutaneous respiration have evolved morphological adaptations for greatly increasing the surface area of the skin relative to their body mass. The most familiar examples are the extremely loose and wrinkled skin of cryptobranchid salamanders and South American aquatic frogs of the genus *Telmatobius* (fig. 4.7). In the African "hairy" frog, *Trichobatrachus robustus* (fig. 1.12 D in chapter 1), males develop extensive

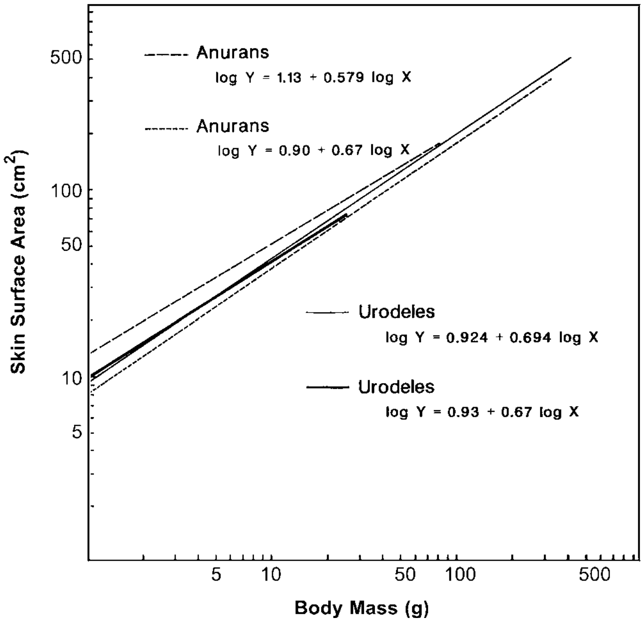

Fig. 4.6. Scaling of skin surface area with body mass for anurans and urodeles. Dashed lines show regressions for anurans, plotted from data in Hutchison, Whitford, and Kohl (1968; top equation) and Czopek (1965; bottom equation). Solid lines show regressions for urodeles, plotted from data in Whitford and Hutchison (1967; top equation) and Czopek (1965; bottom equation). The slopes and intercepts of the regressions for anurans and urodeles are not significantly different.

dermal papillae on the skin, presumably to compensate for increased metabolic demands (Noble 1925).

Skin surface area gives only a rough estimate of an animal's capacity for cutaneous gas exchange because species differ in skin thickness or capillary density (Feder and Burggren 1985a). However, neither variable is closely correlated with dependence on cutaneous respiration. The skin is not consistently thinner nor supplied with more capillaries in plethodontid salamanders, which depend mainly on cutaneous respiration, than in other salamanders or anurans of similar size (Foxon 1964; J. Czopek 1965; Feder 1983b; Feder and Burggren 1985a). Total skin capillary length actually appears to be somewhat higher in anurans than in salamanders of similar mass, particularly in larger species (fig. 4.8). The difference would be even greater if the data were corrected for additional capillaries in the foot webbing (Talbot and Feder 1992). On the other hand, terrestrial anurans often have the most highly vascularized skin on the ventral surface, where it plays little role in gas exchange when the animal is sitting on the ground (J. Czopek 1965; Feder and Burggren 1985a). Such vascularized areas probably are related more to water uptake than to respiration (see chapter 2).

If we consider the total length of capillaries in all respiratory organs (lungs, skin, and oral cavities), anurans consistently have much higher values than salamanders of similar size (fig. 4.9). This is due mainly to the greater development of lungs in anurans, which usually have complex subdivided lungs with many alveoli, compared to the simple saclike lungs of most salamanders (Okada et al. 1962; J. Czopek 1965; Hughes 1970; Smith and Rapson 1977; Goniakowska-Witalinska 1980a, b, 1985, 1986; Burggren 1989; Maina 1989); exceptions to this trend are *Salamandra, Siren,* and *Amphiuma,* all of which have relatively complex lungs (Wilnow 1964, 1968; Guimond and Hutchison 1976; Goniakowska-Witalinska 1978).

Functional aspects of lung structure have not been studied in detail in caecilians, but most species appear to have well-developed, extensively subdivided lungs that provide a large surface area for gas exchange (Jared et al. 1999; Kc et al. 2000). As in many elongate vertebrates, one lung usually is considerably longer than the other. Usually the right lung is longer and the left lung is vestigial, but the opposite condition is seen in some caecilians (Wilkinson and Nussbaum 1999). Several caecilians exhibit unusual modifications of the respiratory system. The aquatic caecilian *Typhlonectes natans* not only has a long, well-developed right lung, but also a separate tracheal lung between the anterior trachea and the heart that provides additional surface area for gas exchange (Kc et al. 2000). In a related species, *T. compres-*

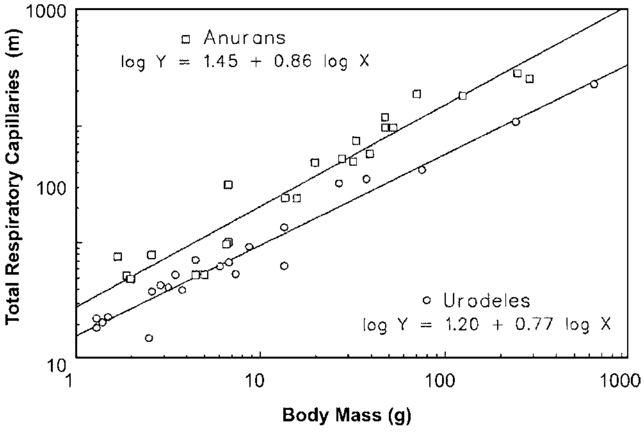

Fig. 4.9. Total respiratory capillary length as a function of body mass in anurans and urodeles. Plotted from data in J. Czopek (1965).

sicauda, up to 94% of oxygen uptake is through the lungs, although the skin becomes more important when the animal is completely submerged (Sawaya 1947; Gonçalves and Sawaya 1978).

Another typhlonectid, *Potomotyphlus,* is unique in having the left lung modified into a hydrostatic organ. Pulmonary respiration appears to be reduced in this aquatic caecilian, and the pulmonary circulation is reduced (Wilkinson and Nussbaum 1997). The most unusual modification is found in a strange typhlonectid related to *Potomotyphlus, Atretochoana eiselti.* This caecilian is completely lungless and is the largest known lungless tetrapod (Nussbaum and Wilkinson 1995; Wilkinson and Nussbaum 1997, 1999; Wilkinson et al. 1998). This species is assumed to be aquatic, based on morphological features, such as a tail fin, but the biology of living animals, including their respiratory physiology, is completely unknown. Wilkinson and Nussbaum (1999) hypothesized that both *Potomotyphlus* and *Atretochoana* have abandoned the habit of most typhlonectids of living in mud burrows, which tend to become hypoxic. Their reliance on cutaneous respiration suggests that they probably live in well-oxygenated water.

The lung membranes present a thinner barrier to gas exchange than the skin, so diffusion capacity of the lungs typically is much greater (Withers and Hillman 1988). In general, anurans have somewhat thinner membranes in the lungs than salamanders (Meban 1980), but neither the thinness of the gas-exchange membranes nor capillary density approach those in mammalian lungs (Weibel 1972; Burggren 1989). For most anurans, pulmonary capillaries account for more than half of all respiratory capillaries (fig. 4.10 B). This also is true for some terrestrial salamanders with complex lungs, such as *Salamandra salamandra;* but in other species, cutaneous capillaries predominate (fig. 4.10 A). The skin of plethodontids contains more than 90% of all respiratory capillaries, with the buccopharyngeal region contributing the rest. In most amphibians, capillaries in the lining of the mouth are less than 3% of the total, suggesting that buccopharyngeal respiration is of relatively trivial importance in species other than plethodontids (Foxon 1964; J. Czopek 1965; Duellman and Trueb 1986). Measurements of capillary length are not available for caecilians, but some species appear to have relatively complex, highly subdivided lungs like those of anurans and *Salamandra* (M. Wake 1974; Smits and Flanagin 1994).

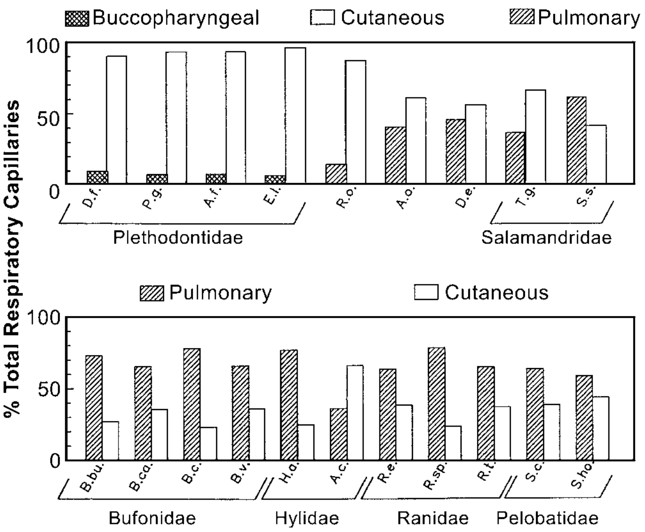

Fig. 4.10. Percentage of total respiratory capillaries found in the skin, lungs, and buccopharyngeal regions in (A) selected terrestrial urodeles and (B) anurans. Most anurans have more capillaries in the lungs than in the skin, whereas most urodeles have more capillaries in the skin. Species abbreviations: *D.f. = Desmognathus fuscus; P.g. = Plethodon glutinosus; A.f. = Aneides flavipunctatus; E.l. = Eurycea longicauda; R.o. = Rhyacotriton olympicus; A.o. = Ambystoma opacum; D.e. = Dicamptodon ensatus; T.g. = Taricha granulosa; S.s. = Salamandra salamandra; B.bu. = Bufo bufo; B.ca. = B. calamita; B.c. = B. cognatus; B.v. = B. viridis; H.a. = Hyla arborea; A.c. = Acris crepitans; R.e. = Rana esculenta; R.sp. = R. sphenocephala; R.t. = R. temporaria; S.c. = Scaphiopus couchii; S.ho. = S. holbrookii.* Plotted from data in J. Czopek (1965).

Ventilation of Respiratory Organs

The surface area, thickness, and capillary density of the various respiratory organs provide a rough estimate of their relative importance in gas exchange, but this also will be affected by ventilation of the respiratory organ with air or water. All air-breathing amphibians employ a positive-pressure buccal pump to force air into the lungs, a mode of ventilation inherited from their sarcopterygian ancestors (Brainerd, Ditelberg, and Bramble 1993; C. B. Jørgensen 2000). Amphibians have a mechanism of buccal pumping that minimizes mixing of inspired and expired air in the buccal cavity (Brainerd, Ditelberg, and Bramble 1993; Brainerd 1994, 1998; Brainerd and Monroy 1998; Kc et al. 2000). Initially, the buccal cavity is partially filled with inspired air, but full expansion of the buccal cavity does not occur until expiration of air from the lungs is complete. Ventilation is accomplished by raising and lowering the floor of the mouth while opening and closing the nares and glottis (De Jongh and Gans 1969). In terrestrial species, a series of shallow ventilatory movements fills the buccal cavity, punctuated by deeper ventilatory movements that fill the lungs (Whitford and Hutchison 1965b; De Jongh and Gans 1969; West and Jones 1975; MacIntyre and Toews 1976). In contrast, fully aquatic species such as *Xenopus, Amphiuma,* and *Siren* ventilate the lungs with each buccal movement, and only a few ventilations are required to fully inflate the lungs. In these species, air is expelled from the lungs as the animal surfaces, thereby reducing the amount of dead space in the lungs and increasing the efficiency of gas exchange (Toews 1971; Toews and McRae 1974; Brett and Shelton 1979; K. Martin and Hutchison 1979; Boutilier 1984, 1988a, 1989). This pattern of rapid emptying and refilling of the lungs enables these animals to spend relatively little time exposed at the surface, where they are vulnerable to predators such as wading birds (Baird 1983). In the aquatic caecilian *Typhlonectes natans,* the pattern of breathing is somewhat different from that seen in other amphibians. Expiration is followed by a series of inspiratory oscillations (M. Gardner, Smits, and Smatresk 2000; Kc et al. 2000). The frequency of breathing episodes and ventilation rates in bimodal breathers are governed mainly by depletion of the body's O_2 stores (Boutilier 1984, 1988a, 1989), but are influenced by other variables such as temperature, water depth, and O_2 and CO_2 content of the water (Shannon and Kramer 1988; Smatresk and Smits 1991; Smatresk 1994; M. Gardner, Smits, and Smatresk 2000).

The three major groups of amphibians differ in the way in which air is expelled from the lungs. In salamanders, the hypaxial body musculature contracts to push air out of the lungs (Brainerd, Ditelberg, and Bramble 1993; Brainerd 1994, 1998; Brainerd and Monroy 1998). Salamanders have three layers of hypaxial muscles, the transverse abdominis, external oblique, and internal oblique, which are closely associated with the rectus abdominis muscle. In *Siren lacertina* and *Necturus maculosus,* only the transverse abdominis muscle is active during expiration. In larval tiger salamanders (*Ambystoma tigrinum*), the transverse abdominis is most active, but the other hypaxial muscles show low levels of activity during expiration. In frogs, the hypaxial muscles have been reduced to two layers. These generally are called the internal and external oblique muscles, but their homologies with salamander muscles are not clear. Frogs do not have active expiration during normal breathing, although the hypaxial muscles are used to force air out of the lungs when males are calling (see chapters 5 and 7). Instead, expiration is passive, relying on elastic recoil of the inflated body wall (Brainerd, Ditelberg, and Bramble 1993). Caecilians also employ passive exhalation (Bennett, Summers, and Brainerd 1999; Kc et al. 2000). These animals are unusual in that they maintain very high pressure in the lungs and peritoneal cavity, apparently to keep the body rigid to aid in locomotion. They also employ an unusually large number of buccal pumping cycles when filling the lungs with air, probably to maintain this high pressure (Carrier and Wake 1995; Kc et al. 2000). Brainerd, Ditelberg, and Bramble (1993) suggested that active exhalation using the trunk musculature is an ancestral trait for all amphibians that has been lost in frogs and caecilians because of their highly derived modes of locomotion.

Aquatic amphibians that live in still water face a special problem in using the skin as a respiratory organ. At low flow rates, the water around the body of the animal tends to form a hypoxic boundary layer that can be a major limitation on gas exchange through the skin (Feder and Burggren 1985a, b; Burggren and Feder 1986; Feder and Pinder 1988). These boundary layers typically are only 1–3 mm thick, but can increase resistance to O_2 diffusion up to eight times, even in water with normal O_2 content (Feder and Booth 1992; Booth 1994). Even amphibians associated with running water, such as the aquatic plethodontid salamander *Desmognathus quadramaculatus,* often are found in microhabitats in which hypoxic boundary layers are the major impediment to O_2 uptake (Booth and Feder 1991). Relatively small movements by the animals can break up hypoxic boundary layers around the skin (Pinder and Feder 1990). Even frogs hibernating under water move periodically (Emery, Berst, and Kodaira 1972), perhaps to break up boundary layers around the skin. The effects of skin ventilation on gas exchange in adult bullfrogs (*Rana catesbeiana*) has been simulated by placing the frogs in stirred and unstirred water, with only the nares exposed to air. Cutaneous O_2 uptake declined significantly in water that was not stirred (Burggren and Feder 1986). Other amphibians have been shown to rise to the surface to breathe more frequently in unstirred than in stirred water (Feder and Booth 1992; Booth 1994).

Some highly aquatic amphibians engage in more pronounced movements to ventilate the skin. For example, hellbenders (*Cryptobranchus alleganiensis*) rock the body from side to side, and these rocking movements increase as the O_2 content of the water decreases (Boutilier and Toews 1981b; Harlan and Wilkinson 1981). If the animals are prevented from rocking under hypoxic conditions, O_2 uptake decreases, but artificial ventilation of the skin restores PO_2 to normal levels (Harlan and Wilkinson 1981). The fully aquatic leptodactylid frog *Telmatobius culeus* ventilates its skin by waving the very large flaps of skin in the water (Hutchison, Haines, and Engbretson 1976). In some neotenic salamanders, active movements of the external gills presumably serve to break up any boundary layer formed around the gills in still water. For example, gill movements by *Necturus* are more frequent at high temperatures or when the animal is active (Guimond and Hutchison 1972, 1976), but rates of ventilatory movements and their effect on O_2 uptake have not been quantified.

Perfusion of Respiratory Organs with Blood

Many models of cutaneous gas exchange in amphibians have assumed that exchange is diffusion limited and not affected by changes in blood flow to respiratory exchangers (e.g., Gatz, Crawford, and Piiper 1975; Piiper, Gatz, and Crawford 1976; Piiper 1988). However, for some amphibians, changes in perfusion of respiratory capillaries can affect rates of gas exchange (Feder and Burggren 1985a, b; Burggren 1988) and are under active physiological control (for a review, see Malvin 1994). This has been studied mostly in anurans. When adult bullfrogs (*Rana catesbeiana*) were exposed to air, the number of perfused skin capillaries decreased and the rate of CO_2 elimination declined as well; the opposite effect was obtained when the frogs were placed in water (Burggren and Moalli 1984). Poczopko (1957) demonstrated that *Rana esculenta* breathing high levels of CO_2 in air increased perfusion of skin capillaries, while Szarski (1959) showed that large changes in PO_2 or PCO_2 of air in contact with the skin also could affect capillary recruitment. Aquatic hypoxia results in a redistribution of blood from the cutaneous to the pulmonary circulation, while aerial hypoxia has the opposite effect. This has been interpreted as a mechanism to prevent loss of O_2 to the hypoxic medium and enhance gas exchange where it is most effective (Boutilier, Glass, and Heisler 1986). Work by Gary Malvin and his colleagues showed that both PO_2 and PCO_2 at the skin surface can affect cutaneous blood flow and gas exchange. Blood flow increases when skin surface PO_2 increases, while it decreases when PCO_2 increases. An even greater effect is produced by changes in lung ventilation. When frogs are breathing air through the lungs, blood flow to the skin decreases. Most of this change occurs in the skin on the ventral surface and the legs, but not the dorsal surface (Malvin 1994; Malvin and Hlastala 1986a, b, 1989).

Several unusual features of the circulatory system of frogs, some of which are not present in most salamanders, facilitate the redistribution of blood flow between the pulmonary and cutaneous circulation. Although amphibians have only a single ventricle, oxygenated and deoxygenated blood remain largely separated in the ventricles of anurans and *Amphiuma.* This continues as the blood leaves the ventricle and enters a large vessel, the *conus arteriosus.* Here a spiral valve directs most of the deoxygenated blood from the right atrium into the pulmocutaneous circuit, while oxygenated blood coming from the lungs via the left atrium is selectively distributed to the systemic circulation (fig. 4.11). A similar separation of pulmonary and systemic blood occurs in the caecilian *Typhlonectes compressicauda,* but the anatomy of the heart and associated vessels is somewhat different (Toews and Macintyre 1978). Because amphibians are periodic breathers (Shelton and Boutilier 1982), resistance to blood flow in the lungs changes as a function of breathing activity. When the lungs are inflated, resistance is low and more blood is diverted to the pulmonary circuit; conversely, when pulmonary resistance is high, blood is shunted to the systemic arteries. Hence, perfusion of the lungs is matched to ventilation, thereby increasing the efficiency of gas exchange (Johansen 1963; Johansen and Ditadi 1966; Johansen, Lenfant, and Hanson 1970; Shelton 1970, 1976, 1985; Emilio and Shelton 1974; Johansen 1985; Boutilier, Stiffler, and Toews 1992).

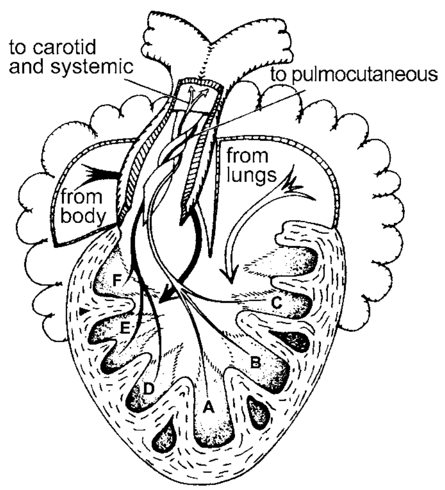

Fig. 4.11. Diagram of the heart of a frog (*Xenopus*) and associated blood vessels, showing partial separation of blood flow through the ventricle. Black arrows show the route of deoxygenated blood. White arrows show the route of oxygenated blood. After Shelton (1976).

Perfusion of skin capillaries in anurans is affected by the dual origin of the cutaneous circulation. While some skin capillaries are supplied by the general systemic circulation that carries oxygenated blood, others are supplied by a cutaneous branch of the pulmocutaenous artery, which receives mainly deoxygenated blood from the heart (fig. 4.12). Capillaries supplied by the pulmocutaneous artery will have a more favorable PO_2 gradient for cutaneous O_2 uptake than those supplied by the systemic arteries because of lower blood PO_2. Increased resistance to blood flow through the lungs, coupled with decreased peripheral resistance, will channel more blood through the cutaneous branch of the pulmocutaneous artery. Blood flow through each circuit appears to be regulated in part by the action of muscular sphincters on the two branches of the pulmocutaneous artery (fig. 4.12). These in turn are regulated by mechanoreceptors sensitive to changes in lung inflation and chemoreceptors sensitive to levels of CO_2 and O_2 (for reviews, see Feder and Burggren 1985a, b; Malvin and Boutilier 1985; Burggren 1988; Malvin 1988, 1994; Boutilier, Stiffler, and Toews 1992; other studies include Shelton 1970; Emilio and Shelton 1972; De Saint-Aubain and Wingstrand 1979; Moalli et al. 1980; De Saint-Aubain 1982; West and Burggren 1984; Boutilier, Glass, and Heisler 1986).

Some amphibians have an additional mechanism to regulate the oxygen-carrying capacity of the blood flowing to the tissues, including the skin. Experiments with European newts (*Triturus carnifex*) showed that, at low temperatures, newts exposed to well-oxygenated water accumulate red blood cells in the spleen. These are released into the circulation when the animals are exposed to lower oxygen levels, thereby increasing the concentration of oxygen-carrying

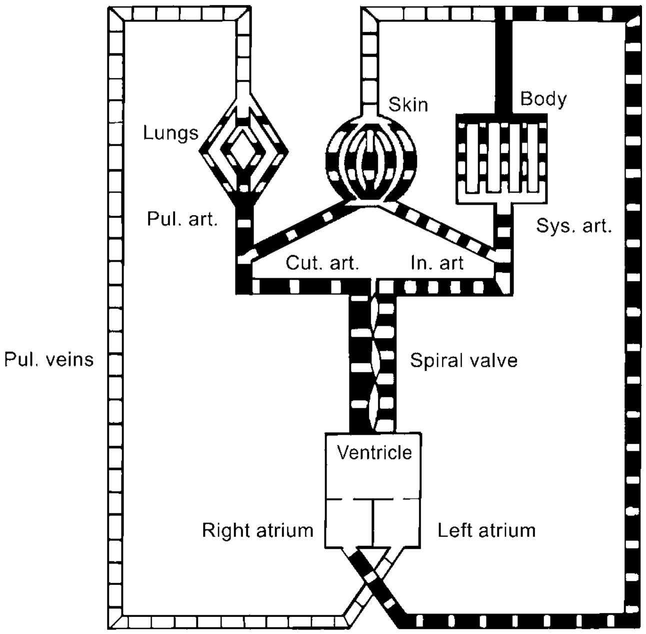

Fig. 4.12. Diagram of blood supply to skin and other parts of the body in a frog. Black indicates the route of deoxygenated blood. White indicates the route of oxygenated blood. After Feder and Burggren (1985a).

cells in the blood (Frangioni and Borgioli 1989, 1991a, b, 1993b). A similar compensatory mechanism has been described in *Rana esculenta*, but in this case, red blood cells accumulate in the liver rather than the spleen (Frangioni and Borgioli 1993a, 1994). Storage of red blood cells does not occur at warm temperatures, presumably because higher oxygen demands at warm temperatures require all available red blood cells to be in circulation.

Respiratory Properties of the Blood

The availability of O_2 to support tissue metabolism is mediated not only by structural features of the respiratory and circulatory systems, but also by oxygen-combining properties of the blood. Many investigators have attempted to correlate respiratory properties of amphibian blood with variation in habitat, O_2 availability, mode of respiration, or developmental stage (e.g., Redfield 1933; McCutcheon 1936; McCutcheon and Hall 1937; Lenfant and Johansen 1967; Coates and Metcalfe 1971; Johansen and Lenfant 1972; S. Wood et al. 1975; Hutchison, Haines, and Engbretson 1976; Johansen and Weber 1976; Boutilier and Toews, 1981a; Boutilier, Stiffler, and Toews 1992). The most common approach is to compare O_2 dissociation curves and O_2 affinity of the blood, as measured by P_{50} (the O_2 tension at which the blood is 50% saturated). In general, air-breathing species are thought to have relatively low blood O_2 affinity (i.e., the O_2 dissociation curve is shifted to the right) compared to higher O_2 affinity in the blood of water-breathers, while aquatic species in oxygen-poor environments have higher O_2 affinity than those in oxygen-rich environments.

A much-cited example is Johansen and Lenfant's (1972) comparison of *Necturus, Amphiuma,* and *Rana,* which exhibit a shift toward lower O_2 affinity as dependence on air breathing with lungs increases (fig. 4.13). This would be advantageous because O_2 is readily available to air-breathers, and lower O_2 affinity would facilitate unloading of O_2 in the tissues. A shift to lower O_2 affinity also has been described in the transition from water to air-breathing during metamorphosis and is generally assumed to have the same adaptive function (McCutcheon 1936; McCutcheon and Hall 1937; Riggs 1951; Foxon 1964; Hamada et al. 1966; Gahlenbeck and Bartels 1970; S. Wood 1971; Maclean and Jurd 1972; Hattingh and Bartels 1973; Watt and Riggs 1975; Broyles 1981; Pinder and Burggren 1983; Jurd 1985; Burggren and Just 1992). There is a similar shift in blood O_2 affinity in viviparous species at birth (Toews and Macintyre 1977; Garlick et al. 1978). On the other hand, prolonged exposure of adult frogs (*Rana catesbeiana*) to hypoxic water has the opposite effect, resulting in increased blood O_2 affinity, blood O_2 capacity, and hemoglobin concentration (Pinder and Burggren 1983).

While adaptive explanations relating O_2 affinity of the blood to O_2 availability in the environment are appealing, caution is required in interpreting these patterns (R. Wells 1990). As pointed out by S. Wood and Lenfant (1987), mea-

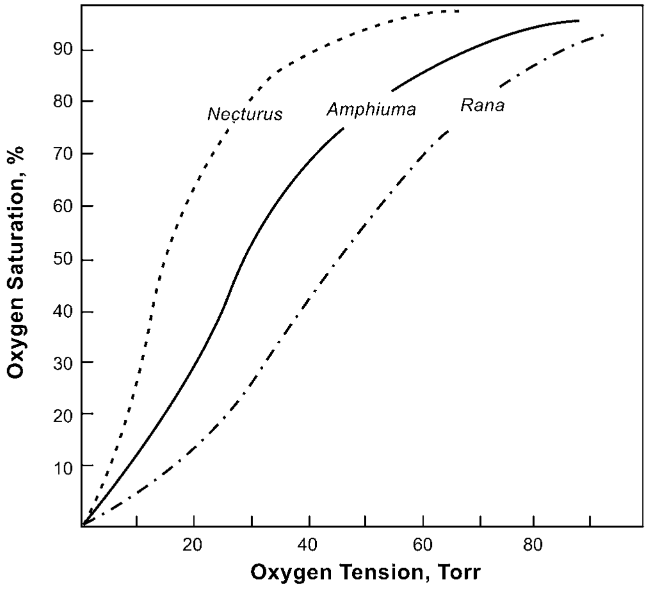

Fig. 4.13. Oxygen dissociation curves of blood of *Necturus, Amphiuma,* and *Rana* measured at pH 7.6. The curves show percent saturation of the blood with oxygen at different levels of oxygen availability. After Johansen and Lenfant (1972).

surements of PCO_2, arterial and venous PO_2, O_2 capacity, and blood pH in intact, unrestrained animals are required to properly interpret the significance of the O_2 dissociation curve for O_2 delivery to the tissues, because other components of the O_2 transport system compensate for changes in O_2 affinity. Very few such measurements are available, so broad comparisons among species living in different habitats remain largely speculative. Nevertheless, it seems likely that the unusually high O_2 affinity of blood in a fossorial caecilian, *Boulengerula taitanus* (S. Wood et al. 1975), and a high-altitude aquatic frog, *Telmatobius culeus* (Hutchison, Haines, and Engbretson 1976), are adaptations to reduced environmental PO_2. Actual levels of O_2 in the natural habitat have been measured only for the latter species, however. In that case, the lakes in which the frog lives are saturated with O_2, but PO_2 of the water is relatively low because of the high altitude (nearly 4,000 m).

Another problem with much of the literature on O_2 affinity in amphibians is that adaptive explanations sometimes have been based on studies of separated hemoglobin instead of whole blood (e.g., Riggs 1951; Hamada et al. 1966; Taketa and Nickerson 1973; Watt and Riggs 1975; Meirelles et al. 1979; Condo et al. 1981, 1983, 1989; Brunori et al. 1985). Because other components of blood can affect its O_2 affinity, functional interpretations based solely on isolated hemoglobin probably are not justified (S. Wood and Lenfant 1987). Much of the work in this field has been done by biochemists concerned more with the structure of the hemoglobin molecule than with physiological implications for the whole animal. This is particularly true of the extensive work on changes in hemoglobin at metamorphosis, where the main focus has been on mechanisms controlling hemoglobin structure and synthesis (for reviews, see B. Sullivan, 1974; Broyles 1981; Jurd 1985).

Interspecific comparisons of blood O_2 affinity are complicated by variation in sensitivity to both temperature and pH. Often such comparisons are made at a single temperature and pH that does not always reflect conditions normally encountered by animals in the field. Temperature can affect O_2 affinity of blood directly (O_2 affinity decreases with increasing temperature) or indirectly through its effect on pH (pH declines with increasing temperature). In some amphibians, there is a relatively small direct effect of temperature on O_2 affinity (Kirberger 1953; Straub 1957; Gahlenbeck and Bartels 1968; Jokumsen and Weber 1980; S. Wood 1980; S. Wood and Lenfant 1987). This would be particularly advantageous in species that regularly experience large daily fluctuations in temperature, such as the African tree frog *Chiromantis petersi,* which often is exposed to hot sun during the day and experiences a 15° C temperature change in a few hours (Johansen, Abe, and Weber 1980). Some species exhibit long-term temperature acclimation that reduces the effect of seasonal temperature change on O_2 affinity (Kirberger 1953; Straub 1957; Gahlenbeck and Bartels 1968; S. Wood 1980).

Many amphibians, particularly those in aquatic habitats, are subjected to daily fluctuations in environmental pH, in addition to changes in blood pH resulting from metabolism. Consequently, typical pH levels experienced by animals in the field vary among species and will affect O_2 affinity of the blood. Interspecific comparisons made at only a single pH, like that of Johansen and Lenfant (fig. 4.15), do not take into account the range of conditions experienced by animals in the field. In addition, many early studies of amphibian blood and even some more recent ones are flawed because they report O_2 dissociation curves measured at pH 7.4 (e.g., McCutcheon 1936; McCutcheon and Hall 1937; F. Hall 1966; Lenfant and Johansen 1967; Gahlenbeck and Bartels 1968, 1970), a level that is too low for amphibians at ecologically realistic temperatures; a pH of about 7.8 is more typical for 20° C (S. Wood and Lenfant 1987).

Jokumsen and Weber (1980) reported that O_2 affinity of *Xenopus* blood increased during dormancy when the frogs burrow into the mud of drying ponds. They attributed this to the effect of increased concentrations of urea in the blood (see chapter 2) and suggested that the shift might be advantageous because it would inhibit unloading of O_2 to the tissues, thereby favoring low metabolic rates and conservation of energy. A similar shift was reported earlier by Seymour (1973c) in dormant *Scaphiopus couchii,* but he did not suggest a mechanism to account for the increase in O_2 affinity. His adaptive explanation was somewhat different. He suggested that a high affinity would enhance the storage of O_2 in the blood during dormancy, while reduced affinity during the activity season would facilitate unloading of O_2 to the tissues when demand is highest. Neither hypothesis has been rigorously tested. Human hemoglobin shows a response to urea similar to that of *Xenopus* blood (Jokumsen and Weber 1980), suggesting that the change in O_2 affinity is not a specific adaptation to dormancy in frogs. A more definitive test would be to examine the effect of urea on blood O_2 affinity in anurans that do not undergo periodic dormancy and do not accumulate urea in the blood.

When CO_2 is released into the blood during respiration, the blood is acidified (see the following), and this in turn decreases the O_2 affinity of the blood, a process known as the Bohr Effect. At the level of tissue gas exchange, a moderate Bohr shift can be advantageous because it decreases the tendency for hemoglobin to bind with O_2, thereby facilitating release of O_2 to the tissues. On the other hand, a pronounced Bohr shift also can reduce the tendency for hemoglobin to take up O_2 from the environment and therefore would be disadvantageous under conditions of low O_2 availability. Attempts have been made to relate the magnitude of the

Bohr Effect to environmental conditions. For example, S. Wood et al. (1975) suggested that a relatively small Bohr Effect, coupled with high O_2 affinity in the blood of the caecilian *Boulengerula taitanus,* is an adaptation that facilitates O_2 uptake under hypoxic conditions in burrows. Conversely, Jokumsen and Weber (1980) interpreted the relatively large Bohr Effect in *Xenopus* blood as an adaptation facilitating O_2 delivery to tissues during dives. However, there is not a straightforward correlation between the magnitude of the Bohr Effect and habitat (S. Wood and Lenfant 1987), presumably because a number of other variables affect O_2 delivery to the tissues.

Several investigators have reported "reversed" Bohr Effects in salamanders (i.e., O_2 affinity increases with decreasing pH). This was studied in detail in *Amphiuma means* by Bonaventura et al. (1977), who suggested this might be an adaptation for enhancing O_2 uptake during hibernation. Other investigators have described "reversed" Bohr effects in the hemoglobin of other salamanders and have proposed rather vague adaptive explanations related to O_2 availability in the environment (Morpurgo, Battaglia, and Leggio 1970; Taketa and Nickerson 1973; Condo et al. 1981, 1983, 1989). However, the reversed Bohr Effect in salamanders appears to be a property of isolated hemoglobin, not whole blood, which exhibits a Bohr Effect similar in direction and magnitude to that of anurans (S. Wood and Lenfant 1987; Condo et al. 1989; Boutilier, Stiffler, and Toews 1992). Consequently, adaptive explanations relating "reversed" Bohr effects to environmental variables probably are unwarranted.

Elimination of Carbon Dioxide

Carbon dioxide passes through membranes in the gaseous state, but readily goes into solution in water or plasma, where it dissociates into hydrogen (H^+) and bicarbonate (HCO_3^-) ions. Hence, release of CO_2 into the blood can alter the concentration of H^+ ions (pH), and this in turn can influence many physiological processes, including the changes in O_2 affinity of the blood that were just discussed. Major changes in internal pH can have negative effects on a variety of other physiological processes, and most organisms must maintain pH within a fairly narrow range. Hence, the process of CO_2 elimination is tightly linked with acid-base regulation (Howell 1970; Randall et al. 1981; Toews and Boutilier 1986; Stiffler, Ryan, and Mushkot 1987; Boutilier 1988b).

For terrestrial amphibians, excretion of CO_2 has little effect on the CO_2 content of the surrounding air. Both skin conductance and the magnitude of the PCO_2 gradient across the skin determine the rate of CO_2 loss. Desiccation of the skin reduces conductance to CO_2, again leading to an increase in blood CO_2 concentrations and a decrease in blood pH (Boutilier et al. 1979b). A reduction in CO_2 permeability is most likely to occur in species with special adaptations to retard cutaneous water loss, such as cocoon formation during dry-season dormancy (see chapter 2). In at least one such species, *Pyxicephalus adspersus,* dormant cocooned frogs had reduced blood pH, apparently resulting from increased resistance to gas diffusion (Loveridge and Withers 1981). In the "waterproof" frog, *Hyperolius viridiflavus,* juveniles spend the dry season sitting on exposed, dry plants. The skin becomes highly impermeable to water, and virtually all cutaneous respiratory exchange stops (Geise and Linsenmair 1986). Whether this results in respiratory acidosis has not been determined, nor is it known whether changes in the acid-base balance of dormant frogs have any detrimental physiological effects.

Nearly all amphibians exposed to high CO_2 show an initial increase in plasma PCO_2 and a decrease in blood pH. This respiratory acidosis can remain uncompensated for several hours, but eventually an increase in bicarbonate (HCO_3^-) ions in the blood gradually raises its pH (Toews and Boutilier 1986; Boutilier 1988b). Some species, including *Amphiuma means, Siren lacertina,* and *Xenopus laevis,* show little or no compensation (Heisler et al. 1982; Toews and Boutilier 1986; Boutilier, Glass, and Heisler 1987), while others, such as the aquatic caecilian *Typhlonectes compressicauda,* exhibit very pronounced compensation (Toews and Macintyre 1978). Still others show intermediate responses (Boutilier et al. 1979a, c; Boutilier and Toews 1981b; Toews and Heisler 1982; Stiffler, Tufts, and Toews 1983). Most amphibians exhibit only partial compensation of extracellular pH under conditions of elevated CO_2, independent of the habitat in which they are found (Heisler 1986; Toews and Boutilier 1986; Toews and Stiffler 1990). Intracellular compensation often is much greater, especially in critical tissues such as heart or skeletal muscle, where pH remains largely unchanged even during prolonged exposure to elevated CO_2 (Heisler et al. 1982; Toews and Heisler 1982; Toews and Boutilier 1986; Boutilier, Glass, and Heisler 1987; Boutilier, Stiffler, and Toews 1992). This probably facilitates survival in extreme environments such as swamps, but it appears to be a general feature of amphibians and not a specialized adaptation to such habitats.

Terrestrial air-breathing vertebrates such as reptiles, birds, and mammals regulate internal CO_2 concentrations and pH mainly by increasing lung ventilation rates in response to high arterial PCO_2 (Scheid and Piiper 1986; Shelton, Jones, and Milsom 1986; Tenney and Boggs 1986). In amphibians, most CO_2 is rapidly eliminated through the skin and CO_2 concentrations in the blood are relatively low. Consequently, it is difficult to maintain a concentration gradient between the blood and lungs that will favor pulmonary excretion of CO_2 (Guimond and Hutchison 1976; Shelton, Jones, and Milsom 1986; Toews and Boutilier 1986). Some amphibians increase ventilation rates in response to increased CO_2 in inspired air or in the water (Macintyre and Toews 1976; Toews and Macintyre 1978; Boutilier et al. 1979a; Jackson and Braun 1979; Jones 1982; Boutilier and Shelton 1986b; Smatresk 1994; Gardner, Smits, and Smatresk 2000). In terrestrial anurans with relatively well-developed lungs, and probably in caecilians as well, this provides some active regulation of plasma PCO_2 and pH; but in *Cryptobranchus,* which has poorly developed lungs, increased ventilation has virtually no effect on these variables. At least one species that lives in high CO_2 environments, *Amphiuma tridactylum,* is relatively insensitive to high levels of CO_2 and does not increase ventilation rates (Toews 1971). There is an extensive literature on the neural control of breathing in amphibians, but I will not discuss that in detail here (Wakeman and Ultsch 1976; Boutilier 1988a; Smatresk 1994; Kinkead 1997).

Gas Exchange by Larval Amphibians

Newly hatched anuran and urodele larvae probably are very similar in their respiratory physiology. In both groups, hatchlings have short external gills that are perfused with blood, but not actively ventilated by moving them in the water. The cardiovascular system of newly hatched larvae is relatively poorly developed as well. Because of their very small size, high surface/volume ratios, and low levels of activity, newly hatched larvae probably take up relatively little O_2 through the gills, depending instead on simple diffusion through the body wall (Adolph 1979; Burggren 1984; Burggren and Just 1992; Burggren and Infantino 1994; Orlando and Pinder 1995; Ultsch, Bradford, and Freda 1999). Under normal conditions, diffusion provides adequate oxygen for metabolism. Under hypoxic conditions in warm ponds, however, metabolic rates of larvae in early stages of development decline as a function of decreasing oxygen availability. These young larvae are oxygen conformers and have little capacity to increase rates of respiration to maintain constant metabolic rates in low-oxygen environments (Hastings and Burggren 1995; Orlando and Pinder 1995). Early stage tadpoles also have little capacity to use anaerobic metabolism to compensate for reduced aerobic metabolism in hypoxic conditions, and even advanced-stage tadpoles have limited capacities for anaerobic metabolism (Crowder, Nie, and Ultsch 1998; Ultsch, Bradford, and Freda 1999). Aquatic caecilian larvae hatch at a more advanced stage than do those of anurans and urodeles, with larger, more elaborate gills (Sarasin and Sarasin 1887–1890; M. Wake 1977a; Duellman and Trueb 1986). This suggests a greater reliance on gills for respiration early in development, but nothing is known about partitioning of gas exchange or other aspects of respiratory physiology in these animals.

Once the larvae of anurans and salamanders begin feeding, the respiratory systems of the two groups diverge. Urodeles retain external gills throughout larval life, while the gills of anuran tadpoles become encased in a closed gill chamber. The size and complexity of the gills in urodele larvae reflect the environment in which they live. Larvae from well-aerated mountain streams have small gills and probably take up most of their O_2 through the skin. Larvae from ponds or other poorly oxygenated waters have large, bushy gills with much greater gas-exchange surfaces (see fig. 12.1 in chapter 12). This suggests a substantial role for the gills in aquatic gas exchange, but quantitative data are scarce. Large ambystomatid larvae can survive when branchial respiration is prevented (Shield and Bentley 1973; Heath 1976), but these experiments tell us nothing about the proportion of O_2 normally taken up through the gills in active, unrestrained animals (Burggren 1984).

Nearly all detailed studies of larval respiration and circulation in salamanders have been done on paedomorphic ambystomatids, mainly because their large size makes them suitable for laboratory studies (Gilmore and Figge 1929; Figge 1934, 1936; McIndoe and Smith 1984b; Malvin and Heisler 1988; Malvin 1989). In *Ambystoma tigrinum,* the first three pairs of aortic arches supply blood to the three pairs of gills, while a fourth arch gives rise to the pulmonary artery (fig. 4.14). Because there is some functional separation of systemic and pulmonary blood flow in the heart, the first arch receives the most highly oxygenated blood, and this in turn gives rise to the carotid arteries supplying the brain. The least-oxygenated blood goes to the posterior aortic arches supplying the third pair of gills and the lungs. Studies using radioactive microspheres to trace blood-flow patterns have shown that the major route of flow is not directly from the heart to the lungs, but through the third arch and the *ductus arteriosus* (fig. 4.14). Under hypoxic conditions, the blood can be shunted through the *ductus arteriosus* to the pulmonary artery without passing through the gills. This is advantageous when O_2 in the water is so low that the gills either cannot take up O_2 effectively or even lose O_2 to the water (Malvin and Heisler 1988; Malvin 1989).

There have been very few detailed studies of anuran tadpole gill morphology or function (Malvin 1989). Most studies of the anatomy of the gill region have focused on their role in feeding, not respiration, and comparisons of gill size and complexity have been related to differences in food habits (Wassersug and Hoff 1979; Wassersug 1980; Viertel 1985, 1987; Wassersug and Heyer 1988; Viertel and Richter 1999; see also chapter 12). McIndoe and Smith (1984a, b) described the gill morphology in tadpoles of *Litoria ewingi* and found evidence of shunts between afferent and efferent blood vessels similar to those reported in salamanders. Similar shunts have been described in other species of tadpoles

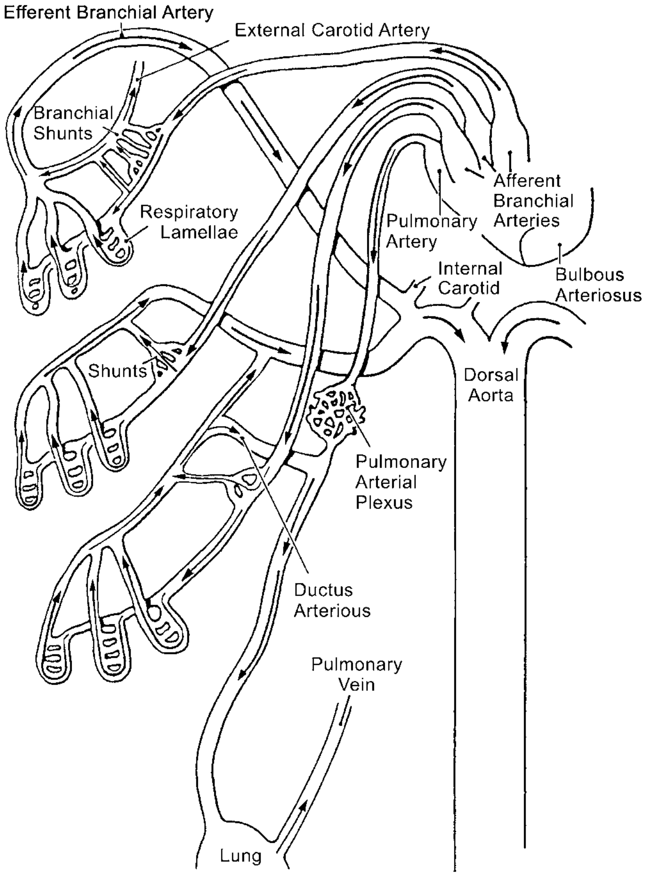

Fig. 4.14. Anatomy of the aortic arches, gills, and lungs of the larva of *Ambystoma tigrinum.* Arrows show routes of blood flow. After Malvin (1989).

as well (de Saint-Aubain 1981), and these presumably enable the tadpoles to alter the pattern of blood flow through the gills (de Saint-Aubain 1985).

There has never been a systematic interspecific comparison of gill size and structure in relation to O_2 availability in different habitats, but there is evidence of both physiological and evolutionary responses to environments with low levels of O_2 (Løvtrop and Pigón 1968). In *Rana catesbeiana* tadpoles, exposure to chronic hypoxia can result in elongation of the gill filaments and thinning of the animal's skin (Burggren and Mwalukoma 1983). However, extreme hypoxic conditions, such as those found in water-filled bromeliads, can favor evolutionary reduction in the size of gill filaments or even a complete loss of functional gills (Noble 1929a). In these environments, aquatic PO_2 can be so low that tadpoles actually lose O_2 to the water, making a large aquatic respiratory surface disadvantageous (Lannoo, Townsend, and Wassersug 1987). Bromeliad-dwelling tadpoles must therefore depend primarily on aerial respiration.

The only quantitative study of respiratory gas exchange in tadpoles has been done on *Rana catesbeiana* (Burggren and West 1982; Burggren and Doyle 1986; Burggren and Just 1992). By cannulating the spiracle of a tadpole placed in an aquatic respirometer, Burggren and West (1982) were able to measure the volume and PO_2 of water passing through the gill chambers. Cutaneous respiration was measured by determining the O_2 content of water before and after it passed through the chamber in which the tadpole was swimming. Aerial respiration of tadpoles with lungs was measured by allowing them access to air in a closed chamber separated from the aquatic chamber by a layer of mineral oil. In tadpoles without lungs, the skin accounted for about 60% of both O_2 uptake and CO_2 release (at 20° C), with the gills accounting for about 40%. The contribution of the skin to both O_2 and CO_2 exchange remained about the same when the lungs first developed, while the gills continued to account for about 40% of CO_2 excretion. However, the gills became less important for O_2 uptake as the tadpoles surfaced more frequently to breathe. In tadpoles undergoing metamorphosis, the lungs became the most important site of O_2 uptake, while CO_2 was eliminated mainly through the skin. This pattern remained largely unchanged in adult frogs (fig. 4.15). A later study of bullfrog tadpoles by Crowder, Nie, and Ultsch (1998) showed that even relatively early

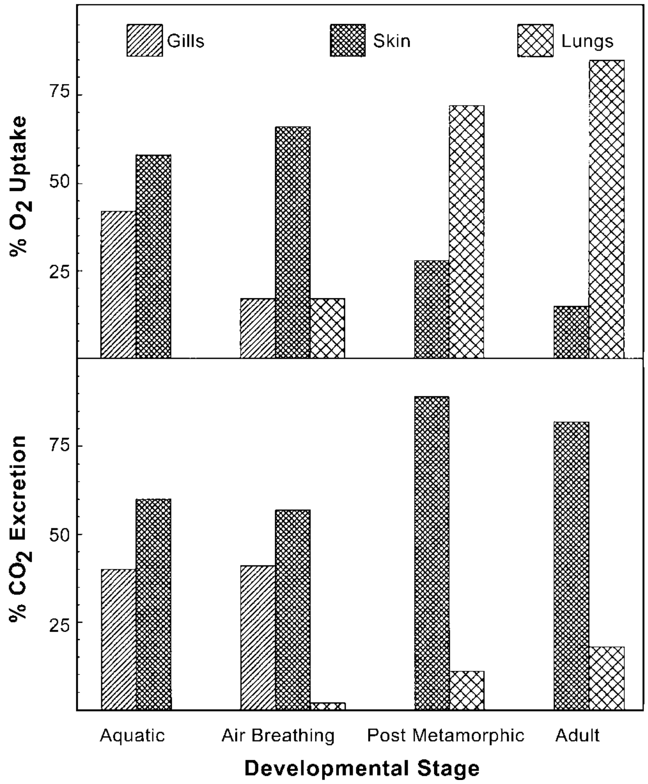

Fig. 4.15. Changes in cutaneous, pulmonary, and branchial respiration in tadpoles of the bullfrog (*Rana catesbeiana*) at different developmental stages. Bars show the proportion of O_2 and CO_2 exchange through the gills, skin, and lungs. Plotted from data in Burggren and West (1982).

stage tadpoles are capable of breathing with their lungs and readily surface to breathe when aquatic PO_2 is low. Additional studies of this species and *R. berlandieri* tadpoles showed that partitioning of gas exchange among lungs, skin, and gills was not greatly affected by temperature over a range from 15° to 33° C, even though total O_2 consumption increased with increasing temperature (Burggren and Feder 1983). This result contrasts with the increased dependence on pulmonary respiration at higher temperatures in adult frogs (fig. 4.4).

Some tadpoles do not develop lungs until just before metamorphosis (Feder 1983a), while others begin breathing air, presumably using the lungs, almost from the first free-swimming stage (Feder 1984; Ultsch, Bradford, and Freda 1999). Tadpoles that live in fast-moving, well-oxygenated streams do not develop lungs until metamorphosis (Nodzenski, Wassersug, and Inger 1989). In contrast, tadpoles that live in oxygen-poor environments, such as bromeliads, develop lungs very early and are obligate air-breathers (Lannoo, Townsend, and Wassersug 1987). In some species, such as toads of the genus *Bufo,* tadpoles metamorphose with many organ systems, including the lungs, relatively undeveloped, probably because selection favors rapid escape from temporary pond-breeding sites.

Tadpoles with lungs breathe air when the O_2 content of the water is low. Air breathing not only provides a more favorable gradient for O_2 uptake, but it also compensates for any O_2 lost to the water through the gills and skin (Wassersug and Seibert 1975; West and Burggren 1982; Feder 1983d; Wassersug and Feder 1983; Feder and Wassersug 1984). Natural bodies of water often become severely hypoxic during warm weather, and the ability to breathe air probably is critical for survival of tadpoles in such habitats (Wong and Booth 1994; Crowder, Nie, and Ultsch 1998). This is particularly true for species such as bullfrog (*Rana catesbeiana*) tadpoles, which tend to stay near the bottom of ponds, where PO_2 is lowest (Nie, Crim, and Ultsch 1999). These tadpoles can survive short periods of submergence in anoxic water by resorting to anaerobic metabolism. They typically die within a few days if deprived of access to air (Crowder, Nie, and Ultsch 1998). Tadpoles also increase rates of air breathing in response to increased activity or disturbance (Feder 1981, 1984). Ranid tadpoles allowed to breathe air have greater stamina during vigorous activity than those restricted to aquatic respiration (Wassersug and Feder 1983). Bufonid tadpoles that do not breathe air appear to be restricted to somewhat more oxygenated water than are ranid tadpoles, although *Bufo* tadpoles actually have a greater capacity to extract O_2 from hypoxic water than do *Rana* tadpoles (Feder 1983a; Noland and Ultsch 1981).

The use of lungs also affects the buoyancy of larvae, which in turn is related to characteristics of the habitat or location of food sources. Presumably the absence of lungs in stream-dwelling tadpoles would be advantageous in reducing buoyancy and decreasing the chances of being swept away in a current. *Bufo* tadpoles forage for food on the bottoms of ponds. Since they lack lungs, they remain negatively buoyant throughout development. Tadpoles of *Rana pipiens,* another bottom-dweller, also are negatively buoyant throughout development. Although they breathe air periodically, they usually release a bubble before swimming to the bottom. Other species of tadpoles, including *Rana sylvatica, Hyla versicolor,* and *Pseudacris triseriata,* are neutrally buoyant and can maintain a position in the water column by adjusting the amount of gas in the lungs, thereby allowing them to feed on particles suspended in the water column (Gee and Waldick 1995). Some tadpoles, such as *Xenopus,* are positively buoyant for much of their development and spend most of their time hovering at the water's surface. They must actually use energy to swim downward against their buoyancy, as they might when trying to escape from surface predators (Van Bergeijk 1959). The risk of predation at the surface probably is a major cost of developing lungs early and relying on breathing air for O2 uptake (Feder 1983c; Burggren and Infantino 1994). Larvae of the salamander *Ambystoma tigrinum* reduce air-breathing during daylight hours, when predation at the surface is most likely to occur. They do, however, increase aerial breathing during the day if zooplankton suspended in the water column are particularly abundant (Lannoo and Bachman 1984b).

Some tadpoles increase rates of aerial respiration when they encounter high concentrations of food particles in the water. Because the ventilation of the gills for respiration also draws in food particles that are trapped in part by the gills themselves (see chapter 12), the gill surfaces can become clogged with food and mucus that reduces the area available for gas exchange. Experiments with *Xenopus* tadpoles, which are midwater suspension feeders, demonstrated that high food concentrations caused tadpoles to decrease gill ventilation and increase aerial breathing (Feder et al. 1984). This in turn promotes faster growth rates because tadpoles are able to feed and take up O_2 simultaneously. When tadpoles were prevented from breathing air in relatively well-oxygenated water, they reduced food intake rates by expelling particles and mucus from the buccopharyngeal region. This presumably increased the surface area available for gas exchange, but lead to a reduction in energy intake and growth rate (Wassersug and Murphy 1987).

Gas Exchange by Amphibian Embryos

Amphibian embryos must take up O_2 as they develop, but differ from larvae or adults in that they are immobile and therefore cannot breathe air directly or make other behavioral adjustments to enhance respiratory gas exchange. Until the mid-1980s, very little was known about the respiration of amphibian embryos in natural environments. Most measurements of O_2 consumption by developing embryos were made on isolated eggs, often removed from their jelly coatings, under ideal laboratory conditions (for references, see Burggren 1984, 1985). These studies tell us very little about gas exchange under field conditions, or the extent to which the availability of O_2 is limiting for embryonic development. More recently, however, a series of studies by Roger Seymour and his colleagues and several other investigators has added considerably to our understanding of respiration by embryos (for reviews, see Seymour and Bradford 1995; Seymour 1999).

O_2 uptake is limited mainly by diffusion of gas into the egg capsule (Seymour 1994, 1999). In a typical amphibian egg, the embryo and its associated yolk reserves are surrounded by a vitelline membrane, which in turn is surrounded by a jelly capsule (fig. 4.16). The rate of O_2 diffusion is limited by the O_2 conductance of the egg capsule and the difference in PO_2 between the embryo and the outside environment. Oxygen conductance is a function of the physical properties of the egg capsule and its thickness. For individual eggs, the jelly capsule is the principal barrier to gas exchange. Many amphibians, however, lay their eggs in compact jelly masses. This means that the amount of O_2 available to an individual embryo also is affected by the size and structure of the egg mass, the distance of individual eggs from the outside of the mass, and the respiration of the surrounding embryos, which tend to deplete O_2 inside the mass (fig. 4.16).

The need for O_2 to diffuse into eggs is a major constraint on the maximum size of amphibian eggs. Interspecific comparisons (Seymour and Bradford 1995) have shown that egg capsule O_2 conductance is well matched to the O_2 consumption of the embryos at the hatching stage for both aquatic and terrestrial egg-layers (fig. 4.17). In general, larger eggs have higher total rates of O_2 consumption, because they have more metabolically active tissue, even though mass-specific rates of O_2 consumption are lower in large eggs. Rates of O_2 diffusion are not normally limiting in early developmental stages for very small eggs, either in air or in water, but larger eggs are more prone to oxygen limitation, especially in water or at high temperatures. Comparisons among species of amphibians have shown that rates of O_2 consumption at the hatching stage are scaled to egg size with a relatively low exponent (0.52), indicating that O_2 becomes increasingly limited at egg volumes of 1 ml or larger (fig. 4.18).

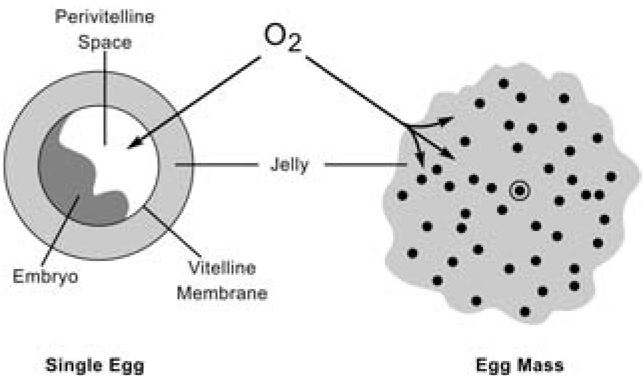

Fig. 4.16. Diagrammatic representation of the pathways of oxygen in individual amphibian eggs (left) and jelly egg masses (right). Oxygen uptake is limited by the rate of diffusion through the jelly surrounding the egg mass and the jelly layers and vitelline membrane of individual eggs. After Seymour and Bradford (1995).

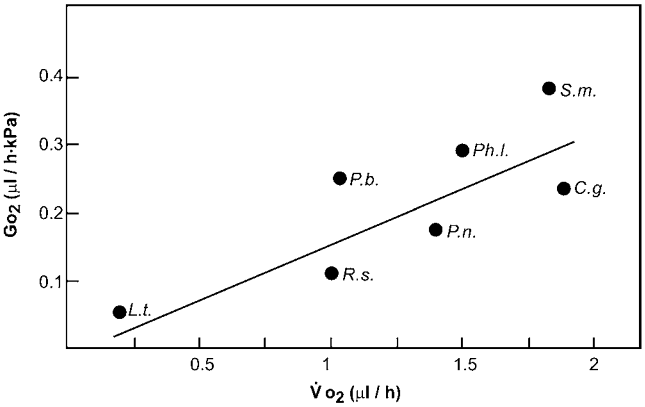

Fig. 4.17. Relationship of between oxygen consumption by hatching-stage embryos (VO$_2$) and oxygen conductance of the egg capsule (GO$_2$) for seven species of anurans. Species names: *C.g.* = *Crinia georgiana; Ph.l.* = *Philoria loveridgei; L.t.* = *Limnodynastes tasmaniensis; P.b.* = *Pseudophryne bibronii; P.n.* = *Phryonbatrachus natalensis; R.s.* = *Rana sylvatica; S.m.* = *Spea multiplicata.* After Seymour and Bradford (1995).

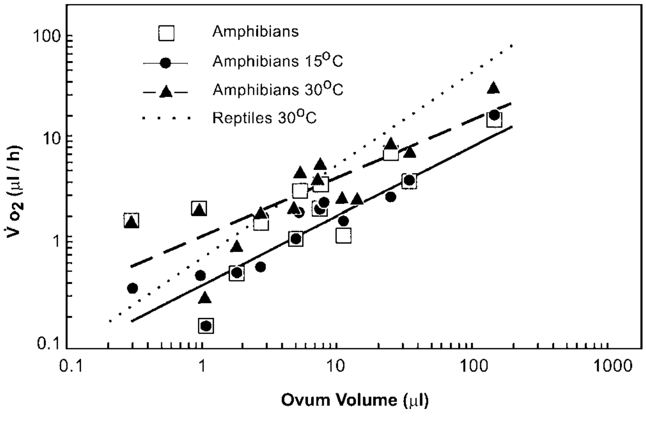

Fig. 4.18. Relationship of oxygen consumption of hatching-stage embryos to ovum volume for 14 species of amphibians. Open squares show uncorrected data for measurements made at different temperatures. Closed symbols show data corrected to 15° C and 30° C. Dotted line shows the same relationship for hatching stage reptiles for 30° C from Vleck and Hoyt (1991). Regression equation for amphibians at 15° C: $\dot{V}O_2 = 0.393V^{0.62}$, where V = ovum volume. Regression for amphibians at 30° C: $\dot{V}O_2 = 1.06V^{0.52}$. After Seymour and Bradford (1995).

The rate at which production of new embryonic tissue proceeds is correlated with mass-specific rates of O_2 consumption, so large eggs not only have metabolic rates lower than expected, but they also have much longer development times (Bradford 1990; Seymour and Bradford 1995; N. Mitchell and Seymour 2000). The size of amphibian eggs is more constrained in aquatic egg-layers than in terrestrial breeders because of the lower O_2 content of water. Egg size also is more constrained in warm, oxygen-poor water than in cold, oxygen-rich water. In both anurans and salamanders, species that breed in warm ponds typically have the smallest eggs and terrestrial breeders have the largest eggs (after correcting for the effect of body size); species breeding in cold streams are intermediate (see chapter 10 for a quantitative analysis of egg size). The metabolic rates of amphibian embryos increase steadily throughout development (H. Brown 1977; Burggren 1984, 1985; Burggren, Infantino, and Townsend 1990; Seymour and Roberts 1991; Seymour, Geiser, and Bradford 1991b; Seymour and Loveridge 1994; Seymour 1995; Seymour and Bradford 1995; Seymour and Roberts 1995; Seymour, Mahony, and Knowles 1995). This means that embryos are most likely to be oxygen-limited during late stages of development.

Gas Exchange in Air

Many amphibians, including most plethodontid salamanders and tropical frogs in a number of different families, lay eggs out of the water in burrows, in hollow logs, under leaf litter, or in other terrestrial sites (see chapter 7). Terrestrial eggs usually are not surrounded by large masses of jelly, but are laid individually or in small clusters. They sometimes are in partial contact with the wall of a burrow or with other eggs, but they usually are relatively well exposed to open air. Oxygen is unlikely to be limiting, even inside a burrow, but the rate of O_2 uptake is limited by the O_2 conductance of the egg capsule, especially for large eggs in late developmental stages that are incubating at high temperatures (Seymour, Geiser, and Bradford 1991a, b).

Eggs laid on moist soil or vegetation take up water from the substrate, or from adults providing parental care (A. Martin and Cooper 1972; Bradford 1984a; Taigen, Pough, and Stewart 1984; Bradford and Seymour 1988b; for further discussion of parental care, see chapter 11). This uptake of water can alter surface-to-volume ratios of the eggs and change diffusion distances between the embryo and the environment. This phenomenon has been studied in terrestrial eggs of an Australian frog, *Pseudophryne bibronii*. Eggs of this species are laid in terrestrial nests that eventually are flooded; the larvae complete development in the water. During dry periods, the eggs can remain in the nest for many weeks before hatching (Bradford and Seymour 1985). Uptake of water in the nest causes the volume of the chamber containing the embryo to increase, while the thickness of the jelly capsule surrounding this chamber decreases (Seymour and Bradford 1987). This increases the O_2 conductance of the egg at a time when O_2 consumption of the embryo is increasing (fig. 4.19). Even under quite dry conditions, O_2 diffusion is sufficient to support the embryo's metabolism (Bradford and Seymour 1988b). This change in conductance is a function of developmental stage and is not directly affected by environmental conditions, such as O_2 availability and temperature (Seymour, Geiser, and Bradford 1991a).

Once the nests of *P. bibronii* are flooded, the eggs are subjected to decreased ambient PO_2. Experimental manipulation of aquatic PO_2 in the laboratory showed that below a certain critical PO_2, metabolic rates of embryos decreased (Bradford and Seymour 1988b). Very low PO_2 induced hatching in eggs that were close to hatching when the experiments began. There was a limit to how much hatching could be accelerated, however, because the embryos must reach a certain stage before they can survive independently. Prolonged exposure to extreme aquatic hypoxia at earlier stages simply retarded development and eventually killed the eggs. Without field data on variation in O_2 levels in flooded nests, it is impossible to estimate the importance of this source of mortality in natural populations. However, a field study of three species of *Pseudophryne* over five breeding seasons revealed that embryonic mortality was very low (usually less than 5%) and occurred mostly in the terrestrial rather than the aquatic phase of development (Woodruff 1976b). Hence, mortality due to low PO_2 in the nest probably is of trivial importance.

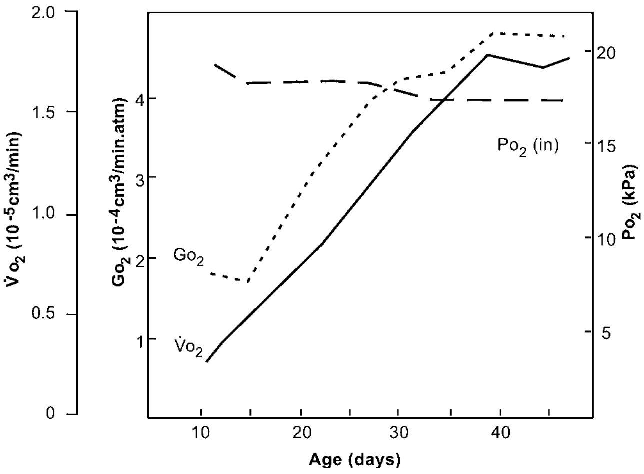

Fig. 4.19. Gas exchange in the terrestrial eggs of *Pseudophryne bibronii.* The figure shows the change in capsule wall conductance [GO_2], oxygen partial pressure in the perivitelline chamber [PO_2 (in)], and oxygen consumption of the embryo [$\dot{V}O_2$] during development. PO_2 (in) is calculated assuming a constant PO_2 (air) of 20.91 kPa. After Seymour and Bradford (1987).

Another Australian myobatrachid frog, *Crinia* (= *Bryobatrachus*) *nimbus,* deposits small clutches of relatively large eggs in damp moss. Upon hatching, the larvae remain in a gelatinous mass in the nest. This frog has one of the thickest egg capsules known for any anuran, and theoretical calculations indicate that embryos in a clutch of up to 20 eggs should suffer hypoxia at temperatures above 5°C. Field measurements, however, failed to reveal evidence of hypoxic conditions. Apparently the porous nature of the moss nest allows for aeration of the embryos, while photosynthesis by the moss provides supplemental oxygen. The relatively small number of eggs in each clutch and low environmental temperatures, which reduce metabolic demand, also enable the embryos to develop without experiencing hypoxic conditions (Mitchell and Seymour 2003).

Many frogs lay nonaquatic eggs attached to vegetation over water, where the eggs eventually hatch and drop into the water to complete development (see chapter 10). In some species, such as phyllomedusine hylids in the genera *Agalychnis, Phyllomedusa,* and *Pachymedusa,* the eggs are surrounded by abundant jelly, which serves as a water reservoir that reduces the chances of desiccation. Other species, particularly Old World tree frogs in the family Rhacophoridae, lay their eggs in arboreal foam nests. These are made from mucus secretions produced by the female that are beaten into a froth as the eggs are laid (see chapter 10 for details of nest construction).

Seymour and Loveridge (1994) studied the effect of the foam nest on embryonic respiration in the African rhacophorid *Chiromantis xerampelina.* These frogs produce foam nests attached to branches overhanging temporary pools that form after heavy rains. The eggs are relatively small and have very thin jelly capsules. They are scattered through the foam inside the nest. The outer foam layer quickly dries out, forming a relatively hard, protective coating that reduces evaporative water loss, but allows for diffusion of O_2 into the nest (fig. 4.20). Before hatching, the eggs could obtain all the O_2 they need from the air trapped in the foam bubbles. After the tadpoles hatch, their metabolic rates increase rapidly, and they must depend on O_2 that diffuses into the nest from outside. Drying of the foam increases the O_2 conductance of the nest. Eventually the tadpoles become very crowded in the small amount of liquid foam remaining in the nest, and O_2 becomes limiting, especially at high daytime temperatures. Low PO_2 in the nest triggers emergence of tadpoles, which drop into the water below to complete development. The main advantage of laying eggs in a foam nest instead of a jelly mass is that it allows for a much larger egg mass and a larger clutch size because of the air trapped in the foam and the permeability of the drying foam to O_2.

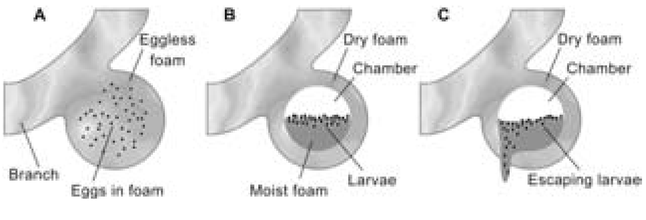

Fig. 4.20. Cross-sections of a foam nest of an African rhacophorid treefrog, *Chiromantis xerampelina,* at three stages of its life. (A) Nest immediately after eggs are laid, with eggs dispersed in the center of the foam and surrounded by eggless foam. (B) After tadpoles have hatched and collected in moist foam in the bottom of a chamber formed by a shell of dry foam. (C) Tadpoles escaping from the nest as the pool of moist foam breaks through the outer shell of dry foam. After Seymour and Loveridge (1994).

Gas Exchange in Water

Eggs laid in water are much more likely to become O_2-limited than those laid on land, especially at high temperatures, because aquatic environments often become hypoxic. Amphibians lay eggs in many different types of aquatic sites, from cold, fast-moving streams to warm ponds and small bodies of water in depressions on the ground, burrows, tree holes, and bromeliads (see chapter 10). These are likely to differ considerably in the availability of O_2 (see table 4.1). There also is great diversity in the structure of egg masses laid in these sites (see chapter 10), and much of this variation probably is related to problems of O_2 uptake.

The first detailed study of respiration of aquatic egg masses was done by Burggren (1985) on *Rana palustris.* This species lays globular egg masses surrounded by a thick jelly coat. Variation in O_2 content of water at natural breeding sites has not been studied, but limited field measurements indicated that eggs were in water that was supersaturated with O_2 at midday (water temperature about 13 C). Burggren used oxygen electrodes to measure PO_2 and PCO_2 at different positions in submerged egg masses maintained in the laboratory. He found only a slight decrease in PO_2 and a slight increase in PCO_2 from the outside to the inside of the egg. At normal ambient PO_2, O_2 concentrations at the interior of the mass were sufficient to maintain aerobic metabolism. There was no evidence of a buildup of lactic acid in centrally located eggs, and changes in pH were quite small. These results contradicted earlier studies that had found substantially lower PO_2 near the center of egg masses in several species, as well as increased levels of lactate that indicated a switch to anaerobic metabolism (R. Savage 1935b; Barth 1946; Gregg 1962).

Given the relatively large size of the egg mass of *Rana palustris,* Burggren (1985) was not able to explain how sufficient oxygen could reach embryos at the center of the mass. Seymour and Roberts (1991) argued that diffusion alone could not account for the relatively high PO_2 at the center of the egg masses and hypothesized that water circulating through channels in the jelly must provide oxygen to central embryos. This was subsequently confirmed in studies of wood-frog (*Rana sylvatica*) egg masses. Female wood frogs often lay their eggs in large communal masses that are tightly clustered in shallow water (see fig. 3.14 in chapter 3). This is thought to aid in heat retention during the day, but it also would reduce the surface area available for diffusion of O_2 into the egg masses. Indeed, even a single wood frog egg mass exceeds the theoretical limit for egg masses containing a high density of eggs. Nevertheless, the eggs can obtain sufficient O_2 throughout development. One reason is that these frogs breed in early spring in relatively cold, oxygen-rich water. In addition, the egg masses are loosely structured, with channels between the eggs that allow water to circulate throughout the mass. Wood frog egg masses start out as compact balls, but rapidly swell as they take up water. This increases the separation of the eggs and the size of the water channels between them. The eggs usually are placed in open sunlight, and as the egg mass warms, convection currents develop that circulate water through the egg mass. Nevertheless, there is a substantial PO_2 gradient from the outside to the inside of the mass, with eggs in the center subjected to lower PO_2 (Pinder and Friet 1994; Seymour 1995). Individual eggs take up water throughout development, which increases the volume of the space inside the egg and increases the O_2 conductance of the egg capsules as the metabolic demands of the eggs increase (fig. 4.21).

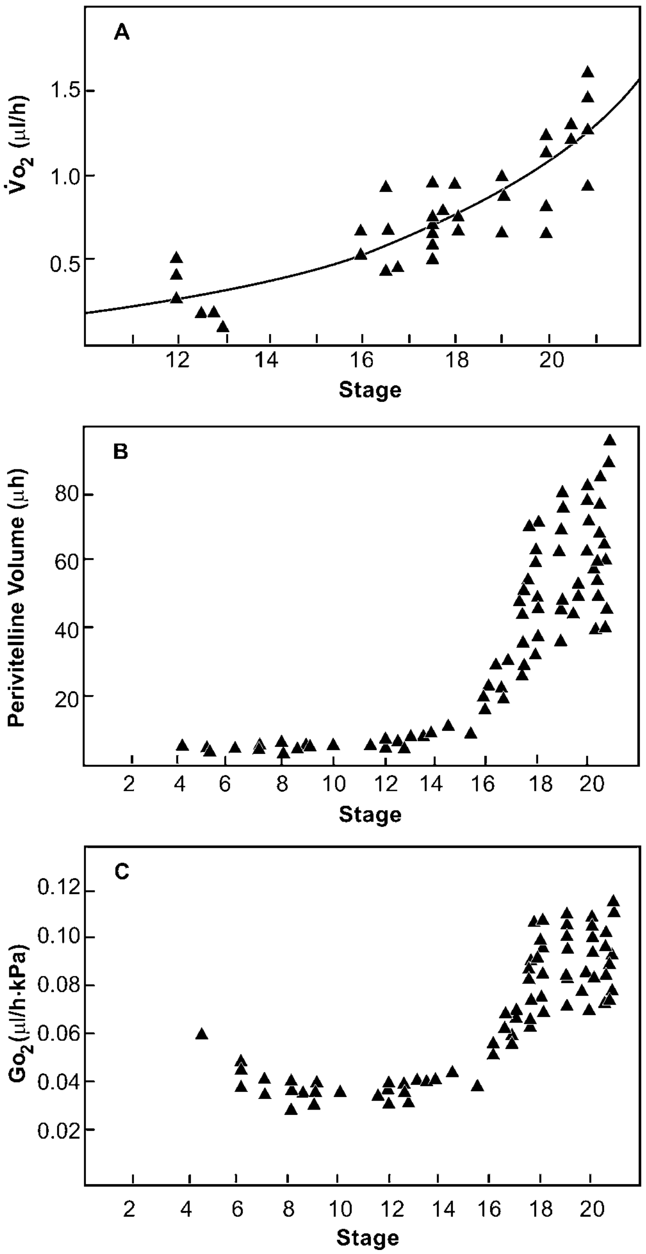

Fig. 4.21. Changes in gas exchange and characteristics of wood-frog embryos as a function of Gosner (1960) stage of development. (A) Oxygen consumption ($\dot{V}O_2$) of individual embryos at 15°C. Regression equation: $\dot{V}O_2 = 0.0793$ stage – 1.549. (B) Changes in volume of the perivitelline chamber. (C) Changes in oxygen conductance of the egg capsule (GO_2). After Seymour (1995).

Spotted salamanders (*Ambystoma maculatum*) also are early spring breeders that often lay eggs in the same ponds used by wood frogs. Their egg masses are readily distinguished from those of wood frogs because they contain fewer, larger eggs, and the masses are very compact. They lack convection channels that would enhance O_2 uptake by the eggs (Pinder and Friet 1994). They do, however, have another source of O_2 for the eggs. Many egg masses are colonized by symbiotic green algae (*Oophila ambystomatis*) that apparently live only in association with amphibian eggs (Gatz 1973). A number of early workers had suggested that these algae might produce O_2 that could be used by the salamander eggs. In an early study, Hutchison and Hammen (1958) reported that the algae consumed more O_2 than they produced, an unlikely result if the algae themselves are growing. Their study, however, was done at 25° C, an unrealistically high temperature for these cold-water breeders. Pinder and Friet (1994) measured O_2 consumption and production at 10° C, which revealed that the algae do produce more O_2 than they consume, and egg masses exposed to light actually contain more O_2 than does the surrounding water. In darkness, when the algae use O_2, but do not produce O_2 by photosynthesis, steep PO_2 gradients developed in salamander egg masses, with central eggs being exposed to nearly anoxic conditions (fig. 4.22). When egg masses were kept in the dark and then exposed to light, PO_2 inside the masses increased immediately, indicating an increase in O_2 production by photosynthesis (see also Bachmann et al. 1986).

In a study of embryonic development in *Ambystoma* and in *Rana palustris*, Petranka, Just, and Crawford (1982) suggested that aquatic amphibian eggs require exposure to low PO_2 to induce hatching. Subsequent work has shown this

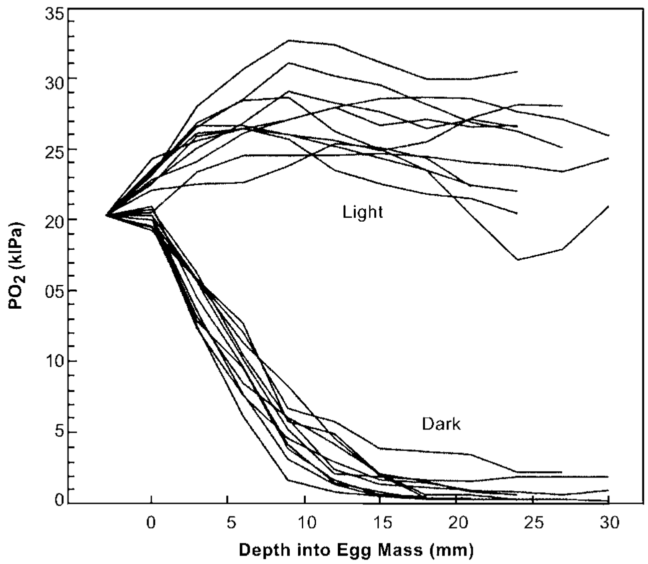

Fig. 4.22. Oxygen partial pressure (PO$_2$) gradients in egg masses of *Ambystoma maculatum* that were kept for at least 10 hours in either darkness or light. Egg masses kept in the dark, where photosynthesis by symbiotic algae was not possible, were nearly anoxic at the center of the mass. After Pinder and Friet (1994).

not to be true. For example, Burggren (1985) found that *R. palustris* eggs hatched even in oxygen-saturated water. Mills and Barnhart (1999) found that chronic exposure to hypoxic conditions resulted in slower development and delayed hatching in *Ambystoma maculatum* and *A. annulatum,* and hatchlings were not as well developed as those reared in normoxic conditions. In *A. annulatum,* posthatching survival of larvae reared in hypoxic conditions was poor. In *Rana palustris* and *R. utricularia,* embryos exposed to hypoxic conditions did hatch earlier than did those in normoxic conditions, but the hatchlings were not as well developed. Overall, these results indicate that prolonged exposure to hypoxic water has detrimental effects on the growth, development, and survivorship of amphibian embryos, but embryos probably can survive brief expose to hypoxic conditions without ill effect. There also is evidence for *Ambystoma* that exposure to low levels of dissolved oxygen causes egg capsules to expand, thereby increasing the oxygen conductance of the capsule and partially compensating for low oxygen availability (Mills, Barnhart, and Semlitsch 2001).

Amphibians that breed in warm, oxygen-poor ponds, or in small bodies of water that are likely to be rapidly depleted of O$_2$ by respiring eggs, face the greatest limitations on O$_2$ availability during development. Seymour and his colleagues have studied the respiration of embryos of several Australian frogs that breed in oxygen-poor environments. One is *Limnodynastes tasmaniensis,* which breeds in the spring and summer (October–December) in shallow, temporary ponds. Most populations produce foam egg masses that are produced by the females, which beat the surface of the water with enlarged, paddle-shaped flanges on their front toes (see chapter 10). This creates a bubble nest that floats on the surface, and eggs rise to the surface as they are laid and are suspended in or under the bubbles. As the eggs develop, the foam eventually breaks down, and the eggs sink. Oxygen concentrations were greatest at the foam-water interface and decreased toward the center of the egg masses (fig. 4.23), but most masses had sufficiently high PO$_2$ levels to support the embryos throughout development. Some populations of this species produce nonfoamy egg masses held at the water's surface by vegetation. Most of these also contained sufficient O$_2$ for the embryos, but some parts of the masses became hypoxic if allowed to sink to the bottom (Seymour and Roberts 1991).

Two other Australian myobatrachid frogs lay eggs in small bodies of water. *Crinia georgiana* breeds in relatively cold weather and lays eggs in shallow, water-filled depressions on the ground. The respiratory characteristics of the aquatic eggs of this species were similar to the terrestrial eggs of *Pseudophryne bibronii* (Seymour and Roberts 1995; Seymour et al. 2000). Metabolic rate increased in an exponential fashion as the eggs developed, while O$_2$ conductance increased in a linear fashion as the eggs swelled with water. Consequently, some embryos experienced reduced O$_2$ availability late in development. Despite substantial variation in nest PO$_2$, most embryos survived to hatching, probably because the embryos are unusually tolerant of low PO$_2$. Although, many eggs tend to be placed in sites where trickling water helps to aerate the eggs, there was little evidence that selection of oviposition sites was directly influenced by PO$_2$. Another myobatrachid, *Philoria loveridgei,* lays much larger eggs in a jelly mass in shallow, flask-shaped depressions in moist soil. This is a subtropical frog that breeds at much warmer temperatures than *Crinia georgiana,* and its eggs are subject to more severe O$_2$ limitation. On average, about 2/3 to 3/4 of the eggs hatch, with mortality being greatest in those located at the bottom of the nest, where embryos often are exposed to anoxic conditions (Seymour, Mahony, and Knowles 1995). This species apparently evolved from ancestors that produced foam nests, but the reasons for the loss of foam nesting is unknown.

Accessory Respiratory Structures in Embryos

While many aquatic and terrestrial embryos probably take up most of their O$_2$ by simple diffusion through the body wall, some species develop elaborate respiratory structures well before hatching. For example, most larvae of salamanders and aquatic caecilians have large branching gills, and some anuran embryos develop large external gills that are lost soon after hatching. Other amphibian embryos have large sheetlike gills or greatly enlarged tail fins that are as-

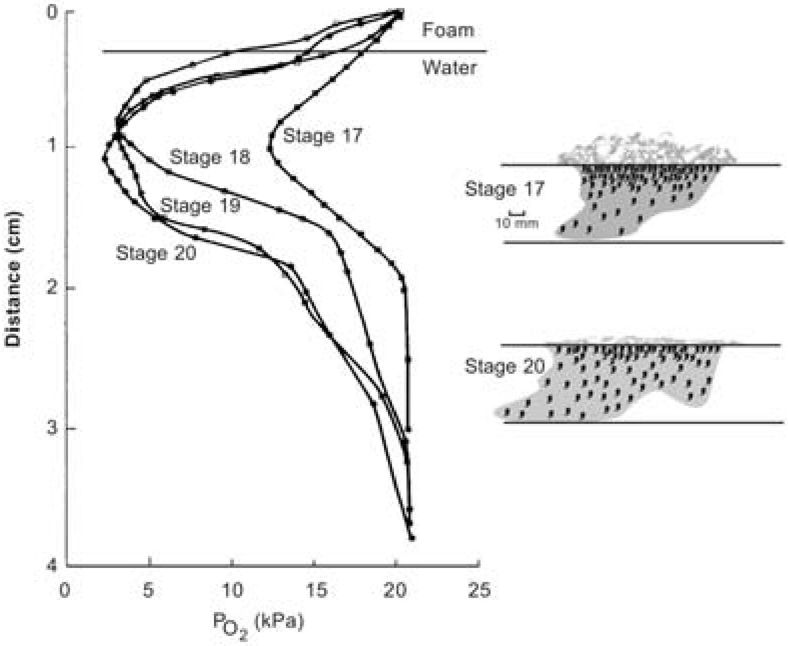

Fig. 4.23. Oxygen profiles through the center of a foamy egg mass of *Limnodynastes tasmaniensis* at four Gosner (1960) stages of development. Distance is measured from the top of the egg mass, which is exposed above the water surface, to the bottom of the egg mass about 3.5 cm underwater. Diagram at right shows the spatial distribution of embryos in the egg mass at stages 17 and 20. After Seymour and Roberts (1991).

sumed to have a respiratory function. These are found even in fully terrestrial species that undergo direct development and lack an aquatic larval stage. For example, embryos of terrestrial salamanders such as *Plethodon glutinosus* have large branching gills (Bishop 1941b), while the embryos of *Eleutherodactylus coqui* have wide, thin tail fins (Townsend and Stewart 1985). Such structures are particularly well developed in the embryos of marsupial frogs, which develop in pouches or cavities on the mother's body, and in embryos of viviparous species (see chapter 10). Detailed descriptions and illustrations of these structures are given by Noble (1927, 1931), Lamotte and Lescure (1977), Duellman and Trueb (1986), and Thibaudeau and Altig (1999), as well as numerous papers on embryology and development (Gasche 1939; Lynn 1942; Lynn and Lutz 1946a, b; Jameson 1950; J. Davis 1952; Gorman 1956; Valett and Jameson 1961; Vial 1968; McDiarmid and Worthington 1970; del Pino et al. 1975; M. Wake 1978; del Pino and Escobar 1981; Townsend and Stewart 1985). Functional interpretations of apparent respiratory structures are based almost entirely on their morphology; physiological studies of their role in gas exchange are lacking.

The Neotropical red-eyed treefrog (*Agalychnis callidryas*) lays relatively large eggs on vegetation overhanging water. The embryos develop elaborate branching external gills well that are fully perfused with blood well before hatching (Warkentin 1999b). These gills apparently are important in providing extra surface area for gas exchange for embryos in an egg mass in which diffusion of oxygen is limited. When eggs were removed from masses and exposed to air, the embryos quickly lost the circulation in their external gills, and some lost the gills altogether. Even when gills were retained, they were about 1/10 the length of those of embryos in natural egg masses (Warkentin 2000a). Once the eggs hatch, circulation to the external gills is cut off almost immediately, and gills are quickly lost. Loss of the gills can be retarded, however, by exposing the newly hatched tadpoles to hypoxic water (Warkentin 2000a). These results not only indicate that embryonic gills play an important role in gas exchange, but they also show that development and loss of gills are plastic responses to the availability of oxygen.

Summary and Conclusions

Amphibians have been used for centuries to answer basic questions about vertebrate respiration, but in many ways, the respiration of amphibians differs from that of other tetrapods. In particular, amphibians rely to a greater extent on cutaneous respiration than do any other vertebrates, and in the case of plethodontid salamanders, reliance on cutaneous respiration has been accompanied by the evolutionary loss of lungs. The use of the skin as a respiratory organ is made possible by the highly permeable nature of the amphibian skin, but is constrained by the need to keep the skin moist at all times. Amphibians cannot achieve dramatic increases in the rate of oxygen uptake through the skin during vigorous activity, so they must either rely on the lungs to supply oxygen during exercise or must depend heavily on anaerobic metabolism.

Amphibians in the terrestrial environment are seldom constrained by the availability of oxygen. Even at the highest altitudes inhabited by amphibians, partial pressures of oxygen (PO_2) are more than sufficient to support activity. The only terrestrial amphibians that might be exposed to hypoxic conditions on a regular basis are burrowing species, but the limited data available suggest that even underground burrows usually have sufficient oxygen for normal activity. Aquatic amphibians, on the other hand, often find themselves in environments with limited oxygen supplies. This is particularly true of warm, swampy habitats and shallow, stagnant bodies of water, but also is characteristic of some ice-covered ponds in winter. Some aquatic salamanders, such as sirens, exhibit physiological adaptations to hypoxic environments, including obligate air-breathing with lungs and high tolerance for dissolved CO_2. Tadpoles that live in hypoxic environments, such as water-filled bromeliads, exhibit similar adaptations and often develop lungs soon after hatching.

In general, anurans have more complex lungs with greater surface area for gas exchange than do urodeles, and the lungs provide more than half of all gas-exchange surface area in most anurans. There are a few exceptions, however, such as *Siren, Amphiuma,* and *Salamandra,* all of which have complex, well-developed lungs. The structure of most caecilian lungs has not been studied in detail, but the limited data available suggest that caecilians depend primarily on their lungs for gas exchange. In some aquatic species, a separate tracheal lung provides increased surface area for gas exchange, but one species of aquatic caecilian has lost its lungs altogether and is the largest lungless tetrapod. Studies of lung structure of some distantly related giant salamanders have revealed a general correlation between complexity of lung structure and the availability of oxygen in aquatic habitats. There have not been any other comparative studies, however, relating lung structure in other groups, such as anurans, to variation in locomotory activity and degree of dependence on aerobic metabolism.

All amphibians ventilate the lungs with a positive-pressure buccal pump, which involves the throat muscles pumping air into the lungs. Buccal pumping is retained even in lungless species, such as plethodontid salamanders, which also use the lining of the buccal cavity and pharynx for gas exchange. Exhalation is accomplished by contraction of the hypaxial (trunk) muscles in urodeles, but anurans and caecilians rely on elastic recoil of the inflated body for passive exhalation. The exception is in male frogs that call; they have enlarged trunk muscles that contract to force air out of the lungs to produce sound.

Despite having only a three-chambered heart with a single, undivided ventricle, amphibians achieve a considerable degree of functional separation of oxygenated and deoxygenated blood through morphological adaptations of the ventricle and the *conus arteriosus.* At the same time, the undivided circulation allows for shunting of blood away from the lungs when the lungs are compressed and toward the lungs when they are inflated. There is some evidence that oxygen affinity of the blood of amphibians is adapted to the environments in which the animals live, with higher oxygen affinity in aquatic species than in terrestrial air-breathers. Nevertheless, such patterns have not been investigated in a meaningful phylogenetic context, but have been determined for distantly related aquatic and terrestrial species that differ in many other aspects of their physiology and ecology. Ontogenetic studies of anuran tadpoles tend to support this pattern, however, because there is a shift toward lower blood-oxygen affinity at metamorphosis as oxygen becomes more readily available to a terrestrial animal.

Among larval salamanders, there is a general correlation between the surface area of the gills and oxygen availability in the environment, with pond-dwelling larvae typically having larger gills with much more surface area for gas exchange than do stream-dwelling larvae. Again, few quantitative comparisons have been made in a phylogenetic context in clades that occupy diverse habitats, such as the plethodontid salamanders. Virtually nothing is known about the relationship of internal gill morphology to gas exchange capacity in anuran tadpoles, nor have there been any comparative morphological studies relating gill morphology to environmental oxygen availability. Interpretation of gill morphology in anuran tadpoles is complicated by the involvement of the gill region in feeding as well as respiration, but a phylogenetically based comparison of respiratory structures would be worthwhile. We also need additional comparative studies of the ontogeny of respiratory physiology in anuran tadpoles. Limited data for a few taxa suggest that tadpoles that live in oxygen-poor environments often develop lungs sooner than do those that live in well-aerated environments, but again most comparisons have been made between distantly related taxa, such as ranid frogs and bufonid toads.

An area of research that was neglected for many years is the respiration of amphibian embryos. There have been detailed investigations in the last 20 years on a relatively limited number of species found mostly in Australia. These have been chosen to represent a range of oviposition strategies, from terrestrial breeding to laying eggs in ponds, in floating foam nests, or in trees. These studies have shown that the structure and placement of egg masses often is affected by the gas-exchange requirements of the embryos and the availability of oxygen in the environment. Expansion of such comparative studies to a wider range of taxa, such as foam-nesting leptodacytlids, stream-breeding frogs, and those that lay eggs in bromeliads and other oxygen-poor environments would be most informative. Many aspects of the evolution of amphibian reproductive modes and life-history strategies, including egg size, clutch size, and the structure and placement of egg masses, traditionally have been interpreted as responses to selective pressures such as predation (see chapter 10). In many instances, however, it appears that responses to the physical environment, and in particular the availability of oxygen, are equally important in shaping the evolution of egg size, clutch size, and clutch structure. We also need more information on the respiratory adaptations of the embryos themselves, particularly those that develop elaborate external gills inside the egg capsule. While such structures appear to provide additional surface area for gas exchange, their actual contribution to embryonic respiration remains almost entirely unknown.

Chapter 5 Metabolism and Energetics

Amphibia are cold-blooded; they lack the mechanisms which give the higher types both freedom from environmental change and constancy of chemical activity at the optimum conditions for the expenditure of their energies. . . . Hence their energy sources, the food and oxygen, are made available at a much slower rate in these forms. . . . Amphibia are not able to make use, to the fullest extent, of either their nervous or their motor systems. They remain slaves of their surroundings.
—G. Kingsley Noble, *The Biology of the Amphibia* (1931)

UNTIL RELATIVELY RECENTLY, biologists tended to view amphibians as somewhat inferior to other terrestrial vertebrates, handicapped by their low body temperatures and metabolic rates, unable to achieve levels of activity equivalent to those of even the most sluggish birds and mammals. Yet amphibians often have been credited with remarkable feats of survival under all sorts of adverse conditions. For centuries, even reputable naturalists thought that toads could survive for many years completely encased in stones or blocks of wood. Typical accounts described toads sealed for years in airtight chambers with no access to food or water, yet miraculously surviving when the chambers were opened (Gosse 1860). Various naturalists tried experiments to determine how long toads could survive under such conditions. For example, the geologist William Buckland performed some experiments in the 1820s in which toads were entombed in stone chambers and buried in a churchyard for a year. Those encased in sandstone all died within a year, whereas some of those in more porous limestone were still alive, but succumbed in the second year (Buckland 1832).

Stories of toads surviving for centuries encased in rock clearly are apocryphal. Nevertheless, amphibians do have unusual metabolic characteristics that allow them to remain underground or underwater during long periods of winter cold or summer heat, often emerging after many months and moving immediately to temporary ponds to breed. Indeed, modern herpetologists have viewed the low metabolic rates of amphibians not as handicaps, but as features that allow them to pursue a low-energy lifestyle not available to endothermic vertebrates (Bennett 1978; Pough 1980, 1983; Feder 1983b; Seale 1987).

This chapter deals with the metabolic characteristics of amphibians. I first discuss sources of variation in resting metabolism and the relative importance of aerobic and anaerobic metabolism during activity. Then I move on to a consideration of the energetics of natural behavior, such as foraging, courtship, aggression, and vocal communication. Finally, I discuss the use of various energy substrates to support metabolic activity and seasonal cycles of energy storage and use.

Metabolism of Amphibians at Rest

Sources of Variation in Resting Metabolism

Physiologists have made thousands of measurements of oxygen consumption by amphibians under various conditions and have investigated the relationship between resting metabolism and both temperature and body mass (Tashian and Ray 1957; Whitford and Hutchison 1967; Hutchison, Whit-

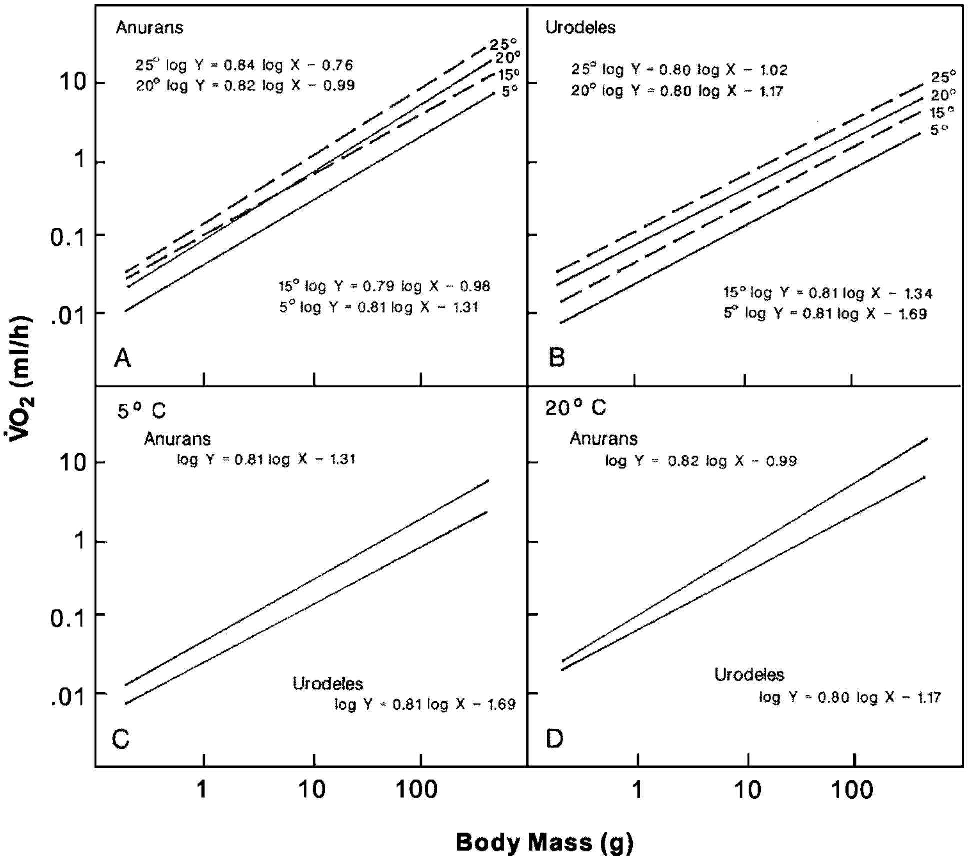

Fig. 5.1. Relationship of resting metabolic rates to body mass for anurans and urodeles. (A) Anurans at four different temperatures. (B) Urodeles at four different temperatures. (C) Anurans and urodeles at 5° C. (D) Anurans and urodeles at 20° C. Regressions plotted from equations in Gatten, Miller, and Full (1992).

ford, and Kohl 1968; Ultsch 1973a, 1974; Feder 1976a, b). A comprehensive review by Gatten, Miller, and Full (1992) summarized this literature and tabulated nearly all known measurements for both larval and adult amphibians. The regressions shown in figure 5.1 are plotted from their equations. Many authors have distinguished between "standard" metabolism, measured during the normal period of inactivity, and "resting" metabolism, measured on quiescent animals during the normal activity period (e.g., diurnal measurements on diurnal frogs), but Gatten, Miller, and Full found that the use of these terms was not consistent enough to analyze these measurements separately. Therefore, I have followed their convention in referring to all measurements made on inactive animals as resting metabolic rates.

The scaling of resting metabolism with body mass is identical in adult anurans and urodeles, with slopes of logarithmic regressions averaging about 0.80 (fig. 5.1 A, B). Anurans and urodeles also show a similar response to temperature, with metabolic rate approximately doubling with a 10° C increase in temperature (i.e., $Q_{10} = 2$). At the same temperature, anurans have consistently higher metabolic rates than urodeles (fig. 5.1 C, D). Regressions for caecilians reported by Gatten, Miller, and Full (1992) had intercepts similar to those for anurans and somewhat higher slopes, but these were based on only three or four species and therefore were insufficient for rigorous statistical comparisons. More recent data have shown that caecilians actually have lower metabolic rates than either anurans or urodeles of the same body mass (Smits and Flanagin 1994; Stiffler and Talbot 2000). Data for larval amphibians were more variable than those for adult anurans and urodeles (Gatten, Miller, and Full 1992). The scaling of metabolic rate with body mass was similar for larval and adult urodeles, but larvae appeared to have somewhat lower metabolic rates at any given temperature. The same seems to be true for anuran tadpoles, but the available data are insufficient to draw definitive conclusions.

Gatten, Miller, and Full (1992) compared metabolic rates of amphibians with those of birds and mammals by extrapolating data collected at 20° or 25° C to a more typical endothermic temperature of 38° C, using a Q_{10} of 2.0. They estimated that resting metabolic rates of mammals and nonpasserine birds are about 10 times those of amphibians at 38° C, while passerine birds have metabolic rates about 10 to 30 times higher (bird and mammal data from Lasiewski and Dawson 1967; McNab 1988). Comparisons with data for squamates or for all reptiles revealed that frogs have metabolic rates similar to reptiles at 20° or 25° C, whereas metabolic rates of urodeles are about 30% lower (reptile data from Bennett and Dawson 1976; Andrews and Pough 1985).

These comparisons actually understate the differences in absolute energy requirements between amphibians, reptiles, and endotherms, for several reasons. First, most amphibians are considerably smaller than the smallest birds and mammals, and many also are smaller than most reptiles (Pough 1980; Feder 1983b), so their total energy requirements would be lower even at the same temperature. Second, few amphibians can actually function at body temperatures near 38° C (see chapter 3); meaningful ecological comparisons are best made at normal activity temperatures for each animal. The metabolic rate and total energy requirements of a temperate-zone plethodontid salamander at 15° C probably should be compared to a diurnal frog at 20–25° C (in summer), a lizard at 25–35° C, and a bird or mammal at 38° C. Such comparisons have shown that amphibians in general, and plethodontid salamanders in particular, have the lowest resting metabolic rates and thus the lowest maintenance energy requirements of any terrestrial vertebrates (Pough 1980, 1983; Feder 1983b; Gatten, Miller, and Full 1992).

Broad interspecific comparisons are useful in revealing general relationships between body mass, temperature, and metabolic rate, but can obscure differences among species that are ecologically significant. For example, the regressions in figure 5.1 are based on pooled data for both tropical and temperate-zone species. Several authors have reported lower metabolic rates in tropical than in temperate-zone anurans. Unfortunately, early studies by Tashian and Ray (1957) and Hutchison, Whitford, and Kohl (1968) are flawed because they compared tropical and temperate-zone species in different families and of different body sizes and did not present rigorous statistical comparisons. Weathers and Snyder (1977) compared metabolic rates of three ranid frogs from Borneo with the regression equation for temperate-zone ranids at 25° C given by Hutchison, Whitford, and Kohl (1968) and found that the tropical species had lower metabolic rates. They did not present regression equations for the tropical species that could be compared statistically with the temperate-zone data, however.

Other authors have used these data to support the generalization that tropical anurans have lower metabolic rates than temperate-zone species (Whitford 1973; Duellman and Trueb 1986), but a rigorous statistical analysis that controls for variation in phylogenetic history and body size is needed. Unfortunately, we do not have sufficient data for anurans to make a tropical–temperate-zone comparison among species in the same family (Gatten, Miller, and Full 1992). Navas (1996c) compared the metabolic rates of high-elevation Andean anurans in four different families to those of species in the same genera from low-elevation tropical sites in Panama. He found that low-elevation species of *Colostethus* (Dendrobatidae) and *Atelopus* (Bufonidae) had slightly lower resting metabolic rates than high-elevation species, but this was true only at low temperatures. High- and low-elevation species of *Hyla* and *Eleutherodactylus* did not show this difference, however. Differences in activity metabolism were much more dramatic. All of the low-elevation species had much lower aerobic capacities for locomotion at low temperatures, and in fact, were virtually incapacitated at temperatures regularly experienced by high-elevation species during their normal activity periods.

Feder (1976b) compared resting metabolic rates of 14 Neotropical and 12 North American plethodontid salamanders and found that tropical salamanders had significantly lower metabolic rates than temperate-zone species at both 15° and 25° C. The ecological consequences of these differences in resting metabolism are hard to predict, because we lack detailed information on the amount of time salamanders spend at different temperatures throughout the year. The activity temperatures of tropical and temperate-zone plethodontids overlap considerably, but tropical species do not experience the very low temperatures characteristic of northern winters. Feder and Lynch (1982) found that maximum activity temperatures of tropical and temperate-zone species were not significantly different, but lowland tropical species were poorly represented in their sample. Nevertheless, because of reduced seasonal variation, tropical salamanders probably have higher average temperatures on a yearly basis than temperate-zone species, and might therefore have similar or even higher energy requirements in spite of their lower metabolic rates (Feder, 1976b).

Another potential source of variation in metabolic rates is the relative importance of skin and lungs in gas exchange. Early work by Whitford and Hutchison (1967) had suggested that plethodontid salamanders had lower resting metabolic rates than ambystomatids and salamandrids with well-developed lungs, and that the difference was particularly pronounced at large body sizes. This was attributed to reduced respiratory surface area in lungless species and increasingly unfavorable surface-to-volume ratios in large species. If this pattern were generally true, then the low metabolic rates of urodeles compared to anurans (fig. 5.1) might simply be a consequence of including many plethodontids in the urodele sample. Subsequent work (Feder 1976a) revealed that neither slopes nor intercepts of mass-metabolism regressions differed between lunged and lungless species. Feder attributed the results obtained by Whitford and Hutchison to their use of plastic masks to measure O_2 consumption, a treatment that could have excited the animals and elevated metabolism above normal resting levels, particularly in species with lungs.

Temporal Changes in Resting Metabolism

Early students of amphibian respiratory physiology reported that frogs collected during the summer had higher metabolic rates than those collected in winter or early spring (Bohr 1900; Krogh 1904; Dolk and Postma 1927). Subsequent workers have reported similar patterns in a variety of temperate-zone amphibians, with metabolic rates generally being highest during spring or summer breeding seasons and lowest in fall and winter, even when measured at the same temperature (Vernberg 1952; Fromm and Johnson 1955; Dunlap 1969, 1973, 1980; Harri and Hedenstam 1972; Knapp 1974). Some studies have shown no significant differences in metabolism at different times of year (Davison 1955; Seymour 1973a). The physiological basis for seasonal variation in metabolic rate is poorly understood because several variables that could affect such variation often are not controlled. These include activity of the animal in the metabolic chamber (Fromm and Johnson 1955), thermal history (see the subsequent discussion of acclimation), food intake (Feder et al. 1984), photoperiod (Whitford and Hutchison 1965b; Guimond and Hutchison 1968), and reproductive condition (Fitzpatrick 1971). Seasonal fluctuations in hormone levels, modulated by the central nervous system, can have a direct effect on metabolic rate (Harri and Hedenstam 1972; Lagerspetz 1977), but it is not clear that these effects always are independent of other variables, such as seasonal changes in activity.

Many amphibians exhibit diel variation in resting metabolism, with nocturnal species generally having higher metabolic rates at night and diurnal species having higher rates during the day (Kasbohm 1967; Dunlap 1969; Hutchison and Kohl 1971; Turney and Hutchison 1974; Weathers and Snyder 1977; Carey 1979a; Miller and Hutchison 1979; Bucher, Ryan, and Bartholomew 1982; Taigen and Pough 1983). In some cases, differences between day and night measurements are considerable (e.g., Hutchison and Kohl 1971; Bucher, Ryan, and Bartholomew 1982), but in others, they are quite small and not statistically significant (e.g., Taigen and Pough 1983). Diel variation in metabolic rate appears to be related mainly to changes in activity of the animals and not necessarily to an underlying physiological cycle. Hutchison and Kohl (1971) simultaneously monitored movements and metabolic rates of *Bufo marinus* during a 24-hour cycle. The toads exhibited a marked increase in metabolic rate during the first two to three hours after the onset of darkness and a marked decrease immediately after the onset of light. These changes in metabolism were paralleled by changes in locomotor activity. Similar results were obtained in experiments with *Necturus maculosus* (K. Miller and Hutchison 1979). Both metabolic rates and levels of activity increased dramatically with the onset of darkness as the salamanders increased rates of air-breathing at the water's surface. In both species, changes in activity and metabolic rates were triggered directly by photoperiod and therefore did not represent a true circadian rhythm.

Metabolic rates of amphibians also vary with food intake. Immediately after feeding and for some time thereafter, metabolic rates are elevated because of the energetic cost of digestion (specific dynamic action = SDA). In general, amphibians experience only moderate changes in metabolic rate after feeding. For example, in *Bufo woodhousii,* metabolic rates three hours after feeding were 1.7 times higher than at 120 hours after feeding (Sievert and Bailey 2000), while in *Plethodon metcalfi,* postfeeding metabolism was about 1.8 times resting metabolism (Feder, Gibbs, Griffith, and Tsuji 1984). In *Bufo marinus,* SDA averaged 5.5 times resting metabolism (Secor and Faulkner 2002). Specific dynamic action was similar in *Ceratophrys cranwelli,* averaging two to five times resting metabolism, and it was not affected by the type of diet (earthworms or mice; Powell, Mansfield-Jones, and Gatten 1999; Grayson et al. 2005). Specific dynamic actions in the same general range have been reported for a number of other anurans as well (Busk, Jensen, and Wang 2000; Secor and Faulkner 2002; J. B. Anderson and Wang 2003). For most anurans, the increase in metabolism after feeding is considerably less than that experienced during vigorous exercise, but specific dynamic action varies with both body size and relative meal size.

The limited data available for amphibians suggests that increases in metabolic rate are higher for species that feed infrequently than for those that feed frequently, but it is not clear whether this difference is mainly a result of differences in meal size, differences in seasonal patterns of feeding activity, or both. For example, two anurans that eat large meals at infrequent intervals, *Pyxicephalus adpersus* and *Ceratophrys ornata,* had peak metabolic rates about eight to nine times higher than resting metabolism, with specific dynamic action accounting for about 21–22% of ingested energy. Four unrelated species of anurans that eat smaller meals at frequent intervals increased metabolic rates after feeding by about three to five times resting rates, and specific dynamic action accounted for only 10–17% of ingested energy. These data, along with data on rates of intestinal uptake of amino acids and glucose, indicated that infrequent feeders tend to upregulate digestive function in response to feeding (Secor 2001). Several other studies have shown some degree of seasonal variation in intestinal size and morphology in South American anurans, although these studies provided less detail on digestive physiology (Naya et al. 2003, 2005; Naya and Bozinovic 2004).

In a subsequent study, Secor (2005a, b) attempted to control for phylogenetic effects by making comparions within anuran families, although in some cases, the species used were not very closely related. He reported that *Pyxicephalus, Ceratophrys,* and a toad, *Bufo alvarius,* had much higher specific dynamic action than did three other representatives of the same families, *Rana catesbeiana, Leptodactylus pentadactylus,* and *Bufo marinus*. One major ecological difference between these two groups of species is that the former spend a long dry season estivating underground, whereas the latter do not estivate, and the two tropical species are active throughout the year. The three estivating species shut down digestive function during estivation, thereby saving considerable energy. After feeding, these species exhibited substantial increases in intestinal mass and intestinal nutrient uptake rates, with a 600–1000% increase in total nutrient uptake capacity and a 600–1200% increase in metabolic rate. This contrasted with an increase in nutrient uptake of less than 70% in the nonestivating species and increase in metabolic rate of 300–400%. Nevertheless, postfeeding increases in metabolic rate in these frogs are not as impressive as those observed in snakes that eat large meals at infrequent intervals. In snakes such as *Boa constrictor* and *Python molurus,* metabolic rates after feeding can be as much as 18 times resting rates (1800% increase) and exceed those attained during vigorous exercise (Secor and Diamond 2000; Wang, Busk, and Overgaard 2001).

Metabolism during Dormancy

Many amphibians undergo a period of dormancy, either to escape desiccating conditions during prolonged dry seasons (see chapter 2) or to survive winter cold (see chapter 3). Dormant amphibians cease all feeding and other activities, and in the case of cocoon-forming species, experience a marked decrease in cutaneous gas exchange capacity (see chapter 4). These changes often are accompanied by reductions in metabolic rates to levels considerably below normal resting levels. In hibernating amphibians, lower metabolic rates are a direct effect of lower body temperature, but this is not the case for estivating animals (Pinder, Storey, and Ultsch 1992). Measurements made during dry-season dormancy are available for nine species in seven families (table 5.1).

All of these species except *Hyperolius viridiflavus* estivate in underground burrows, where they remain for several months, and in extreme cases, for several years. Most of the

[a] Measurements after only one month of simulated estivation in laboratory.

burrowing anurans had metabolic rates during dormancy about 70–80% below resting rates, although less impressive reductions in metabolic rate, averaging 16 and 25%, were obtained for *Ceratophrys ornata* and *Pyxicephalus adspersus* induced to estivate in the laboratory for only one month (Secor 2005b). *Pyxicephalus, Lepidobatrachus, Ceratophrys, Neobatrachus* and *Cyclorana* all form cocoons to reduce evaporative water loss (Loveridge and Withers 1981; McClanahan, Ruibal, and Shoemaker 1983; Van Beurden 1984; Flanigan et al. 1991; Flanagan, Withers, and Guppy 1993; Withers 1993), but the reduction in the metabolism of those species is not any greater than that of *Scaphiopus,* which does not form cocoons (table 5.1). *Hyperolius viridiflavus* remains exposed on vegetation during the dry season, but becomes completely inactive and greatly reduces evaporative water loss (see chapter 3). This species experiences less reduction in metabolism than do burrowing species. The only salamanders for which data are available are sirens. These form thin cocoons and sometimes spend several months encased in drying mud. The reduction in mass-specific metabolic rate is less pronounced than in the anurans (table 5.1), but sirens also suffer greater loss of body mass from desiccation, so the reduction in total energy demand is comparable (Etheridge 1990a, b).

The greatly reduced metabolic rates of dormant frogs cannot be attributed solely to a reduction in gas exchange capacity, because species that do not form cocoons undergo reductions in metabolism equivalent to those of cocoon-forming species. Furthermore, the dramatic decline in metabolism occurs before cocoons are completely formed (Loveridge and Withers 1981; McClanahan, Ruibal, and Shoemaker 1983). Reduced metabolism also does not appear to be a direct result of starvation, although this certainly can reduce metabolic rates (e.g., Merkle and Hanke 1988). The drop in metabolic rate begins almost immediately and generally is complete within a few days, long before lipid reserves and other energy stores are significantly reduced (Seymour 1973a; Loveridge and Withers 1981; McClanahan, Ruibal, and Shoemaker 1983; Geise and Linsenmair 1988; Etheridge 1990a; Pinder, Storey, and Ultsch 1992).

In *Neobatrachus,* the reduction in metabolism is due in part to a reduction in tissue metabolism that is evident even in isolated muscle tissue (Flanigan, Withers, and Guppy 1991; Flanigan et al., 1993). About 85% of the reduction in whole animal metabolism in dormant *Neobatrachus* is due to a reduction in the metabolic rate of muscle tissue, although other tissues, including the brain, have reduced metabolism as well (Flanigan and Guppy 1997). Metabolic depression is affected by changes in enzyme activities and alterations in rates of glycolysis and other metabolic processes in cells (Flanigan et al. 1990; Pinder, Storey, and Ultsch 1992; Guppy, Fuery, and Flanigan 1994; Fuery et al. 1998), as well as down-regulation of organ systems, especially the digestive system (Secor 2005a, b). The reduction in metabolism can prolong life underground for many months and reduces the possibility that the animals will begin to metabolize their own protein (Seymour 1973a; Van Beurden 1980; Loveridge and Withers 1981; Etheridge 1990a). Indeed, the extremely low metabolism of dormant anurans prevents significant atrophy of skeletal muscle during estivation, an important trait for animals that must dig their way out of the soil once dormancy ends (Hudson and Franklin 2002a, b).

Metabolic Responses to Temperature Acclimation

Because amphibians tend to be rather imprecise thermoregulators (Carey 1978; Feder 1982b; Sinsch 1989; Hutchison and Dupré 1992; see also chapter 3), they often are exposed to pronounced temperature fluctuations on a seasonal, daily, or even hourly basis. Since metabolic rates are temperature dependent, these changes will result in substantial temporal variation in resting metabolism. Amphibians probably cannot make physiological adjustments to short-term temperature changes on the scale of a few hours or a few days (Feder 1985a, b), but they do exhibit shifts in temperature-metabolism relationships on a seasonal basis through thermal acclimation. Physiological ecologists have spent a considerable amount of time studying patterns of metabolic acclimation in the laboratory in the hope of understanding the functional significance of acclimation responses in the field (for a review, see Rome, Stevens, and John-Alder 1992). Typically, acclimation is studied by holding animals at a fixed temperature for periods of several days to a few weeks and then measuring resting metabolic rates at a range of experimental temperatures. Usually animals are not fed during acclimation experiments, and they often are housed in darkness. Both feeding (Feder et al. 1984) and photoperiod (Vinegar and Hutchison 1965; Kasbohm 1967; Guimond and Hutchison 1968; Hofer 1972; Dunlap 1989) can affect the direction and rate of metabolic acclimation. The effects often are inconsistent among species and even among acclimation temperatures and are therefore difficult to interpret in an ecological context.

Although acclimation responses of amphibians vary among species, a number of patterns appear to be relatively common. For example, plethodontid salamanders typically exhibit partial compensation of metabolic rate when acclimated to temperatures at which the species is normally active (Fitzpatrick, Bristol, and Stokes 1971, 1972; Fitzpatrick 1973a, b; Fitzpatrick and Brown 1975; A. Brown and Fitzpatrick 1981a, b; Feder 1978b, 1985a, b; Feder et al. 1984). If a salamander initially housed at 15° C is transferred to 20° or 25° C, there is an immediate increase in metabolic rate due to the acute effect of temperature, followed by a

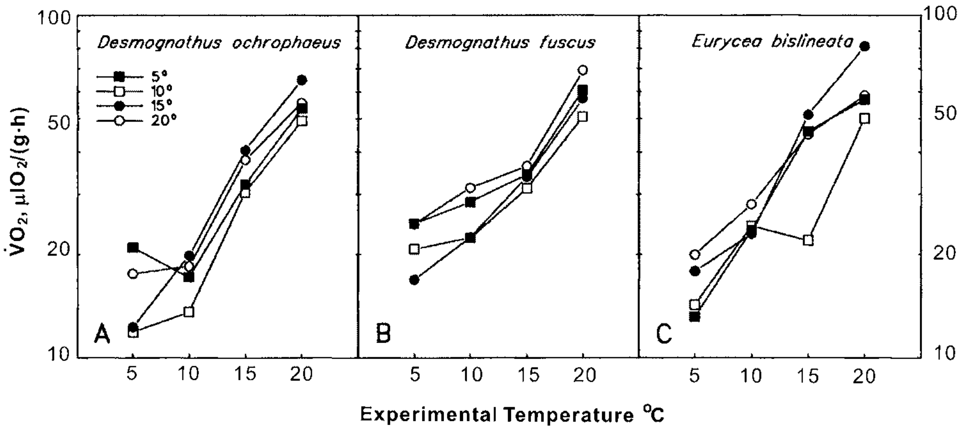

Fig. 5.2. Acclimation of metabolic rates in three plethodontid salamanders. Symbols indicate acclimation temperatures. Experimental temperatures are temperatures at which metabolic rates were measured after acclimation. Plotted from data in Fitzpatrick, Bristol, and Stokes (1971, 1972) and Fitzpatrick (1973a).

gradual decrease in metabolism over a period of days. If the salamander is transferred to 10° C, there is an immediate decrease in metabolic rate, followed by a gradual increase. The result is an inverse relationship between acclimation temperature and metabolic rate at a given measurement temperature (fig. 5.2).

Often this pattern is not apparent in animals acclimated to temperatures below the normal activity range. For example, in many species, acclimation to 5° C either produces a decrease in metabolic rate, or very little change (fig. 5.2). Similar patterns are found in anurans that are active at relatively cool temperatures. *Pseudacris triseriata* exhibits an inverse relationship between acclimation temperature and metabolic rate at measurement temperatures of 20–30° C (Dunlap 1980). When these frogs are acclimated to very low temperatures, they exhibit a marked decrease in metabolic rate, particularly when measured at low temperatures (Packard 1972). *Bufo woodhousii* shows the same pattern at 10–20° C, but warm-acclimated animals have reduced metabolic rates when measured at 25° C (Fitzpatrick and Atebara 1974). Tadpoles of the Australian frog *Limnodynastes peronii,* which often overwinter, do not show acclimation of resting metabolic rate to low temperature (E. Marshall and Grigg 1980). Nevertheless, they do exhibit acclimation of both aerobic and anaerobic metabolic enzymes, perhaps allowing tadpoles to maintain slow but steady growth during the winter (Rogers, Seebacher, and Thompson 2004).

Amphibians that are active at higher temperatures often do not exhibit the classic pattern of partial metabolic compensation seen in plethodontid salamanders. For example, in a number of species, including *Triturus alpestris, Salamandra atra, Ambystoma tigrinum, Acris crepitans, Bufo boreas,* and several species of *Rana,* acclimation of summer-collected animals to warm temperatures actually results in higher metabolic rates at moderate to warm measurement temperatures than in animals acclimated to cooler temperatures. In some cases, just the opposite response is seen in winter-collected animals (Dunlap 1969, 1971, 1972, 1980; Harri 1973; Holzman and McManus 1973; Knapp 1974; Weathers 1976; Carey 1979b; Burggren and Wood 1981; Feder 1982a). Tropical amphibians generally exhibit little or no acclimation response, although only a few species have been studied in detail (Feder 1978b, 1982a, 1987; Navas 1996c).

The results of laboratory acclimation studies often are used as a basis for discussing the adaptive significance of acclimation in the field. Putative benefits usually include energy conservation and metabolic efficiency. For example, most authors assume that a reduction in metabolic rate in animals exposed to warm temperatures helps to conserve energy during the summer. Increased metabolism in animals exposed to cool temperatures would enable them to be active and acquire food in the spring or fall at temperatures that would incapacitate them in summer. The reduction in metabolism in animals exposed to cold, such as that seen in *Pseudacris* and many plethodontids, usually is considered a mechanism to conserve energy during winter dormancy (Fitzpatrick, Bristol, and Stokes 1971, 1972; Packard 1972; Fitzpatrick 1973a, b; Fitzpatrick and Brown 1975; A. Brown and Fitzpatrick 1981a, b; Feder 1978b, 1985a, b; Feder et al. 1984). On the other hand, the higher metabolic rates seen in some warm-acclimated animals at moderate temperatures have been interpreted as adaptations to reduce the temperature-sensitivity of metabolism in the face of fluctuating environmental temperatures (Dunlap 1971, 1972).

Although these adaptive explanations often seem plausible, few of the proposed fitness benefits of acclimation have been rigorously quantified. Furthermore, many laboratory studies have not controlled for differences in activity inside metabolic chambers; hence, the higher metabolic rates seen in some warm-acclimated animals could be due to increased movement at higher temperatures (Rome et al. 1992). Functional interpretations of acclimation responses also are complicated by inconsistencies among species that appear to have similar ecological requirements. For example, Fitzpatrick and his colleagues studied metabolic responses to temperature acclimation in *Desmognathus fuscus, D. ochrophaeus,* and *Eurycea bislineata,* all collected in the same ravine. All three species showed similar types of acclimation responses, but the magnitude of the responses varied, being greatest in *D. ochrophaeus,* intermediate in *D. fuscus,* and least in *E. bislineata* (fig. 5.2). These differences were attributed to the last two species being more aquatic than the first and therefore subject to less pronounced fluctuations in temperature (Fitzpatrick, Bristol, and Stokes 1971, 1972; Fitzpatrick 1973b), but this interpretation is largely speculative. Feder (1985a) found similar differences in the rate and magnitude of thermal acclimation in two fully terrestrial plethodontids, *Plethodon cinereus* and *P. metcalfi.*

Another problem is that temperature regimes to which amphibians are acclimated in the laboratory do not always resemble those encountered in the field. Carey (1979b) compared acclimation responses of *Bufo boreas* subjected to a fluctuating temperature regime with those of animals acclimated to constant temperatures of 10°, 20°, and 30° C. She found that the fluctuating regime produced an acclimation response quite different from the constant regimes, but did not necessarily reflect the metabolic responses of toads subjected to natural temperature fluctuations in field enclosures. Furthermore, responses to the different experimental treatments were not consistent even between two populations of the same species. In a rather complicated experiment, Feder (1985a, b) subjected several species of plethodontid salamanders to acclimation regimes that differed in the magnitude and period of temperature fluctuation. Acclimation responses differed considerably among experimental temperatures and among species, making it difficult to place the results in a simple ecological context. In many cases, the apparent energy savings resulting from metabolic acclimation were minimal under a fluctuating temperature regime, calling into question the standard adaptive explanations for such responses.

In general, acclimation of metabolism is viewed as a means of compensating for the effects of temperature variation in a seasonal environment, thereby enabling amphibians to engage in normal activities over a relatively wide range of temperatures without suffering major reductions in performance. If this is true, then one might expect acclimation in the laboratory to have similar effects on resting and activity metabolism. In fact, thermal acclimation often appears to have different effects on resting metabolism, activity metabolism, and locomotor performance, even in the same species (Rome et al. 1992). For example, acclimation of *Desmognathus ochrophaeus* to 21° C reduced both resting and activity metabolism at 13° C, but had no effect on the maximum sustainable speed of locomotion measured on a treadmill. When animals were measured at 21° C, acclimation did not affect metabolic rate, but did influence stamina (Feder 1986).

In contrast, acclimation temperature had no effect on resting metabolism, activity metabolism, or maximum speed of locomotion at 13° C in a tropical plethodontid, *Bolitoglossa subpalmata* (Feder 1987). Studies of other urodeles, including *Necturus* and *Ambystoma,* generally have shown little or no effect of acclimation on locomotor performance or muscle activity (K. Miller 1982; Else and Bennett 1987). In anurans, thermal acclimation generally has little effect on activity metabolism (Carey 1979b), muscle contraction (Rome 1983; Renaud and Stevens 1981, 1984), or locomotor performance (Putnam and Bennett 1981; K. Miller 1982; Renaud and Stevens 1983b; K. Miller and Zoghby 1986; Whitehead et al. 1989). When acclimation effects are evident, they often vary in magnitude and even in direction, depending on the species involved, test temperature, and the measure of locomotor performance used (Renaud and Stevens1983b; K. Miller and Zoghby 1986; Londos and Brooks 1988). Hence, there does not appear to be a consistent relationship between metabolic acclimation in the laboratory and other measures of behavioral or physiological performance.

Metabolism of Active Amphibians

Early studies of amphibian energetics focused almost exclusively on resting or routine metabolic rates and ignored increases in metabolism needed to support activity. Indeed, some authors constructed detailed energy budgets for amphibians based entirely on resting metabolic rates, with no allowance for increases due to activities such as foraging, searching for mates, territorial defense, or calling (e.g., Merchant 1970; Fitzpatrick 1973a; Burton and Likens 1975a, b; G. Smith 1976). For relatively sedentary species such as plethodontid salamanders, time spent in vigorous activity is such a trivial proportion of an animal's annual time budget that such costs can be safely ignored in calculations of energy budgets. For active foragers, or frogs that call vigorously for many days or weeks, however, the metabolic costs of activity can be considerable. If these are not included in an energy budget, the result can be a gross underestimate of respiratory costs and an overestimate of the amount of energy available for production of new tissue (Seale 1987). Since the early 1970s, physiological ecologists have paid more attention to measuring metabolic rates of active amphibians. We now have a substantial number of measurements of metabolic rates during forced activity (reviewed in Gatten, Miller, and Full 1992), and a small but growing set of metabolic measurements made on animals engaged in natural activities (reviewed in Pough et al. 1992).

Methods for Measuring Activity Metabolism

Several methods have been used to induce bouts of vigorous activity in amphibians. These were reviewed in some detail by Gatten, Miller, and Full (1992) and will be discussed only briefly here. Some workers have stimulated aquatic amphibians to swim by prodding them manually (Hillman and Withers 1981; Withers and Hillman 1981; Pinder and Burggren 1986) or subjecting them to mild electric shocks (Hutchison, Turney, and Gratz 1977; Preslar and Hutchison 1978; K. Miller and Hutchison 1979; Boutilier, McDonald, and Toews 1980). Cushman, Packard, and Boardman (1976) exercised salamanders (*Ambystoma tigrinum*) by having them swim in a moving current in a water tunnel, but they measured only the accumulation of lactic acid, not rates of oxygen consumption. Jiang and Claussen (1992) developed an aquatic respirometer with a circular tube in which a moving magnetic stirrer was used to prod a newt into continuous swimming around the chamber.

Many early studies of activity metabolism in terrestrial amphibians relied on mild electric shocks to elicit vigorous exercise (Bennett and Licht 1973; Bennett and Wake 1974; Turney and Hutchison 1974; Feder 1977, 1978a, b; K. Miller and Hutchison 1980). This technique was largely abandoned after Hillman et al. (1979) showed that it could lead to serious underestimates of aerobic metabolism and overestimates of the importance of anaerobic metabolism in supporting activity. This was particularly true when electric shock stimulation was combined with manometric methods for measuring oxygen consumption that are based on changes in the volume of gas in a chamber. Heating of the air in the chamber by the electric stimulator and by the activity of the animal causes the gas to expand, thereby underestimating the amount of oxygen consumed. The use of these techniques led to the erroneous conclusion that vigorous activity is supported mainly by anaerobic metabolism, with increases in oxygen consumption occurring only during a postactivity recovery period (Bennett and Licht 1973; Bennett and Wake 1974; Feder 1977, 1978a). Later work showed this not to be true (Hillman et al. 1979; Withers 1980; Gatten 1987a).

Most investigators have exercised animals in rotating chambers that are turned manually (Hillman 1976, 1980b, 1982b, 1987; Hillman et al. 1979; Hillman and Withers 1979, 1981; Withers 1980; Loveridge and Withers 1981; M. Ryan, Bartholomew, and Rand 1983; Withers and Hillman 1983; Sullivan and Walsberg 1985; Walsberg, Lea, and Hillman 1986; Withers, Hillman, Simmons, and Zygmunt 1988; Withers et al., Lea, Solberg, Baustian, and Hedrick, 1988; Prestwich, Brugger, and Topping 1989; Stefanski, Gatten, and Pough 1989) or with a variable-speed motor (Seymour 1973c; Harlow 1978; Carey 1979a, b; McDonald, Boutilier, and Toews 1980; K. Miller and Hutchison 1980; Taigen and Pough 1981, 1983; Taigen, Emerson, and Pough 1982; Pough and Kamel 1984; Taigen and Beuchat 1984; Wells and Taigen 1984; Taigen and Wells 1985; Taigen, Wells, and Marsh 1985; Feder 1986, 1987; Mitton, Carey, and Kocher 1986; Gatten 1987a; Walton 1988; Navas 1996c; Rogowitz and Sánchez-Rivoleda 1999). Rotation of the chamber causes the animal to hop, crawl, or make continual attempts to keep itself upright.

There has been some debate about whether manual or motorized rotation yields a more accurate estimate of maximum aerobic capacity for locomotor activity. Walsberg (1986) reported that manual rotation produced higher estimates of aerobic metabolism than motorized rotation for three species of anurans, but Rogowitz and Sánchez-Rivoleda (1999) reported the opposite pattern for *Eleutherodactylus cooki*. The motorized chambers used by both of these investigators were rotated at a constant speed throughout the exercise period. Most other investigators have adjusted rotation speed to ensure that the animal continues to right itself and does not simply tumble passively inside the chamber (e.g., Seymour 1973c; Taigen and Pough 1981, 1983; Taigen, Emerson, and Pough 1982; Pough and Kamel 1984; Wells and Taigen 1984; Taigen and Wells 1985; Taigen, Wells, and Marsh 1985; Gatten 1987a; Navas 1996c). Therefore, the constant-speed rotation method has not been widely used by other workers, and Walsberg's results do not necessarily indicate that these studies have underestimated aerobic capacity for locomotor activity. Both Walsberg (1986) and M. Ryan (1988b) suggested that problems with methods used to elicit locomotor activity might account for reports that metabolic rates during forced exercise in several species of frogs are lower than metabolic rates during peak calling activity (Taigen and Wells, 1985; Taigen, Wells, and Marsh 1985). Prestwich, Brugger, and Topping (1989) refuted this hypothesis by showing that peak metabolic rates of calling frogs were substantially higher than those obtained when the animals were exercised by manual rotation (see subsequent discussion).

Exercising animals in rotating chambers has proved to be a reliable way of measuring maximum aerobic capacity during nonsustainable locomotion, but it is difficult to quantify precisely the animal's rate of movement with this method or to elicit submaximal levels of locomotion. Some investigators have used motorized treadmills enclosed in metabolic chambers to study the energetics of sustained locomotion (Full 1986; Full et al. 1988; Walton 1988, 1993; Walton and Anderson 1988; B. Anderson, Feder, and Full 1991; Longphre and Gatten 1994; Walton, Peterson, and Bennett 1994). These studies have employed an electrochemical oxygen analyzer to measure continuous changes in oxygen consumption in a flow-through respirometry system, whereas the studies with rotating chambers have relied on a single pair of pre- and postexercise air samples taken from a closed respirometer. The treadmill system allows the investigator to follow the time-course of oxygen consumption as the animal exercises and to calculate the maximum speed at which locomotion can be supported entirely by aerobic metabolism. It also makes possible measurements at relatively low speeds that more closely approximate natural rates of movement in the field. Data collected in this way probably provide a more reliable estimate of the energetic costs of activities such as foraging than data collected from animals exercised to exhaustion (Gatten, Miller, and Full 1992). Animals can be exercised to exhaustion on a treadmill as well. Most measurements of maximum metabolic rates using this technique are similar to those obtained using chambers rotated by hand or with a motor (Walton 1988; Walton and Anderson 1988; Prestwich, Brugger, and Topping 1989), but Walton, Peterson, and Bennett (1994) obtained lower values for toads exercised on a treadmill than for those exercised in rotating chambers.

Sources of Variation in Activity Metabolism

Gatten, Miller, and Full (1992) tabulated all of the available data on maximum metabolic rates of amphibians during forced activity and calculated regressions of metabolic rate on body mass using only those data collected with rotating chambers or treadmills. At 20° C, the scaling of aerobic activity metabolism with body mass is similar to the scaling of resting metabolism for both urodeles and anurans, but anurans have consistently higher metabolic rates during vigorous activity. In general, most salamanders cannot elevate their metabolic rates to more than three or four times resting metabolism at 20–23° C, although factorial scopes (the ratio of activity metabolism to resting metabolism) greater than 10 have been reported for some species at 13–15° C (Feder 1986, 1987; Mitton, Carey, and Kocher 1986). Many anurans can achieve rates of metabolism more than 10 times resting levels at 20° C, and some have factorial scopes greater than 35 (fig. 5.3), considerably higher than those of most mammals and reptiles (Bennett and Dawson 1976; Lechner 1978; Taigen 1983). Large species tend to have higher factorial scopes than small species when all anurans are combined (Gatten, Miller, and Full 1992), but this is not necessarily true within families. For example, *Pseudacris crucifer* (1.3 g), *Hyla arenicolor* (3.4 g), and *Hyla versicolor* (6.1 g) all have factorial scopes between 9 and 10 at 20° C (Taigen, Emerson, and Pough 1982; Kamel, Marsden, and Pough 1985). Aerobic capacity increases with temperature in both anurans and urodeles, but the precise degree of temperature sensitivity has not been determined for urodeles because of insufficient data. For anurans, Q_{10} values for both aerobic capacity and aerobic scope range from about 1.5 to 4.5, with sensitivity being greatest at low temperatures (Gatten, Miller, and Full 1992).

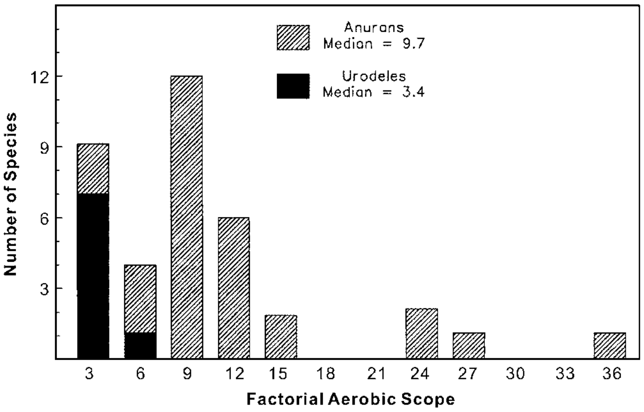

Fig. 5.3. Distribution of factorial aerobic scopes for eight species of urodeles and 30 species of anurans measured at 20–22° C. Numbers under each bar are midpoints for each interval. Urodele data are combined for one species each of *Ambystoma, Amphiuma,* and *Taricha,* two species of *Desmognathus,* and three species of *Plethodon.* Anuran data include one species each of *Agalychnis, Bombina, Dendrobates, Discoglossus, Eleutherodactylus, Gastrophryne, Hyperolius, Kaloula, Odontophrynus, Osteopilus, Pseudacris, Pternohyla, Pyxicephalus,* and *Spea.* Also included are two or more species of *Bufo, Colostethus, Hyla, Kassina,* and *Rana.* Plotted from data in tables 12.7 and 12.13 in Gatten, Miller, and Full (1992).

One might expect that the greater aerobic capacity of anurans would allow them to move at higher speeds than urodeles, but an analysis of published and unpublished data by Gatten, Miller, and Full (1992) showed that maximum aerobic speeds did not differ significantly for walking salamanders and hopping frogs and toads. Apparently this is because the cost of locomotion is much higher at any given speed for anurans than for salamanders. For example, a toad (*Bufo fowleri*) moving at its maximum aerobic speed of 0.27 km/h has a metabolic rate about nine times its resting rate (Walton and Anderson 1988). A salamander (*Ambystoma laterale*) moving at a similar speed (0.20 km/h) would have a metabolic rate only about 36% as high, or about four times its resting rate (Full et al. 1988). Indeed, the cost of transport (the energy required to move a given amount of body mass) is relatively high in anurans compared to other vertebrates. For example, the cost of hopping by toads is about twice as high as the cost of running in lizards of the same body mass (Walton and Anderson 1988), whereas the cost of walking by salamanders is considerably lower than that for lizards (Full et al. 1988). The cost of transport also is higher for a hopping or swimming toad (*Bufo marinus*) than for a walking or swimming turtle (*Emydura macquari;* Baudinette, Miller, and Sarre 2000). In part, this is due to a difference in body size, because it is more expensive for a small animal than for a large animal to move a given amount of body mass.

Compared to other terrestrial vertebrates, amphibians do not have much capacity to sustain rapid locomotion. Maximum aerobic speeds of the few species studied to date are one to three orders of magnitude lower than those of mammals or lizards of similar size (Feder, 1986; Full et al. 1988; Walton and Anderson 1988; Gatten, Miller, and Full 1992). Similar differences have been found in comparisons of maximum rates of movement by lizards and frogs engaged in natural foraging behavior (Pough et al. 1992).

The energetic cost of locomotion can be affected by changes in the gaits of animals. Some amphibians rely exclusively on one type of locomotion, such as walking, whereas others, including some toads, switch from walking to hopping at faster movement speeds. B. Anderson, Feder, and Full (1991) measured the cost of locomotion in toads using mixed gaits and those using only walking or hopping gaits. They found that individual hops are more expensive than individual strides during walking, but the distance covered by a hop is greater. This resulted in the cost of transport being about half as great for hopping toads as for walking toads. Toads can therefore save energy by switching to the more economical hopping gait at faster speeds. Some toads, such as *Bufo boreas halophilus,* never hop, but switch from walking to running at high speeds. Walton, Peterson, and Bennett (1994) predicted that this would result in a higher cost of transport at high speeds and perhaps a higher maximum aerobic capacity, but in fact, this species was not very different from other toads that hop. Thus, walking does not appear to be an especially costly form of locomotion, at least in toads, and species that move mainly by walking do not necessarily have higher aerobic capacities than those that combine walking and hopping.

All frogs have lungs, and in most species, lungs are the principal site of oxygen uptake (see chapter 4). Many salamanders, including the entire family Plethodontidae, lack lungs, and one might expect the reduced respiratory surface area in lungless species to limit their ability to increase oxygen consumption during vigorous exercise. The problem would be particularly acute for large individuals, which have higher oxygen demands but relatively lower surface-to-volume ratios. Indeed, comparisons of metabolic rates of ambystomatid salamanders and one large plethodontid, *Desmognathus quadramaculatus,* exercised on a treadmill showed that the ambystomatids had higher maximum metabolic rates, higher factorial aerobic scopes, and higher maximum aerobic speeds. *Desmognathus quadramaculatus* was exhausted in less than 20 minutes by rates of movement that ambystomatid salamanders could sustain for one to two hours. Smaller lungless species, such as *D. ochrophaeus,* appear to be less constrained by their lack of lungs and achieve higher maximum aerobic speeds than *D. quadramaculatus.* The degree to which the activities of lungless salamanders are limited in the field is uncertain, because it is not clear how frequently they are called upon to move as quickly as the speeds used in the treadmill studies (Full et al. 1988).

Individual Variation in Activity Metabolism and Behavior

Because adaptive evolutionary change depends on natural selection operating on variation among individuals in a population, studies of individual variation in physiological capacities are essential for understanding the relationships between physiological characteristics and individual fitness (Pough 1989). Unfortunately, the study of individual variation has been largely neglected by physiologists (Bennett 1987). Several investigators have begun to document individual variation in metabolic physiology or morphology in reptiles and have attempted to relate this to variation in behavioral performance (Garland 1984, 1985, 1988; Garland and Else 1987; Garland, Hankins, and Huey 1990), but relatively few such data are currently available for amphibians.

Replicated laboratory measurements of aerobic capacity, sprint speed, or stamina have revealed consistent differences among individual salamanders and frogs from the same population (data of Taigen, cited in Pough 1983; Wells and Taigen 1984; Sullivan and Walsberg 1985; Walsberg, Lea, and Hillman 1986; Walton 1988; Bennett, Garland, and Else 1989; Austin and Shaffer 1992; Rogowitz and Sánchez-Rivoleda 1999; Gomes et al. 2004). Other investigators have assumed that such differences among individuals exist, but did not present formal statistical analyses of intra- and interindividual variation (Marker and Gatten 1993; Longphre and Gatten 1994; Watkins 1996). Several studies also have documented individual variation in the behavior of animals in the field, based on such measures of performance as movement at a breeding site (Wells and Taigen 1984), calling rate (B. K. Sullivan 1983b; Wells and Taigen 1984; B. K. Sullivan and Walsberg 1985; Runkle et al. 1994) or foraging velocity (Walton 1988; Pough and Taigen 1990).

Only a few studies have attempted to correlate individual variation in behavioral performance with laboratory measures of physiological capacity. In some cases, aerobic capacity was not correlated with field measurements of behavioral performance. In the study of toads by Walton (1988), locomotor velocities of foraging toads in the field were much lower than were those of animals exercised to exhaustion in laboratory chambers. This suggests that toads engaged in routine foraging probably do not approach their physiological limits, and a close correlation between aerobic capacity and behavioral performance would not be expected. Wells and Taigen (1984) found that movements of male toads in breeding ponds were not correlated with laboratory measures of aerobic capacity. Again, velocities of searching males probably were too low to stress the animals physiologically. Both Wells and Taigen (1984) and Sullivan and Walsberg (1985) reported that calling rates of toads were not correlated with aerobic capacities measured during forced exercise. Subsequent work revealed that the aerobic capacities of muscles used for call production are much higher than those used for locomotion (Pough et al. 1992), so one would not necessarily expect a close relationship between aerobic capacity for locomotion and calling rate (see subsequent discussion of calling energetics).

The Role of Anaerobic Metabolism

Most routine, low-intensity activities in amphibians probably are supported mainly by aerobic metabolism. Anaerobic metabolism can be important during bursts of high-intensity activity, when the demand for adenosine triphosphate (ATP) production in the muscles exceeds the capacity of the respiratory and circulatory systems to supply oxygen to the tissues (Bennett 1978; Gatten 1985; Gatten, Miller, and Full 1992). Most work has focused on anaerobic glycolysis, yielding lactic acid as an end product, but another anaerobic pathway contributes to the first few seconds of burst locomotion. This involves the direct utilization of stored high-energy phosphates, particularly phosphocreatine, to generate ATP. K. Miller and Sabol (1989) found that *Xenopus laevis* forced to swim at maximum speeds depended mainly on breakdown of phosphocreatine to supply energy in the first few seconds of swimming, with rates of ATP production through this pathway being about nine times the rate of ATP production from anaerobic glycolysis. Phosphocreatine stores in muscles are quickly exhausted, so anaerobic glycolysis is essential for continued activity. The breakdown of phosphocreatine also is an important source of energy during rapid burst swimming in some anuran tadpoles (Gatten, Caldwell, and Stockard 1984).

The role of anaerobic glycolysis in supporting vigorous activity in amphibians generally has been studied by exercising animals at maximal rates for several minutes and then homogenizing the animal to determine whole-body lactate levels. Measurements of lactate concentrations in blood do not provide a satisfactory quantitative estimate of anaerobic metabolism because of variable rates of lactate accumulation in different tissues (Gatten, Miller, and Full 1992). Unfortunately, this means that lactate accumulation cannot be measured in the same individual before and after activity, and investigators must rely on separate pre- and postactivity samples. This approach has shown that capacities for anaerobic ATP production vary considerably among species of amphibians subjected to similar exercise regimes. Species that move mainly by rapid jumping, such as *Rana pipiens,* or by flipping the body to escape from predators, such as *Plethodon jordani,* can derive more than 60% of their energy during vigorous exercise from anaerobic glycolysis. In contrast, species that move at slower, more sustained rates, such as *Bufo americanus* or *Physalaemus pustulosus,* generally have much lower capacities for anaerobic ATP production and rely more heavily on aerobic metabolism. Some of the variation in dependence on aerobic and anaerobic metabolism during vigorous exercise appears to be related to ecological differences among species, and these are discussed in more detail later.

The principal advantage of anaerobic metabolism for amphibians is that it provides high power output more rapidly than is possible through aerobic pathways. In addition, the temperature sensitivity of anaerobic metabolism generally is lower than for aerobic metabolism, making it especially useful to amphibians when they are cold (Bennett 1978; Gatten 1985; Gatten, Miller, and Full 1992). Anaerobic glycolysis is not, however, completely independent of temperature. In *Rana pipiens,* for example, total whole-body lactate accumulation, an index of anaerobic glycolysis, increased with both temperature and duration of exercise. The rate of lactate formation was much greater during short bursts of activity than during longer bouts, especially at high temperatures, and jumping performance improved at warm temperatures (Wine and Gatten 1992).

The disadvantage of anaerobic metabolism is that animals fatigue very quickly and require up to an hour of rest before recovering full locomotor capabilities after a bout of vigorous exercise (Rand 1952; Bennett and Licht 1973; Feder and Olson 1978; Putnam 1979; Zug 1985; Gatten and Clark 1989; Rogowitz and Sánchez-Rivoleda 1999). The physiological basis of fatigue is not fully understood. Fatigue does not appear to be due solely to accumulation of lactate in muscle tissue, because recovery of locomotor abilities precedes complete elimination of lactate (Bennett and Licht 1973; Feder and Olson 1978; Putnam 1979; Gatten and Clark 1989; Gatten, Miller, and Full 1992). It also cannot be attributed to depletion of glycogen stores, which sometimes show little change after brief bouts of exhaustive locomotion (Putnam 1979). Whatever the proximate basis of fatigue, the limited endurance of animals utilizing anaerobic metabolism means that only those activities that are supported by aerobic metabolism can be sustained for long periods of time.

Amphibians use anaerobic glycolysis during short bursts of activity when escaping from predators (Feder and Arnold 1982) or in fighting over territories (Wells 1978a), but it seems unlikely that anaerobic metabolism plays an important role in supporting other routine activities such as migratory movements, foraging, or courtship. Significant increases in whole-body lactate have been reported following bouts of courtship in a salamander, *Desmognathus ochrophaeus,* and nest-building in a frog, *Physalaemus pustulosus,* but in both cases, anaerobic glycolysis accounted for less than 10% of total ATP production (Bennett and Houck 1983; M. Ryan, Bartholomew, and Rand 1983). Anaerobic metabolism also makes an insignificant contribution to calling activity (see the following discussion). Early studies of diving in anurans suggested that frogs might depend on anaerobic metabolism during prolonged submersion (e.g., D. Jones 1967, 1972; Emilio and Shelton 1974). Subsequent work with *Xenopus* showed that significant lactate accumulation occurs during forced dives, whereas voluntary dives appear to be almost entirely aerobic (Boutilier and Shelton 1986a, c; Boutilier 1989). These results parallel those obtained for voluntarily diving lizards, turtles, and snakes (Seymour 1982; Gatten 1985).

In addition to using anaerobic metabolism to support locomotor activity, some animals rely on anaerobic pathways for survival under hypoxic or anoxic conditions. This is particularly common in many aquatic invertebrates, but occurs in some vertebrates as well (De Zwaan and Thillart 1985). For example, some freshwater turtles that hibernate in anoxic mud at the bottom of ponds can survive entirely by means of anaerobic glycolysis and accumulate enormous quantities of lactate (see Gatten 1987b and Ultsch 1989 for reviews). A number of studies have shown that amphibians placed in anoxic conditions in the laboratory can survive for extended periods on anaerobic metabolism alone and exhibit significant accumulations of lactate (F. Rose and Drotman 1967; Armentrout and Rose 1971; F. Rose, Armentrout, and Roper 1971; Christiansen and Penney 1973). It has been suggested that this might be important during winter dormancy, but in fact, we do not have any data on lactate accumulation in overwintering amphibians in the field. The very low metabolic rates of dormant amphibians and their ability to take up oxygen through the skin probably reduce their dependence on anaerobic metabolism. Nevertheless, anaerobic glycolysis is essential in species of anurans that tolerate freezing, including *Rana sylvatica* and *Hyla versicolor,* because it provides the energy for synthesis of glucose and glycerol used as cryoprotectants (K. Storey and J. Storey 1984, 1986b; J. Storey and K. Storey 1985a; K. Storey 1987a; see chapter 3 for further discussion).

Ontogenetic Changes in Energy Metabolism

When amphibian larvae first hatch from their eggs, their capacities for movement are severely limited because muscles, the cardiovascular system, and metabolic capacities are poorly developed. Both aerobic and anaerobic metabolic capacities probably develop gradually as the larvae grow, but changes in activity metabolism have not been well documented for larval amphibians. The metabolic rates of actively swimming *Bufo fowleri* tadpoles were only about three times those of tadpoles engaged in routine activities (Feder 1983a). This difference probably underestimates aerobic capacities for locomotion, because it is difficult to obtain a true resting metabolic rate for tadpoles. Nevertheless, the capacity of tadpoles to sustain activity aerobically clearly is far below that of adult toads. Factorial aerobic scope did not change significantly with increasing body size in this species, presumably because they do not develop lungs until just before metamorphosis and therefore can do little to increase rates of oxygen consumption. Hillman and Lea (1983) did find an increase in activity metabolism as a function of developmental stage in *Rana catesbeiana* tadpoles, a species that develops lungs well before metamorphosis. Their experiments were ecologically unrealistic, however, because the tadpoles were exercised in air, with only a small amount of water to keep them moist.

Because of their low aerobic capacities, most tadpoles probably depend on anaerobic metabolism to support vigorous activity and therefore are limited in how long such activity can be sustained. Tadpoles also appear to have rather low capacities for ATP production by means of anaerobic glycolysis during short bursts of swimming. Instead, they must depend heavily on breakdown of stored phosphocreatine, and therefore probably are limited to a few seconds of vigorous activity at a time (Gatten, Caldwell, and Stockard 1984). At slower swimming speeds, tadpoles do accumulate lactate (Quinn and Burggren 1983). They also have some capacity to use anaerobic metabolism when exposed to hypoxic conditions, but generally do so only if they are not able to breathe air (Feder 1983a, d).

Watkins (1996) examined the effect of burst swimming speed on the ability of tadpoles (*Pseudacris regilla*) to escape from predators. He first measured sprint speed in plastic troughs and divided tadpoles into fast and slow groups. Only those that differed considerably in speed were used in subsequent experiments. The tadpoles were marked with dye and released into swimming pools with garter snakes (*Thamnophis sirtalis*) as predators. Tadpoles from the fast group were more likely to survive than were those from the slow group. Those that escaped predation swam away from snakes nearly twice as fast as those that were captured. These results suggest a strong potential for predator-mediated selection on burst swimming speed in tadpoles, assuming that there is some genetic variation for physiological or morphological traits that affect swimming speed.

After metamorphosis, anuran species differ in the rate at

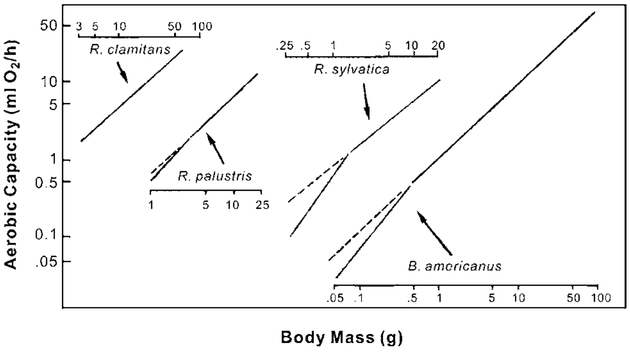

Fig. 5.4. Ontogenetic change in aerobic capacity in four species of frogs. Rates of oxygen consumption during exercise are presented on logarithmic scales as a function of body mass. Body mass for each species is shown on a separate horizontal scale. Dashed lines extend slopes for postdispersal individuals to body size range of predispersal juveniles. *Rana sylvatica* and *Bufo americanus* metamorphose with relatively poorly developed aerobic capacities and exhibit a rapid increase before dispersal. After Taigen and Pough (1985).

which their metabolic capacities develop. In species with long larval periods, such as *Rana clamitans,* the lungs and circulatory system are fully functional when the young frogs emerge onto land, and the aerobic capacities of juvenile frogs are indistinguishable from those of adults. In contrast, species that breed in temporary water, such as *Bufo americanus* and *Rana sylvatica,* are under strong selective pressures to leave the water quickly. They emerge in a physiologically underdeveloped state, with poorly developed lungs, small hearts, and low hematocrits. They have relatively low aerobic capacities immediately after metamorphosis, but their performance improves with age (fig. 5.4). *Rana palustris* is somewhat intermediate, with juveniles having slightly lower aerobic capacities than adults, but similar endurance (Taigen and Pough 1981, 1985; Pough 1983; Pough and Kamel 1984). It seems likely that similar patterns of ontogenetic change in physiological performance correlated with differences in breeding ecology and timing of metamorphosis occur in other families of anurans and would be a productive area for future research.

Morphological Correlates of Activity Metabolism

Vertebrate muscles typically exhibit morphological features that are closely related to the type of work the muscles must perform. Species that engage in sustained periods of exercise have muscles with fiber types, contractile properties, mitochondrial densities, and capillary supplies that enable them to meet demands for high levels of sustained aerobic activity. This correspondence between muscle structure and function is evident in comparisons of anurans with different modes of locomotion. The leg muscles of anurans are composed primarily of fast glycolytic fibers (about 75–80% of total muscle area), but some fast oxidative fibers are present as well (R. S. Smith and Ovalle 1973; Putnam and Bennett 1983; R. Marsh and Taigen 1987; De Costa et al. 1989; Gans and De Gueldre 1992; Wilson et al. 2004). The former depend on anaerobic glycolysis to supply their energy requirements, whereas the latter make use of aerobic pathways. Comparisons among species of *Hyla, Rana, Bufo,* and *Xenopus* have revealed only minor variation in gross fiber type that can be related to differences in mode of locomotion (Putnam and Bennett 1983; R. Marsh and Taigen 1987). However, Mendiola, De Costa, Lozano, and Agulleiro (1991) reported that leg muscles of *Bufo* have higher proportions of fast oxidative and tonic fibers than do leg muscles in *Rana.* The muscles of these two genera also differ in contractile properties. Leg muscles in *Rana pipiens* have relatively fast shortening velocities and high mechanical power under low loads. Muscles of *Bufo americanus* have slower shortening velocities and greater tetanic tension, providing more mechanical power under high loads, such as the animal might experience while burrowing (Renaud and Stevens 1983a).

Biochemical Correlates of Activity Metabolism

The activities of enzymes involved in catalyzing reactions in anaerobic glycolysis or the Krebs cycle often are used as indicators of an animal's dependence on anaerobic or aerobic metabolism to support muscular work (Alp, Newsholme, and Zammit 1976; Holloszy and Booth 1976; Hochachka and Somero 1984). In studies of amphibians, the glycolytic enzymes phosphofructokinase (PFK), pyruvate kinase, lactate dehydrogenase (LDH), phosphorylase, and hexokinase (HK) have been used to investigate the relationship between enzyme activities and anaerobic capacity. The Krebs cycle enzymes citrate synthase (CS) and oxoglutarate dehydrogenase (GDH) have been used as indicators of aerobic metabolism (Bennett 1974; J. Baldwin, Friedman, and Lillywhite 1977; Cummings 1979; K. Miller and Camilliere 1981; Newsholme and Paul 1983; Putnam and Bennett 1983; Taigen, Wells, and Marsh 1985; Walsberg, Lea, and Hillman 1986; R. Marsh and Taigen 1987; Molina, Mendiola, and De Costa 1987; Given and McKay 1990; Mendiola, Molina, and De Costa 1991; Choi and Park 1996; James et al. 2005). In addition, activities of lipases and β-hydroxylacyl-CoA dehydrogenase (HOAD) have been used as indicators of capacities to use lipids as an energy substrate during muscular activity (Newsholme and Paul 1983; R. Marsh and Taigen 1987).

In comparisons among species, aerobic enzyme activities in muscle tissue generally are correlated with dependence on aerobic metabolism. For example, Putnam and Bennett (1983) found that *Bufo boreas* and *Xenopus laevis* had higher leg-muscle CS activities than did *Rana pipiens.* These differences parallel differences in mode of locomotion in the three species: hopping in *Bufo,* swimming in *Xenopus,* and jumping in *Rana.* In contrast, Newsholme and Paul (1983) reported slightly higher CS activity in sartorius muscles of *Rana temporaria* than in the same muscles of *Xenopus,* but they found that GDH activities were much higher in leg muscles of *Xenopus.* They attributed this difference to the greater aerobic demands of swimming compared to jumping. Mendiola, Molina, and De Costa (1991) reported higher activities of glycolytic enzymes (HK, PFK, LDH) in leg muscles of *Rana perezi* than in the muscles of *Bufo calamita,* again correlating with the greater reliance on anaerobic metabolism in *Rana.* A comparison of LDH and CS activity in leg muscles of *Rana nigromaculata, Rana rugosa,* and *Bombina orientalis* did not yield a clear correlation with mode of locomotion. The two ranid species are jumpers, whereas *Bombina* is a walking or hopping species. The three species did not differ in LDH activity, but CS activity was higher in *R. rugosa* and *Bombina* than in *R. nigromaculata* (Choi and Park 1996). All of these comparisons suffer from a lack of phylogenetic control, because putative differences in mode of locomotion are confounded by differences in phylogenetic history. Comparisons among closely related species that differ in mode of locomotion would be preferable, but difficult in practice, because closely related species usually have similar morphology and behavior.

There has been very little work on individual variation in muscle enzyme activities among members of the same species. Walsberg, Lea, and Hillman (1986) did not find any correlation between CS activity and aerobic capacity for locomotion among individual bullfrogs (*Rana catesbeiana*) from a single population. Like most ranid frogs, this species probably relies heavily on anaerobic metabolism for short bouts of jumping, so one would not necessarily expect a correlation between CS activity and locomotor performance. James et al. (2005) also did not find a significant relationship between individual variation in CS activity and jumping performance in *Hyla multilineata.* There was a positive relationship between jumping performance and the glycolytic enzyme pyruvate kinase, as well as total hindlimb muscle mass. Longphre and Gatten (1994) worked with a more aerobic species, *Bufo marinus.* They found a positive correlation among individuals between maximum aerobic speed of locomotion and leg-muscle CS activity, as well as ventricle mass, and iliofibularis muscle mass. Rate of oxygen consumption, however, was not related to any of these variables or to several other morphological traits. In *Rana pipiens,* which relies heavily on anaerobic metabolism, individual variation in sprint speed was not related to variation in glycolytic enzyme activities (Marker and Gatten 1993).

Ecological and Behavioral Correlates of Activity Metabolism

Physiological ecologists have had some difficulty correlating laboratory measures of physiological performance with behavioral or ecological variables that affect individual fitness in the field (for general discussions, see Taigen and Pough 1985; Arnold 1988; Pough 1989; Pough et al. 1992; and several chapters in Feder et al. 1987). Laboratory measurements of aerobic capacity, anaerobic capacity, or stamina often require animals to perform tasks that do not accurately reflect modes or intensities of locomotor activity in the field. Nevertheless, a correlation between field and laboratory measurements can provide a starting point for understanding the interrelationships among physiology, morphology, ecology, and behavior.

The first attempt to compare the activity metabolism of several species of amphibians in an ecological context was the work of Bennett and Licht (1973, 1974) on a limited number of North American anurans (*Bufo boreas, Rana pipiens,* and *Pseudacris regilla*) and urodeles (*Batrachoseps attenuatus, Notophthalmus viridescens, Aneides flavipunctatus,* and *A. lugubris*). These investigators found a general dichotomy between species with relatively high aerobic capacities and low anaerobic capacities and those with relatively low aerobic capacities and high anaerobic capacities. Although the species studied differed in a number of respects, including body size and shape, mode of locomotion, foraging behavior, and antipredator behavior, Bennett and Licht focused mainly on differences in antipredator behavior. They suggested that species that depend mainly on passive defenses, such as toxic skin secretions, tend to move at relatively slow but steady rates and rely more on aerobic than anaerobic metabolism for locomotion. Conversely, those species that use rapid escape as their principal defense against predators were found to move mainly in short bursts of activity and relied more on anaerobic than aerobic metabolism.

The apparent relationship between antipredator behavior and dependence on aerobic or anaerobic metabolism remained the principal focus of studies of activity metabolism in amphibians for several years (e.g., J. Baldwin, Friedman, and Lillywhite 1977; Hutchison, Turney, and Gratz 1977; Bennett 1978, 1980; Hutchison and Miller 1979a, b; K. Miller and Hutchison 1979). Seymour (1973c), however, had previously suggested that any sustained activity, such as burrowing or active foraging, would be facilitated by a high aerobic capacity. Carey (1979a) argued that reliance on passive defenses and a lack of selection for high anaerobic capacity was an inadequate explanation for the high aerobic capacities of toads. She suggested that positive selection for high aerobic capacities was more likely, but did not specify what the selective pressures might be. Earlier, Emerson (1976) had pointed out that those species of anurans used by previous investigators as exemplars of the passive defense strategy (*Bufo* and *Scaphiopus*) also tended to be burrowing species that forage actively on small prey such as ants. Consequently, differences in mode of locomotion, foraging behavior, or burrowing might be just as important as mode of defense in determining metabolic characteristics of these animals.

These considerations led Taigen, Emerson, and Pough (1982) to examine ecological correlates of activity metabolism in a wider range of species from seven families. Using the same techniques for all species, they measured both aerobic and anaerobic capacities during brief bouts of vigorous exercise. These data were used to calculate an aerobic dependence index, an estimate of the relative importance of aerobic metabolism in supporting activity. Species also were classified as having active or passive antipredator behavior, active or sit-and-wait foraging behavior, jumping or nonjumping locomotion, and terrestrial or arboreal habits. Species placed in each ecological or behavioral category were then tested for statistical associations between the ecological variables and the aerobic dependence indexes.

Two major findings of this study failed to support the earlier conclusions of Bennett and Licht. First, the apparent negative correlation between aerobic and anaerobic capacities that Bennett and Licht found in a limited number of North American anurans disappeared in the larger sample of species. In fact, there was no clear relationship between these two variables (fig. 5.5), indicating that anurans do not cluster into two distinct groups of high aerobic/low anaerobic and low aerobic/high anaerobic species. Second, Taigen, Emerson, and Pough (1982) found that dependence on aerobic metabolism was not significantly associated with antipredator behavior, but was related to both foraging behavior and mode of locomotion. In general, active foragers that depend on walking rather than jumping are more aerobic in their metabolic characteristics than sit-and-wait predators that move mainly by rapid jumps. They also found that burrowing species form a subset of the walking, actively foraging anurans, and accounted for most of the difference in metabolic characteristics related to mode of locomotion. Taigen, Emerson, and Pough suggested that high dependence on aerobic metabolism also might be associated with the occurrence of intensive male combat and competition for territories, but they did not have sufficiently detailed data on aggressive behavior to test this hypothesis statistically. Phylogenetic differences did not explain much of the variation in metabolic characteristics, since variation within families was nearly as great as variation between families.

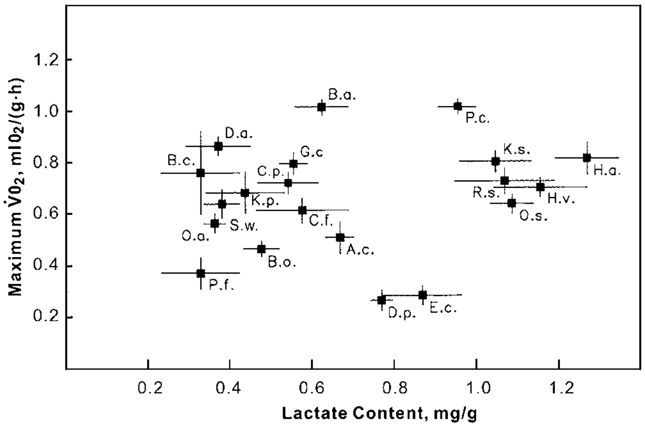

Fig. 5.5. Relationship of maximum aerobic capacity during exercise to whole-body lactate content after maximum exercise for 20 species of anurans. Species abbreviations: *A.c. = Agalychnis callidryas; B.a. = Bufo americanus; B.c. = Bufo calamita; B.o. = Bombina orientalis; C.f. = Colostethus flotator; C.p. = Colostethus panamensis; D.a. = Dendrobates auratus; D.p. = Discoglossus pictus; E.c. = Eleutherodactylus coqui; G.c. = Gastrophryne carolinensis; H.a. = Hyla arenicolor; H.v. = Hyperolius viridiflavus; K.p. = Kaloula pulchra; K.s. = Kassina senegalensis; O.a. = Odontophrynus americanus; O.s. = Osteopilus septentrionalis; P.c. = Pseudacris crucifer; P.f. = Pternohyla fodiens; R.s. = Rana sylvatica; S.w. = Semnodactylus wealii.* After Taigen, Emerson, and Pough (1982), with additional data for dendrobatid frogs from Taigen and Pough (1983).

The study by Taigen, Emerson, and Pough (1982) provided a new ecological framework for understanding the evolution of metabolic characteristics that emphasized the complexity of relationships between morphology, ecology, behavior, and physiology. This was subsequently adopted by other authors (e.g., Pough 1983; Duellman and Trueb, 1986; Seale 1987), but it should be considered only a starting point for future work. Much of the information on behavior and ecology available to these authors was based on descriptive studies and scattered natural history notes, so the quality of the ecological data did not match the detailed quantitative physiological data. They were forced to classify species into general ecological categories, but real ecological variation among species is more like a graded continuum. Anurans exhibit a spectrum of foraging modes rather than falling into two distinct categories of sit-and-wait and active foragers (Pough 1983; Strussmann et al. 1984; Pough et al. 1992; Toft 1995), and correlated morphological, behavioral, and dietary characteristics of species probably are similarly graded. Some species also exhibit considerable seasonal, annual, or geographic variation in diet that could cause them to be placed in different categories depending on when and where the data were collected (e.g., Toft 1980a, b, 1981; Strüssmann et al. 1984). Even antipredator behavior varies among populations or in response to different types of predators (Marchisin and Anderson 1978; Bajger 1980; Arnold 1982; Ducey and Brodie 1983; see also chapter 14) in ways that make very different demands on an animal's metabolic physiology (Pough 1983; Taigen and Pough

1985). Another limitation of the study by Taigen, Emerson, and Pough (1982) is the inclusion of a phylogenetically diverse array of species into a single analysis, leading to possible confounding of adaptive patterns with phylogenetic history (a common problem in nearly all comparative physiological studies of amphibians).

To address some of these problems, Taigen and Pough (1983) conducted a comparative study of three species of dendrobatid frogs (*Dendrobates auratus, Colostethus panamensis,* and *C. nubicola*) and one leptodactylid (*Eleutherodactylus coqui*). The dendrobatids are all relatively active, diurnal foragers, whereas *E. coqui* is a nocturnal sit-and-wait predator. By using previously published data on the diets of these species, Taigen and Pough showed that aerobic capacity during forced locomotion was positively correlated with a tendency to feed preferentially on ants. Although all three dendrobatids were much more dependent on aerobic metabolism than was *E. coqui,* the three species formed a graded series (fig. 5.6 A). *Dendrobates auratus* tended to specialize on ants and was the most aerobically dependent species, whereas the other two dendrobatids had more generalized diets and were intermediate in metabolic characteristics between *D. auratus* and *E. coqui.* Subsequent studies with these species and a fourth dendrobatid, *Colostethus talamancae,* demonstrated positive relationships between aerobic capacity, rates of movement, and number of prey capture attempts per hour (fig. 5.6 B). These data confirmed that the most active foragers are the most dependent on aerobic metabolism (Taigen and Pough 1985; Pough and Taigen 1990).

These studies, along with investigations of functional morphology in anurans (Emerson 1976, 1978, 1979, 1982, 1985, 1988a; Emerson and de Jongh 1980; Zug 1985), have shown that various aspects of morphology, mode of locomotion, burrowing behavior, foraging ecology, and activity metabolism are intercorrelated in a complex manner (see chapter 1). It is much more difficult to establish a clear cause-and-effect relationship among these variables. For example, when we find that an actively foraging species such as *Dendrobates auratus* has a high aerobic capacity, it is not clear whether that is because active foraging has favored the evolution of enhanced aerobic metabolism, or because active foraging is possible because of preexisting metabolic characteristics. When we find that a species such as *Eleutherodactylus coqui* has a very poor capacity to sustain activity aerobically, is this because there has been no selection for enhanced aerobic metabolism, or because the high cost of maintaining metabolic machinery (Taigen 1983) has favored dependence on anaerobic metabolism? At present, it is hard to answer these questions, precisely because we lack detailed information on the direction of evolutionary change in metabolic characteristics within clades of amphibians. Additional studies that place the evolution of locomotor modes, foraging behavior, and metabolic physiology in an explicitly phylogenetic context (Huey 1987) might help to resolve these issues.

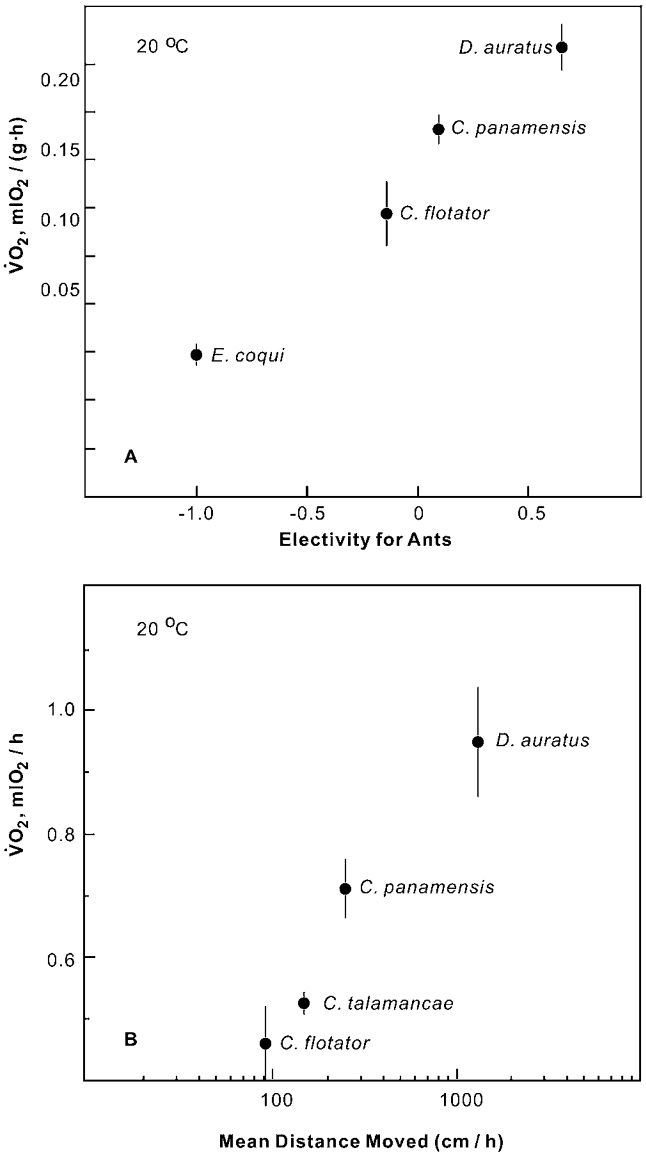

Fig. 5.6. Relationship of aerobic capacity to foraging behavior in several species of frogs. (A) Mass-specific aerobic capacity as a function of degree of specialization on ants for *Eleutherodactylus coqui* and three species of dendrobatid frogs. Positive electivity values indicate that frogs take ants in higher proportions than expected from their abundance in the environment. An electivity value of –1.0 indicates avoidance of ants. Metabolic measurements were made at 20° C. Plotted from data in Taigen and Pough (1983). (B) Aerobic capacity as a function of distance moved during natural foraging bouts for four species of dendrobatid frogs. Movement data were collected at natural field temperatures (about 23–27° C). Metabolic measurements were made at 20° C and were adjusted to a grand mean body mass for all four species of 0.95g. Plotted from data in Pough and Taigen (1990).

One also must be cautious in attributing differences in foraging behavior among species directly to physiological constraints imposed by their metabolic physiology. Taigen and Pough (1985) argued that a species such as *E. coqui,* with its poor aerobic capacity, is physiologically incapable of adopting the active foraging mode of *D. auratus,* whereas the latter species is less effective at making sudden lunges to capture large prey. It is not at all clear, however, that the three species of *Colostethus* studied by Pough and Taigen (1990) are incapable of moving as fast as *D. auratus* during normal foraging bouts. Even the fastest moving frogs in the field did not match the rates of locomotion achieved by frogs exercised in rotating chambers. Similarly, Walton (1988) found that natural foraging velocities of toads (*Bufo fowleri*) were only about 20% of the lowest speed at which oxygen consumption was measured in laboratory experiments. It seems unlikely that foraging is an activity that pushes amphibians to their physiological limits, so it is hard to document behavioral differences among species that can be attributed solely to differences in metabolic physiology.

Evolutionary Consequences of High Activity Metabolism

If frogs or other animals are to achieve high metabolic rates during vigorous activity, then they must have the metabolic machinery to support these high metabolic rates in the form of higher concentrations of mitochondria and higher densities of capillaries to carry oxygen to exercising muscles. This machinery cannot be maintained without cost, however, and several authors have suggested that selection for high levels of activity results in higher resting metabolic rates and consequently higher maintenance costs. It also has been suggested that the evolution of endothermy was a byproduct of increased resting metabolic rates brought about by this type of selection for high activity metabolism (Regal 1978; Bennett and Ruben 1979; Taigen 1983; Walton 1993; Hayes and Garland 1995). Ectotherms such as amphibians lack insulation that would allow them to retain metabolic heat, but increased resting metabolic rates can be viewed as an ecological cost of supporting high levels of aerobic metabolism.

Taigen (1983) analyzed the relationship between maximum aerobic metabolism during exercise and resting metabolism for a number of anurans in several different families. He found a positive correlation, which was consistent with the aerobic capacity model for the evolution of high metabolic rates. Walton (1993) refined Taigen's analysis by making comparisons within the family Hylidae and using modern comparative methods to remove the effect of phylogeny on the relationship between resting and activity metabolism. Again, there was a positive correlation between resting and activity metabolism, regardless of which model of evolutionary change was adopted.

Limited data also have shown a positive correlation between resting and activity metabolism among individuals within a population (Walton 1988), but information on the genetic correlation between these variables is lacking for amphibians. Gomes et al. (2004) conducted a comprehensive survey of metabolic rates in South American anurans. They found that activity metabolism and resting metabolism were not correlated for many species, but were positively correlated in species with the most active lifestyles, especially those with high calling rates. This suggested that maintenance costs are likely to be higher for amphibians that depend heavily on aerobic metabolism to support activity than for species that depend mainly on anaerobic metabolism. Similar results have been obtained for insects (Reinhold 1999). Data for squamate reptiles, on the other hand, have been less supportive of a relationship between resting and activity metabolism. Hayes and Garland (1995) argued that data of the type presented by Taigen (1983) and Walton (1993) are consistent with the aerobic capacity model for the evolution of high metabolic rates, but do not necessarily falsify a number of other hypotheses advanced to explain the evolution of endothermy.

Energetics of Reproductive Behavior in Male Urodeles

The search for relationships between metabolic capacities of animals exercised in the laboratory and ecological or behavioral traits can, at best, provide only a general correlation between physiology and behavior. This approach cannot be used to estimate the energetic costs of specific types of behavior, because the mode and intensity of locomotion utilized in a forced exercise regime usually does not very closely resemble patterns of activity during foraging, courtship, fighting, burrowing, or other natural activities. Fortunately, amphibians are small enough to enable investigators to make direct measurements of energetic costs, particularly those related to reproduction (for reviews, see Seale 1987; M. Ryan 1988b; Pough 1989; Pough et al. 1992; Prestwich 1994).

The only attempt to directly measure the energetic cost of reproductive behavior in male salamanders is Bennett and Houck's (1983) study of *Desmognathus carolinensis.* They measured oxygen consumption of noncourting pairs of males and females, courting pairs, and pairs of males engaged in aggressive interactions. Courtship bouts lasted more than an hour on average, but metabolic rates of courting pairs were only slightly higher than those of noncourting pairs and less than three times resting rates measured in a closely related species, *D. ochrophaeus* (fig. 5.7). By comparison, the metabolic rates of inactive desmognathine salamanders can increase by as much as 77% simply as a result of feeding (Feder et al. 1984). Metabolic rates of males engaged in aggressive behavior were slightly higher, but courting and fighting pairs of *Desmognathus* did not approach levels of

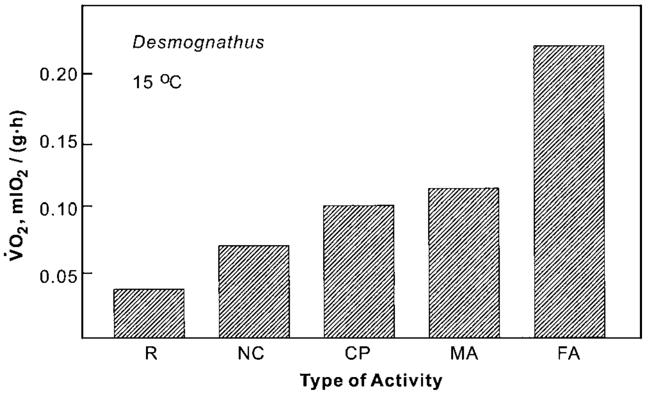

Fig. 5.7. Metabolic rates of several closely related species of *Desmognathus* engaged in various activities at 15° C. R = resting metabolism. NC = noncourting pairs. CP = courting pairs. MA = male-male aggression. FA = forced activity. Resting metabolic rate is for *Desmognathus ochrophaeus* from Ohio (Fitzpatrick 1973b). Forced activity is for *D. ocoee* from North Carolina (Feder 1986). All others are for *D. carolinensis* from North Carolina (Bennett and Houck 1983). All of these populations were considered to be *D. ochrophaeus* when the studies were done.

oxygen consumption achieved by individuals during forced exercise. Bennett and Houck (1983) found that at least 90% of ATP production during courtship or aggression was supported by aerobic metabolism. Total energy expenditure during a typical courtship bout was very low, amounting to only about 1–2% of a salamander's daily energy intake. In fact, the energy expended by a male *Desmognathus carolinensis* during courtship was less than the energetic cost of spermatophore production in a closely related species, *D. ocoee,* even though the latter also represents a trivial proportion of the animal's daily energy budget (Marks and Houck 1989).

The urodeles most likely to have energetically costly courtship are aquatic newts (*Triturus, Notophthalmus,* and *Paramesotriton*). Newts have prolonged breeding seasons lasting from several weeks to several months (Verrell and Halliday 1985b; Verrell, Halliday, and Griffiths 1986; Verrell and McCabe 1988). Breeding males of most species develop elaborate secondary sexual characters, such as bright coloration and enlarged tail fins, and the development of these display characters apparently depends on previous foraging success (A. Green 1991b; Baker 1992). Males engage in vigorous courtship that can last up to several hours (Halliday 1974, 1975a, 1976, 1977a; Verrell 1982; Sparreboom 1983, 1984a; Giacoma and Sparreboom 1987). A male's ability to court females for long periods of time is directly related to his reproductive success (see chapter 9 for further discussion). Males of some species also engage in aggressive interactions that can lead to prolonged struggles for possession of females (Verrell 1983, 1984a, 1986a; Sparreboom 1984b; Zuiderwijk and Sparreboom 1986). Although metabolic rates of courting and fighting newts have not been measured, the length and vigor of courtship and aggressive interactions suggest that such behavior is supported mainly by aerobic metabolism.

Several observations suggest that physiological constraints limit the courtship activities of newts (Halliday 1987). In *Triturus vulgaris,* the frequency with which males go to the surface to breathe is directly related to level of activity (Halliday and Worsnop 1977). Breathing frequency increases during sexual activity, and the need to breathe can significantly limit the duration of courtship bouts (Halliday and Sweatman 1976; Halliday and Houston 1991). Breathing rates increase if dissolved oxygen in the water, or oxygen in the atmosphere over the water, is decreased, whereas breathing rates decrease when the water is saturated with oxygen (Spurway and Haldane 1953; Halliday 1977b). Courtship activity also is limited by the need to breathe in *Notophthalmus viridescens* (Verrell 1985a). These results do not demonstrate that newts are energy limited during courtship, but they do suggest that metabolic rates during vigorous activity exceed levels that can be supported solely by extrapulmonary respiration.

A. Green (1991a) provided several lines of indirect evidence that displays of great crested newts (*Triturus cristatus*) are energetically constrained. He found that the number of tail beats in a bout of fanning display decreased as the number of beats per minute increased. Furthermore, tail beat rates decreased as a display bout progressed, suggesting the animals become fatigued. Display bout lengths also decreased over time. Male newts increased both the number of fan beats and the number of display bouts in the presence of competing males, suggesting that they increase their use of energetically costly displays when competition is high, but conserve energy by reducing display activity when competition is low. Green argued that if displays given by male newts are energetically costly, then they can serve as indicators of male condition and possibly male quality to females searching for a mate (see also chapter 9).

Energetics of Calling in Anurans

Male anurans often call for many hours per night during a breeding season that can last from a few days to several months (table 5.2). Their calls are very loud compared to sounds produced by animals such as birds and insects (Pough et al. 1992; see also table 7.1 in chapter 7). Production of such signals appears to be the most expensive activity performed by male anurans during their lifetimes (Pough et al. 1992; Prestwich 1994; Wells, 2001a). This means that energetic constraints limit the ability of individual males to produce calls, and this in turn can directly affect male mating success (Halliday 1987; M. Ryan 1988b). Limitations

Table 5.2 Estimates of calling effort for selected anuran species

		Measure of calling effort			
Species (source no.)	Temperature (°C)	Notes/h	s/h	h/Night	Notes/Night
Bufonidae

J. Smith, Withers, and Roberts 2003.

Notes: Data are based on average calling rates and call duration in the field. Calling times (s/h) are periods of actual sound production and do not include inter-call intervals.

[a] Measurements for frogs in laboratory.

[b] Number of calls per hour; calls composed of two distinct types of notes.

on stored energy reserves or foraging time can have a major impact on how long a male frog remains in a chorus (C. Murphy 1994a, b) and how much he calls while in the chorus (Lucas, Howard, and Palmer 1996). Consequently, the study of calling energetics provides a unique opportunity to integrate studies of metabolic physiology and sexual selection (see also chapter 8).

In all anurans studied so far, maximum O_2 consumption while calling is more than 10 times resting metabolism, and even average levels for males in the field are 6 to 20 times resting rates (table 5.3). These values probably are not representative of frogs as a whole, because all of these species have relatively high calling rates compared to other frogs (table 5.2). Oxygen consumption increases as calling rate or calling effort increase (fig. 5.8). For species such as *Pseudacris crucifer, Hyla microcephala, Hyla arborea, Hyperolius viridiflavus, Hyperolius marmoratus,* and *Crinia georgiana,* there is little variation in call note duration, and note rate alone explains most of the variation in O_2 consumption (Taigen, Wells, and Marsh 1985; Wells and Taigen 1989; Grafe, Schmuck, and Linsenmair 1992; Grafe 1996a; Grafe and Thein 2001; M. J. Smith, Withers, and Roberts 2003). In contrast, *Hyla versicolor* gives relatively long trills that vary in duration, and the best predictor of O_2 consumption is the product of note rate and duration (Taigen and Wells 1985; Wells and Taigen 1986), or the total number of pulses produced per hour (fig. 5.8 C; McLister 2001).

Interspecific variation in calling rate is positively correlated with the cost of calling, but absolute costs vary considerably (Prestwich 1994). In most species, maximum O_2 consumption during calling equals or exceeds O_2 consumption during forced exercise (table 5.3), so the latter cannot be considered the maximum aerobic capacity of these animals. Bucher, Ryan, and Bartholomew (1982) reported that noncalling *Physalaemus pustulosus* males exposed to a chorus had metabolic rates elevated above resting levels, but there is little evidence that this is generally true. In nearly all subsequent studies, predicted O_2 consumption at zero calling effort was not significantly different from resting metabolism (Taigen and Wells 1985; Taigen, Wells, and Marsh 1985; Prestwich, Brugger, and Topping 1989; Wells and Taigen 1989; Grafe, Schmuck, and Linsenmair 1992; Grafe 1996a; Grafe and Thein 2001; McLister 2001; M. J. Smith, Withers, and Roberts 2003). The results reported by Bucher, Ryan, and Bartholomew (1982) very likely were the result of noncalling males moving around inside the metabolic chamber.

Table 5.3 Oxygen consumption of male frogs at rest, during forced exercise, and while calling

		$\dot{V}O_2$ (ml O_2/g h)			
Species (source no.)	Temperature (°C)	Rest	Exercise	Call (avg.)	Call (max.)
Crinia georgiana (13)	12			0.49	1.80[a]
Hyla arborea (12)	16	0.08		1.44	1.78

Notes: $\dot{V}O_2$ call (avg.) is the estimated metabolic rate at the average calling rate measured in the field. $\dot{V}O_2$ call (max.) is the highest metabolic rate for a frog calling in a metabolic chamber.

[a] Maximum value estimated from graphical data.

[b] Average calling rate in field exceeded those of males in metabolic chambers.

[c] Data from Taigen, Emerson, and Pough 1982, adjusted to 25° C assuming Q_{10} of 2.

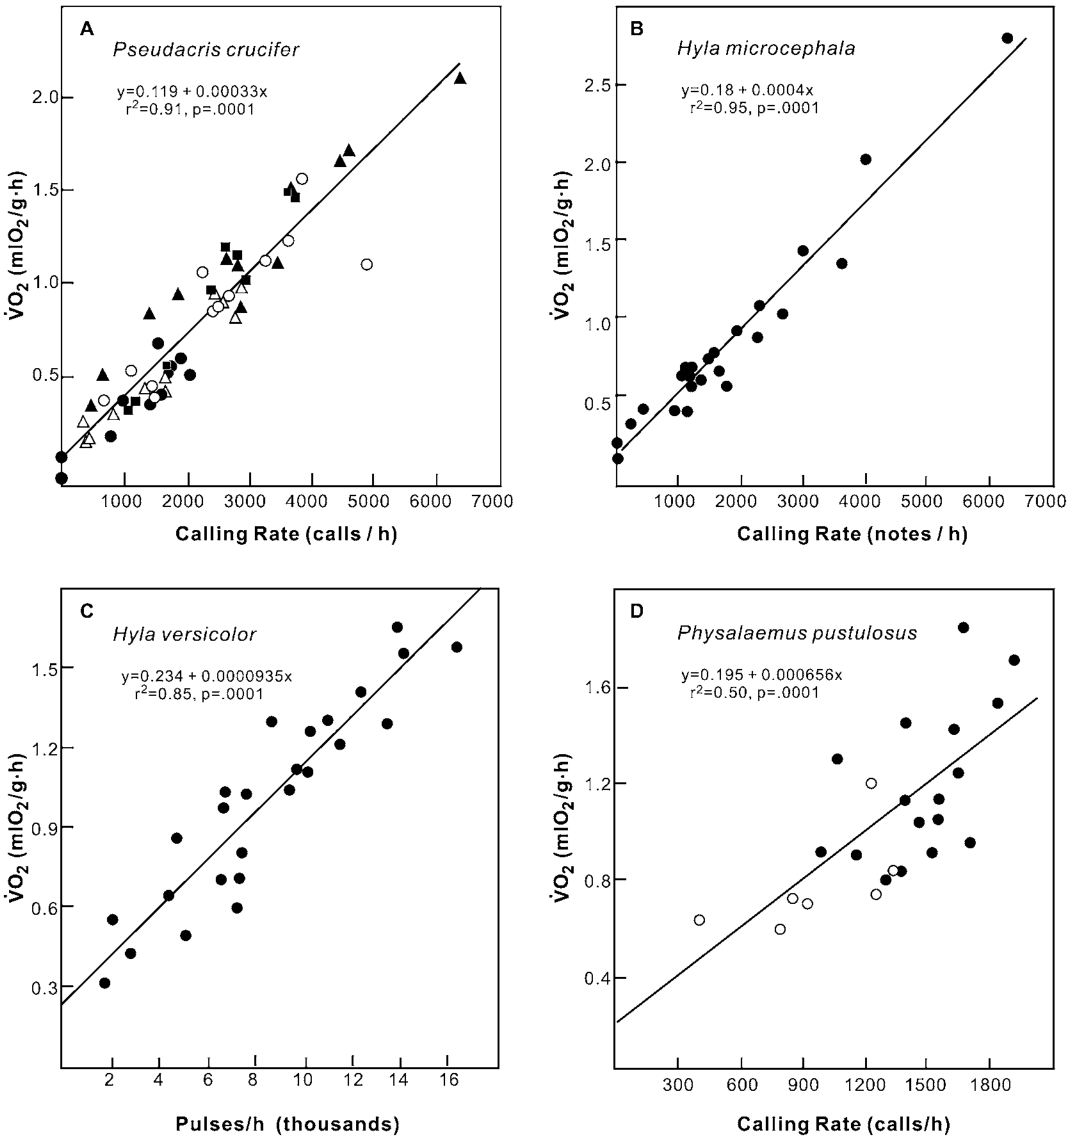

Fig. 5.8. Oxygen consumption as a function of calling effort for several species of frogs. (A) *Pseudacris crucifer* from Connecticut measured at five different temperatures (Wells, Taigen, and O'Brien 1996). (B) *Hyla microcephala* from Panama (Wells and Taigen 1989). (C) *Hyla versicolor* from Connecticut (Taigen and Wells 1985; Wells and Taigen 1986). (D) *Physalaemus pustulosus* from Panama (open circles are data from Bucher, Ryan, and Bartholomew 1982, with the two lowest values omitted; closed circles are data collected by T. L. Taigen and K. D. Wells, from Pough et al. 1992).

Social Interactions and the Cost of Calling

Social interactions among males can have a major effect on calling energetics, but not necessarily in the same way in all species. Male frogs often respond to the calls of other individuals by increasing calling rate, call duration, or the number of notes in calls (see chapter 10). In *Hyla microcephala,* males add notes to their calls as vocal competition increases, leading to a linear increase in metabolic rate (fig. 5.8 B). Males appear to conserve energy by maintaining a low calling effort when only a few males are present, but increasing calling effort and energetic expenditures when competition among males is intense (Wells and Taigen 1989). This species calls in distinct bouts in which several males respond to each others' calls, followed by periods of silence (Schwartz 1991). These periodic pauses appear to be essential for conserving energy because of the extremely high calling rate of this species. Males regularly achieve calling rates of 6,000 notes per hour, and some individuals produce 10,000 notes per hour for short periods of time. Schwartz, Ressel, and Bevier (1995) estimated that males would deplete most of the glycogen reserves in their trunk muscles in less than two hours if they called continuously at such high rates (see the following further discussion of energy substrates).

In *Hyla versicolor,* males increase call duration in response to the calls of other males, but they simultaneously decrease calling rate (fig. 5.9). The result is a relatively constant level of energy expenditure, regardless of chorus density (Wells and Taigen 1986). Playback experiments with females have shown that long calls are preferred over short calls, and high calling rates over low rates (Klump and Gerhardt 1987). More importantly, as predicted by Wells and Taigen (1986), females prefer long calls delivered at slow rates to short calls delivered at fast rates, even when total calling effort is equal (Klump and Gerhardt 1987). Therefore, males in dense choruses alter their calls in ways that enhance their attractiveness to females. Most individuals appear to be calling near maximum sustainable levels, even when calling in isolation, and males probably cannot increase calling rate and call duration simultaneously because of energetic constraints (fig. 5.10).

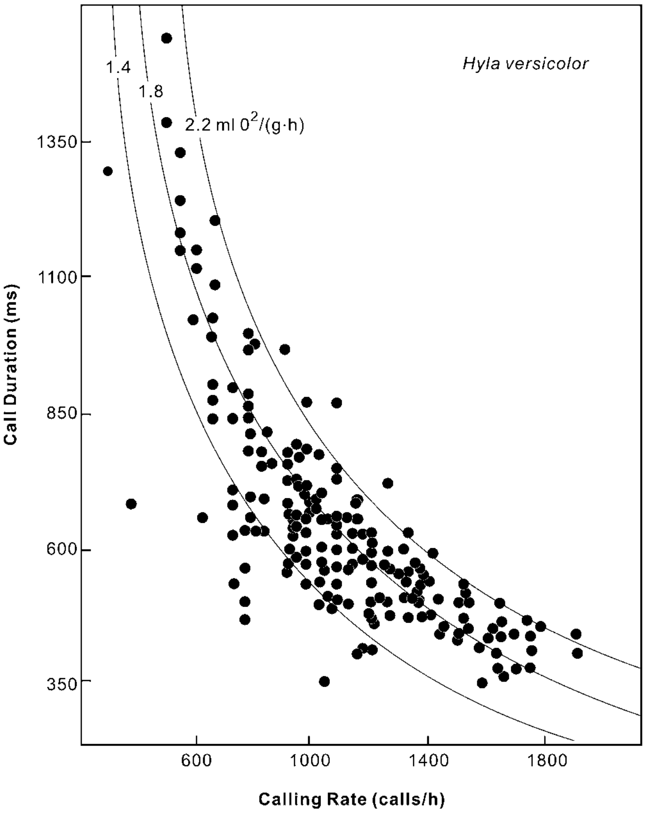

Fig. 5.10. Relationship of calling rate to call duration for male gray treefrogs (*Hyla versicolor*) calling in Connecticut. Lines show estimated rates of oxygen consumption for different combinations of rate and duration, calculated from metabolic rates of males measured in chambers placed in a natural chorus. Males cannot produce very long calls at high rates. After Wells and Taigen (1986).

Runkle et al. (1994) studied individual and seasonal variation in calling behavior and energy expenditure in *Hyla versicolor.* Differences in calling behavior among males in a chorus sometimes persisted for several nights. Some males consistently gave relatively long calls at low rates, whereas others consistently gave relatively short calls at higher rates (see Gerhardt, Dyson, and Tanner [1996] for similar results for another population of this species). The behavior of individuals was plastic, however, and this consistency appeared to reflect local differences in chorus density. Neighboring males often responded to each other's calls and therefore tended to have similar levels of energy expenditure. As the season progressed, males dropped out of the chorus, and overall chorus density decreased. This resulted in a significant reduction in average call duration, but a coincident increase in calling rate; average hourly energy expenditures changed very little. Nevertheless, there was a substantial decrease in total energy expenditure for call production over the course of the season, because chorus duration decreased from nearly four hours per night at the beginning of the season to only an hour and a half at the end of the season. This decrease in chorusing time was not related to changes in temperature and did not appear to be a result of decreased energy reserves (Wells et al. 1995), but probably was related to decreased availability of females.

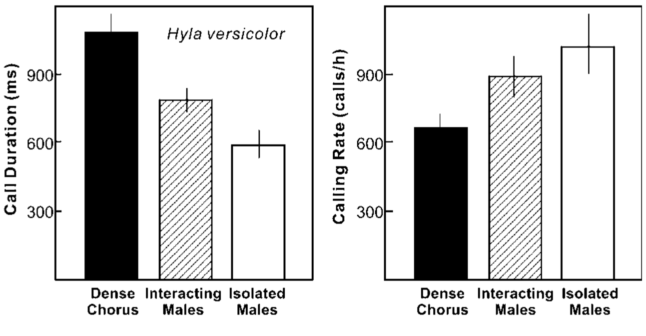

Fig. 5.9. Changes in call duration and calling rate as a function of chorus density in gray treefrogs (*Hyla versicolor*) from Connecticut. Males increase call duration but decrease calling rate as chorus density increases. Bars show means ± 1 SE. After Wells and Taigen (1986).

The effect of social interactions on calling energetics also has been examined in *Physalaemus pustulosus.* This species has an unusual call consisting of a frequency-modulated "whine" note that sometimes is combined with one or more secondary "chuck" notes. The latter are given simultaneously with the whine note, and are not added onto the end of the call as in other species with complex multinote calls (M. Ryan 1985a). Males calling in low-density choruses generally give calls with relatively few chucks. In dense choruses, males call at faster rates and add more chuck notes to their calls. Females prefer high calling rates to low rates and calls with chuck notes to whines alone (Rand and Ryan 1981). Although energetic expenditures increase with increasing calling rate, there is no evidence from the data of Bucher, Ryan, and Bartholomew (1982) or the data collected by Taigen and Wells (unpublished data) that number of chucks is related to the cost of calling. Probably this is because the chuck is produced by passive vibration of a fibrous mass in the airstream of the larynx, not by additional contractions of the trunk muscles (Drewry, Heyer, and Rand 1982; see also chapter 10).

Temperature and Calling Energetics

Most of the frogs studied to date are tropical species or summer-breeding temperate-zone species that call at a relatively narrow range of temperatures. Consequently, variation in temperature explains little of the variation in O_2 consumption while calling (Bucher, Ryan, and Bartholomew 1982; Wells and Taigen 1985; Wells and Taigen 1989; Grafe, Schmuck, and Linsenmair 1992). Spring peepers (*Pseudacris crucifer*), however, call at a wide range of temperatures during a breeding season that can last from late March through late May in New England. Early in the season, males call at air temperatures as low as 3° to 4° C, but late in the season, temperatures can be as high as 25° C. Calling rate is tightly correlated with ambient temperature (Lemon and Struger 1980), and the cost of calling is a function of calling rate (Taigen, Wells, and Marsh 1985). One would expect an increase in the cost of calling as the season progresses. Wells, Taigen, and O'Brien (1996) measured metabolic rates of calling spring peepers at temperatures from 5° to 23° C. Intercepts of regressions for different temperatures changed because of changes in resting metabolism, but the relationship between calling rate and metabolic rate was similar at all temperatures (fig. 5.8 A). Temperature had relatively little effect on the energetic cost of calling independent of its effect on calling rate. Both air and water temperatures increase during a typical breeding season, and the estimated cost of calling at the end of a season was double the cost at the beginning (fig. 5.11). Males of *Hyla versicolor* call at a much narrower range of temperatures, but temperature can still affect the energetic cost of calling through its effect on calling rate. As in *P. crucifer,* temperature does not affect the cost of calling independent of calling rate. It does appear to affect the efficiency of call production (the conversion of metabolic energy to sound energy), however. Calling efficiency increased with increasing temperature, although the reasons for this are unclear (McLister 2001).

Contributions of Anaerobic Metabolism

Because calling is such a vigorous activity that is sustained for many hours, it seems unlikely that anaerobic pathways could make a substantial contribution to calling metabolism. Measurements of lactate accumulation by calling frogs support this prediction. Pough and Gatten (1984) reported levels of whole-body lactate in calling male spring peepers that were double those of animals resting in the laboratory and slightly above those of noncalling males in the field. They concluded that calling animals sometimes exceed their maximum aerobic capacity and obtain some of their energy for calling through anaerobic pathways. Nevertheless, whole body lactate levels in calling frogs were less than 10% of those found in animals exercised to exhaustion and would make a trivial contribution to total ATP production. In *Pseudacris regilla* and *Physalaemus pustulosus,* whole-body lactate levels of calling males were not significantly different from those of resting animals (Whitney and Krebs 1975a; M. Ryan, Bartholomew, and Rand 1983), and in *Hyla versicolor,* lactate levels actually decreased after several hours of calling (Taigen and Wells 1985). Prestwich, Brugger, and Topping (1989) and Grafe, Schmuck, and Linsenmair (1992) found that elevated whole-body lactate levels were due almost entirely to increased lactate in the leg muscles, not trunk muscles, and probably were due to frogs moving around while calling. Therefore, it appears that anaerobic metabolism does not make a significant contribution to ATP production to support routine calling behavior and can be ignored in calculations of the cost of calling.

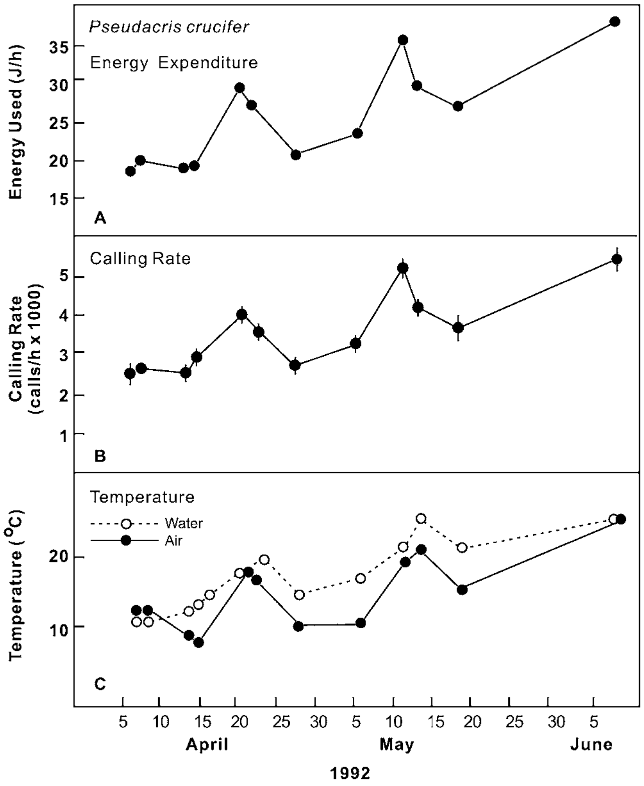

Fig. 5.11. Seasonal changes in temperature, calling rate, and estimated energy expenditure by calling spring peepers (*Pseudacris crucifer*) in Connecticut. Energy expenditure was estimated from measurements of metabolic rates of calling frogs at five different temperatures. After Wells, Taigen, and O'Brien (1996).

Total Energetic Costs of Calling

Estimates of total energetic costs of calling for several species of frogs are given in table 5.4. These estimates are based on metabolic rates of average size males calling at average rates in the field and do not indicate the range of variation within species. Such variation can be considerable if males differ substantially in size or calling rate. For example, a *Hyla microcephala* male calling at the highest rate measured in the field would have a net cost of calling nearly double the average figure for this species (Wells and Taigen 1989). Total energy expenditure of calling *Hyperolius marmoratus* males in a high-density chorus was nearly three times that of males in a low-density chorus. A large *Hyla versicolor* male can have a body mass more than double that of the smallest male in the chorus. If these frogs have the same calling effort, the larger male will use more energy, and this will be reflected in the greater sound power output of large males (Taigen and Wells 1985).

Interspecific differences in net cost are due in part to the louder calls and greater sound power output of larger species. For example, *Hyla versicolor* males have much louder calls than those of *Physalaemus pustulosus* and a net cost of calling about 10 times higher. Nevertheless, some very small species, such as *Hyla microcephala* and *Pseudacris crucifer,* have remarkably loud calls for their body size, but net costs of calling are not proportionally higher. This suggests that these frogs are more efficient at converting metabolic energy to sound energy. Prestwich (1994) estimated that *Pseudacris crucifer* has a sound production efficiency of about 5%, nearly five times higher than in *Physalaemus pustulosus*. One must be cautious in interpreting these comparisons, however, because they do not take into account intraspecific variation in calling effort or call intensity. In general, frogs are relatively inefficient at converting metabolic energy into sound energy, with efficiencies ranging from 0.5 to 5%. The efficiency of the muscles that actually produce the sound, however, would be much higher (Prestwich 1994; McLister 2001).

Also shown in table 5.4 is the cost per minute of actual sound production. With the exception of *Hyperolius,* all of the small species (body mass = 1–2 g) have similar costs per minute of calling, despite major differences in the structure of their calls. *Pseudacris crucifer* has a simple tonelike call, whereas *Physalaemus pustulosus* has a much longer and more complex frequency-modulated call. *Hyla microcephala* and *H. squirella* both have rather broad-spectrum calls, but the former has distinct pulses in the calls, while the latter does not. Most of the differences in call structure reflect differences in the structure and action of the larynx and laryngeal muscles (M. Ryan 1985a; Schneider 1988), and these probably contribute relatively little to total energetic costs.

Energetic Costs of Other Activities

Information on the energetic cost of natural activities other than calling in amphibians is very limited, but the available data indicate that calling is likely to be the most expensive behavior performed by these animals (tables 5.4 and 5.5).

Table 5.4 Net cost of calling in selected anuran species, listed in order of decreasing body mass

Species (source no.)	Temperature (°C)	Mass (g)	Net cost of calling J/h	J/g·h	J/min
Hyla arborea (11)	16	6.3	172	27	11.6

[a] Estimated from field measurements of movement speed and laboratory measurements of oxygen consumption.

The only activity that entails elevations in oxygen consumption approaching that of calling males is construction of foam nests, which has been studied in *Physalaemus pustulosus*. The male uses his back legs to beat the mucus coating around the eggs into froth as the eggs are laid, a process that requires about one hour (M. Ryan 1985a). Metabolic rates of nest-building pairs of males and females are about five times resting rates (M. Ryan, Bartholomew, and Rand 1983), and the net cost of nest building is about 70 to 80% of the cost of calling (tables 5.4 and 5.5). M. Ryan, Bartholomew, and Rand (1983) estimated that frogs actually kick their legs only about 20% of the time, so the net cost per minute of activity would be about 1.7 J, or about 45% of the cost of a minute of sound production.

Another vigorous activity performed by many species of anurans is burrowing (see chapters 1 and 2). Seymour (1973c) measured the energetic cost of burrowing in a spadefoot toad, *Spea hammondii*. Metabolic rates of burrowing toads were about four and a half times resting rates, and the cost of an hour of burrowing for a 12-g toad was about 95 J (table 5.5). The cost of calling is unknown, but in two hylids of about the same size, *Hyla gratiosa* and *Hyla versicolor*, the cost of calling is about three times the cost of burrowing in *Spea* (tables 5.4 and 5.5). Seymour estimated that the toads were actually burrowing only about 22% of the time, or about 13 minutes per hour, so the cost per minute of burrowing is approximately 7.3 J at 30° C. By comparison, a minute of sound production by *H. gratiosa* at a similar temperature costs about three and a half times as much (table 5.4).

Other routine activities by amphibians probably are much less expensive. For example, Walton (1988) reported that foraging toads (*Bufo fowleri*) typically move at a very slow rate (mean = 0.018 km/h). From a regression of metabolic rate versus movement speed (Walton and Anderson 1988), estimated O_2 consumption during foraging is about 2.3 times resting metabolism, yielding a net cost of 85 J/h for a 26-g toad (table 5.5). This is a downward extrapolation from the metabolic data, because natural foraging velocities were only 20% of the lowest speed at which O_2 consumption was measured. This figure is well below maximum O_2 consumption during forced exercise, indicating that toads probably do not approach their physiological limits during routine foraging (Walton 1988). The costs of calling by frogs are much greater than the costs of reproductive activities in salamanders. For example, the cost of courtship in *Desmognathus* is only about 5% of the cost of calling by a frog of similar size (tables 5.4 and 5.5).

Comparisons to the Cost of Signaling in Other Animals

The acoustic signals used by frogs are analogous in function to those of some fishes, insects, and birds. There is abundant evidence for both insects and birds that high singing rates make males attractive to females (Andersson 1994; Gerhardt and Huber 2002), so sexual selection is likely to favor the production of energetically expensive signals, just as it does in frogs. On the other hand, mechanisms of sound production differ in different kinds of animals, and some are capable of producing acoustic signals at relatively low cost. For example, the cost of calling appears to be low in the oyster toadfish (*Opsanus tau*). Like many fishes, this species produces sound by exceedingly rapid contractions of sonic muscles associated with the swim bladder. These muscles are tiny compared to the trunk muscles of frogs—1% of male body mass, compared to up to 15% in some male frogs. Consequently, the elevation of metabolic rate above resting levels is minimal (Amorim et al. 2002; these results are based on electrical stimulation of sonic muscles, not spontaneous calling, so they are not strictly comparable to the data on frogs).

Several studies have been done on the energetic cost of sound production in insects, and discussions of the energetics of sound production by frogs and insects can be found in Pough et al. (1992), Prestwich (1994), and Gerhardt and Huber (2002). Insect songs typically have lower sound pressure levels than the calls of frogs, but total sound power output is greater for some insects, especially species that call more or less continuously (Pough et al. 1992). Comparisons both within and among species have shown that metabolic rates of calling insects increase as a linear function of syllable rate, just as the cost of calling in frogs increases with calling rate. Because of the much greater number of syllables produced per minute, mass-specific metabolic rates of calling insects often are much higher (0.4–13 ml O_2/g·h, mean = 5.2) than those of calling frogs (0.78–4.20 ml O_2/g·h, mean = 1.8; Prestwich 1994).

Insects have higher mass-specific resting metabolic rates than do frogs, so factorial aerobic scopes for calling average about 1.5 times higher in frogs (Prestwich 1994). Two species of mole crickets, for example, had factorial scopes of about five to eight times resting metabolism (Prestwich and O'Sullivan 2005). The Australian bladder cicada (*Cystosoma saundersii*), on the other hand, had a metabolic rate during singing that was 21 times resting metabolism, comparable to the highest factorial metabolic scopes measured in frogs (Mac Nally and Young 1981). This species produces a loud, continuous call, sometimes for a half an hour or more at a time, so the energetic cost of signaling is considerable. Not all insects produce such expensive signals, however. A wax moth (*Achroia grisella*), which produces ultrasonic signals while fanning its wings, has an average factorial scope of only about 2.75 (Reinhold et al. 1998), while the tock-tock beetle (*Psammodes striatus*), which produces sound by tapping on the ground, has a factorial scope of about 2.5 (Lighton 1987). A chirping cricket (*Requena verticalis*), which has a very low calling rate, has a factorial scope of only 2 (Bailey et al. 1993). Despite the relatively low cost of calling in *R. verticalis,* males appear to be under some energy stress. Individuals that were fed a high-quality diet devoted more of their time to calling than those fed a low-quality diet (Simmons et al. 1992). Frogs appear to be more efficient in converting metabolic energy into sound energy (0.5–5% efficiency) than insects (0.03–6%), but the highest estimates are comparable for the two groups (Prestwich 1994; Reinhold et al. 1998; Prestwich and O'Sullivan 2005).

Several lines of evidence suggest that birds are stressed energetically by singing. In some species, singing rates decline in cold weather, perhaps because of the increased energetic costs of thermoregulation (Garson and Hunter 1979; Higgins 1979; Gottlander 1987; Reid 1987; Santee and Bakken 1987). Some birds increase singing rates when food is abundant, or when they are provided with supplemental food (Searcy 1979; Wilhelm, Comtesse, and Phlumm 1980; Davies and Lundberg 1984; Gottlander 1987; Radesäter et al. 1987; Reid 1987; Strain and Mumme 1988; Lucas, Schraeder, and Jackson 1999). Several authors have suggested that females might use song rate as an indicator of male condition or quality. If males sing at times when food is scarce or energy reserves are limited, then only males in good condition could sing at peak rates (McNamara, Mace, and Houston 1987; Reid 1987; Hutchinson, McNamara, and Cuthill 1993). Nevertheless, the main constraint imposed by singing may be a time constraint on foraging rather than the energetic cost of singing per se (Thomas et al. 2003; Ward, Lampe, and Slater 2004).

There have been a number of measurements of the energetic cost of singing in birds. Horn, Leonard, and Weary (1995) measured O_2 consumption in crowing roosters. Metabolic rate increased as a function of crowing rate, but even at peak rates, the cost of crowing was relatively low, with metabolic rate elevated only about 15% above resting levels. Roosters produce, at most, only 200–250 crows per day, equivalent to the number of calls produced in one hour by frogs with relatively low calling rates (table 5.2). Mass-specific metabolic rates during crowing were only 1.25 ml O_2/(g·day), less than the hourly metabolic rate of a calling spring peeper. In zebra finches (*Taeniopygia guttata*), canaries (*Serinus carnaria*), and starlings (*Sturnus vulgaris*), metabolic rates during singing averaged 1.1–3.4 times resting metabolism, depending on singing rate (Oberweger and Goller 2001; Ward, Speakman, and Slater 2003; Ward and Slater 2005). For pied flycatchers (*Ficedula hypoleuca*), the cost of singing was about 2.7 times resting metabolism and only 1.12 times the cost of standing (Ward, Lampe, and Slater 2004). This species produces only about 90–240 songs per hour, much lower than the calling rates of many frogs. More comparable to calling in frogs is the singing of Carolina wrens (*Thryothorus ludovicianus*), which produce up to 2100 songs per hour. Metabolic rates of singing males were three to nine times resting rates and increased as a linear function of singing rate. At typical singing rates, singing would account for 10–25% of the daily energy budget for male wrens during the breeding season (Eberhardt 1994).

Although factorial increases in metabolic rate by many calling frogs appear to be considerably higher than for birds, this is largely a result of the very low resting metabolic rates of frogs. Mass-specific comparisons of the absolute amount of oxygen consumed for each second of vocal signal showed that costs are similar for birds and frogs (Oberweger and Goller 2001). In birds, both the respiratory muscles and muscles of the syrinx are involved in song production. Birds may save energy during singing because the syrinx modulates a one-way airstream produced during normal respiration, whereas frogs use large trunk muscles to force air out of the lungs and through the larynx only for calling (see chapter 7). The relative contribution of these two sets of muscles to the energetic cost of singing in birds is unknown, but the cost of contracting muscles of the syrinx is likely to be small. These muscles constitute a tiny proportion of a bird's body mass compared to the trunk muscles of frogs. For example, the trunk muscles of a 1.25 g male spring peeper (*Pseudacris crucifer*) weigh about 0.185 g, or nearly 15% of total body mass (Taigen, Wells, and Marsh 1985). In contrast, the syrinx muscles of a male zebra finch weigh about 0.027 g (Wade and Buhlman 2000), about 1% of its 13 g body mass (Nudds and Bryant 2000).

It appears that flying, particularly flights involving vertical takeoffs, is considerably more expensive than singing. In zebra finches, for example, the cost of short flights is 10 times the cost of singing and 28 times resting metabolism (Nudds and Bryant 2000; Ward, Lampe, and Slater 2004). This means that some nonvocal displays of birds are like to be more energetically costly than singing, because they often require moving the total body mass of the bird. Many species, especially those that display on leks, perform displays that involve vigorous and repeated jumping or flying. Norberg (1991) estimated that the flight display of the flappet lark (*Mirafra rufocinnamomea*) requires a metabolic rate 16 times resting metabolism. Male sage grouse (*Centrocercus urophasianus*) perform repeated strut displays to attract females. Instantaneous metabolic rates of displaying males, measured with the doubly labeled water technique, were 14–17 times resting metabolism, comparable to the factorial scopes of some calling frogs. Daily energy expenditure was about twice as high for displaying males as for nondisplaying males on the same lek and about four times as high as for males at rest (Vehrencamp, Bradbury, and Gibson 1989). Total energetic expenditures for all of these bird species are an order of magnitude higher than for frogs because of their much higher metabolic rates and larger size. Nevertheless, singing and other sexual displays probably represent a much smaller proportion of the daily energy budget of a bird than that of a frog simply because so much of a bird's energy budget is consumed by heat production and by flight powered by massive flight muscles (> 20% of total body mass in finches; Nudds and Bryant 2000).

Morphological Correlates of Calling Energetics

The muscles involved in call production by frogs are quite distinct in morphology and histochemistry from anuran leg muscles. The action of these muscles is described in detail in chapter 7. Briefly, the power for call production is provided by muscles in the trunk region, including the rectus abdominus, external oblique, and internal oblique (= transverse) muscles. The trunk muscles of males generally are much larger (3–15% of body mass) than those of females (1–3%; Pough et al. 1992; Bevier 1995b; Girgenrath and Marsh 2003). Relative trunk muscle mass is greater in species with high calling rates than in species with low calling rates (Bevier 1995b). The laryngeal muscles are involved in opening and closing the larynx during call production, and in some species are actively involved in fine-scale amplitude modulation of the call. These muscles also are larger in males than in females. Both sets of muscles are composed mainly of fast oxidative fibers (> 90%), along with a few tonic fibers, and have rapid shortening velocities (Eichelberg and Schneider 1973, 1974; Schneider 1977, 1988; R. Marsh and Taigen 1987; McLister, Stevens, and Bogart 1995; Boyd et al. 1999; Girgenrath and Marsh 1999, 2003; R. Marsh 1999).

Elastic fibers associated with the trunk muscles increase the efficiency of call production. In male frogs, the rectus abdominus muscle is separated from the other trunk muscles by a band of fibrous tissue, the linea masculina. In at least one species, *Physalaemus pustulosus,* this band of tissue is highly elastic and provides elastic recoil during deflation of the lungs, which increases the efficiency of sound production (Jaramillo, Rand, Ibáñez, and Dudley 1997). Elastic fibers also are found in the vocal sac of *Physalaemus,* and these might increase the efficiency with which air is pumped back into the lungs after a call is produced.

Trunk and laryngeal muscles are dramatically different from leg muscles in ultrastructural characteristics. The muscles involved in call production are well supplied with sarcoplasmic reticulum and have several times as many mitochondria per unit volume as the leg muscles (fig. 5.12). Capillary densities also are much higher in trunk and laryngeal muscles than in leg muscles, reflecting the much higher oxygen demand of the trunk muscles (Eichelberg and Schneider 1973, 1974; Schneider 1977, 1988; R. Marsh and Taigen 1987; Ressel 1993, 2001; McLister, Stevens, and Bogart 1995). In a detailed analysis of muscle ultrastructure in relation to calling behavior, Ressel (1996) found that both mitochondrial volume density and capillary density were positively correlated with calling rate among tropical frogs from two families that call at similar temperatures. Indeed, comparison of mitochondrial volume density for a variety of tropical and temperate-zone species reveals a positive correlation with calling rate that does not appear to be related to phylogeny (Ressel 2001). Ranid frogs with very low calling rates have mitochondrial volume densities similar to those of hylids with low calling rates, such as *Agalychnis callidryas* (fig. 5.13 A). Two leptodactylid frogs, *Physalaemus pustulosus* and *Eleutherodactylus coqui,* have muscle characteristics similar to those of hylids with comparable calling rates.

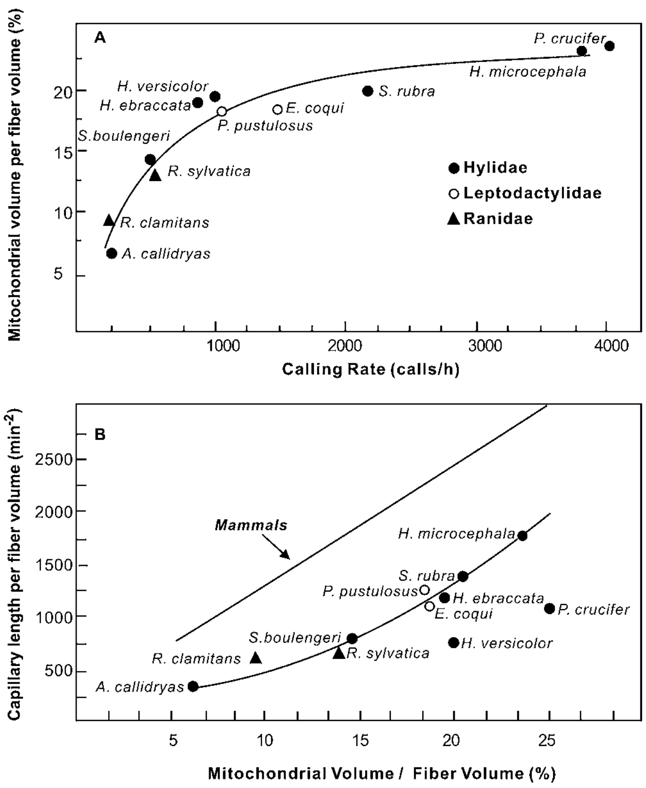

Fig. 5.13. (A) Relationship of mitochondrial volume density of trunk muscle tissue to calling rate for several species of anurans in three families. The curve is for Neotropical hylids and leptodactylids only (After Ressel 1996). Data for two temperate zone hylids (*Hyla versicolor* and *Pseudacris crucifer*) and two temperate zone ranids (*Rana clamitans* and *R. sylvatica*) are shown for comparison (data from Ressel 1993). (B) Relationship of trunk-muscle capillary length to mitochondrial volume density for several anurans and for mammals. The curve is for Neotropical hylids and leptodactylids (after Ressel 1996), with other species shown for comparison (data from Ressel 1993).

In mammals, capillary supply to skeletal muscle is closely correlated with mitochondrial volume density, because oxygen supply must increase with metabolic demand. This also appears to be true for frogs, but frogs have fewer capillaries for a given mitochondrial volume than do mammals (fig. 5.13 B). Presumably this reflects the lower activity temperatures of frogs, which in turn result in lower metabolic demands (Ressel 1996). Indeed, points for some temperate-zone frogs that call at lower temperatures than most tropical frogs fall below the curve for tropical frogs alone (fig. 5.13 B). This is particularly true for species with high calling rates, such as *Pseudacris crucifer.*

Biochemical Correlates of Calling Energetics

Both citrate synthase (CS) and β-hydroxyacyl-CoA-dehydrogenase (HOAD) activity have been used as indicators of aerobic metabolism and lipid metabolism in the trunk muscles of frogs (Taigen, Wells, and Marsh 1985; R. Marsh and Taigen 1987; Given and McKay 1990; Bevier 1995a), as they have been for sexually dimorphic sound-producing muscles in other animals (Rice and Lobel 2002). Activities of both enzymes are consistently higher in trunk muscles than in leg muscles (fig. 5.14), and variation in the activities of these enzymes is closely correlated with variation in calling rate (fig. 5.15). The activities of these enzymes are closely correlated with each other in both trunk and leg muscle. This suggests that species with high calling rates not only have high aerobic capacities, but also depend more heavily on lipids to fuel call production (Bevier 1995a; see subsequent discussion of energy substrates). The enzymes involved in aerobic metabolism are located in the mitochondria, and a comparison of Bevier's (1995a) data on enzyme activities with Ressel's (1993) data on mitochondrial volume density shows a strong positive correlation for both tropical and temperate-zone species (fig. 5.16).

A comparison of two Neotropical hylids in same genus, *Scinax rubra* and *S. boulengeri* (fig. 5.17), nicely illustrates the relationship between calling behavior and trunk muscle

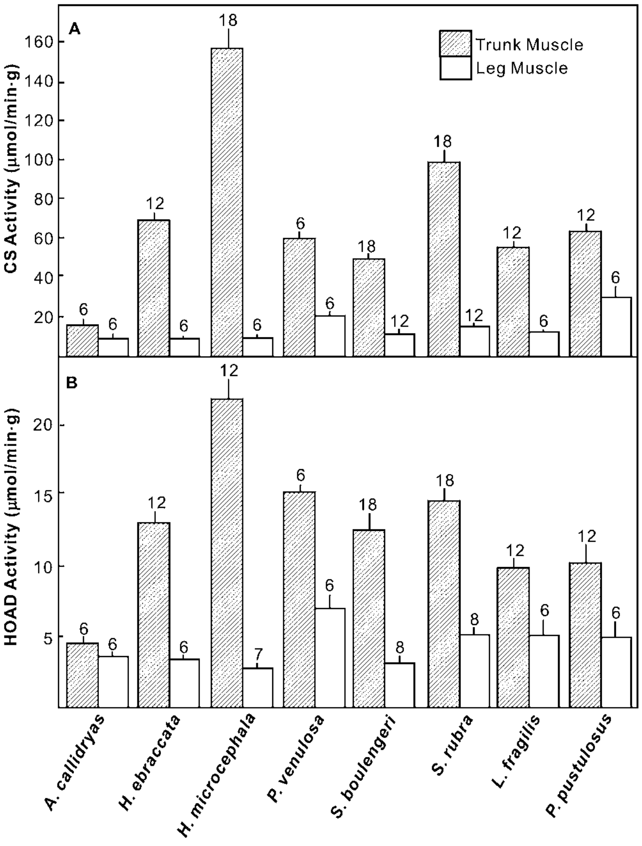

Fig. 5.14. Comparison of activities of the enzymes citrate synthase (CS) and β-hydroxyacyl-CoA-dehydrogenase (HOAD) at 25° C in trunk muscles and leg muscles of tropical hylids and leptodactylids. characteristics (Ressel 1996; Bevier 1997a). These species are about the same size (40 mm snout-vent length) and mass (3.5 g), and they call at the same temperatures. *Scinax rubra* males have larger trunk muscles (10% of body mass) than do *S. boulengeri* males (6.6%), and their muscles are more aerobic, with much higher mitochondrial volume densities, greater capillary length, and higher enzyme activities, especially CS activity (table 5.6). They differ dramatically in calling behavior as well. *Scinax rubra* is an explosive breeder that calls only after heavy rains, and individual males are seldom present in a chorus for more than one or two nights. Males call at relatively high rates (more than 2,000 calls/hour) for up to seven hours per night, and they move actively about the chorus area in search of females. *Scinax boulengeri,* on the other hand, is a continuous breeder, with some males present in choruses for weeks at a time. Males call at relatively low rates, usually for only about three hours per night, and they reduce calling rates after the first hour. The trunk muscles of *S. rubra* are adapted for very high levels of calling activity during the short periods when females are available, whereas those of *S. boulengeri* are designed for slow but sustained activity over much longer periods of time. This difference in behavior is reflected in their use of energy substrates as well. *Scinax rubra* has much larger stores of lipids and glycogen in the trunk muscles, but also depletes them more rapidly than does *S. boulengeri.*

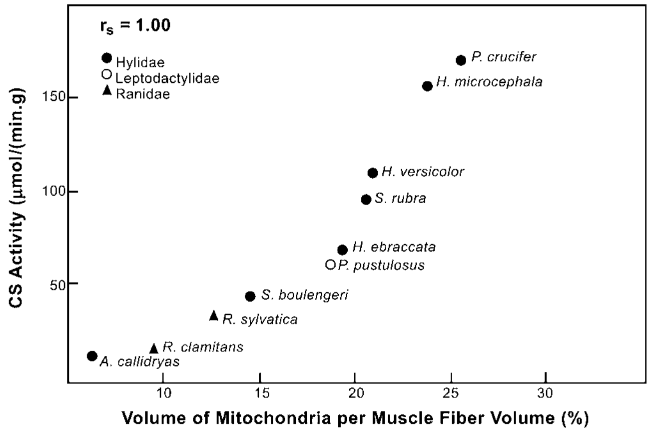

Fig. 5.16. Relationship of citrate synthase (CS) activity at 25° C to mitochondrial volume density in anurans. Abbreviations as in fig. 5.14, with the addition of *R* = *Rana* and *P. crucifer* = *Pseudacris crucifer.* r_s = Spearman rank correlation coefficient. Plotted from data in Marsh and Taigen (1987), McKay (1989), Pough et al. (1992), Ressel (1993, 1996), and Bevier (1995b).

A study of spring peepers (*Pseudacris crucifer*) by Zimmitti (1999) was the first to examine variation in trunk muscle enzyme activities among males in the same population. He collected pairs of individuals on the same night, choosing males with unusually high or low calling rates. He found that males with high calling rates consistently had higher activities of both CS and HOAD in their trunk muscles than did males with low calling rates, and the activities of the two enzymes were positively correlated within males. In a multiple regression analysis, trunk muscle CS activity was positively correlated with calling rate after accounting for the effects of temperature and body mass. Differences in calling rate among males of this species are consistent from night to night (B. K. Sullivan and Hinshaw 1990), and females are most likely to be attracted to males

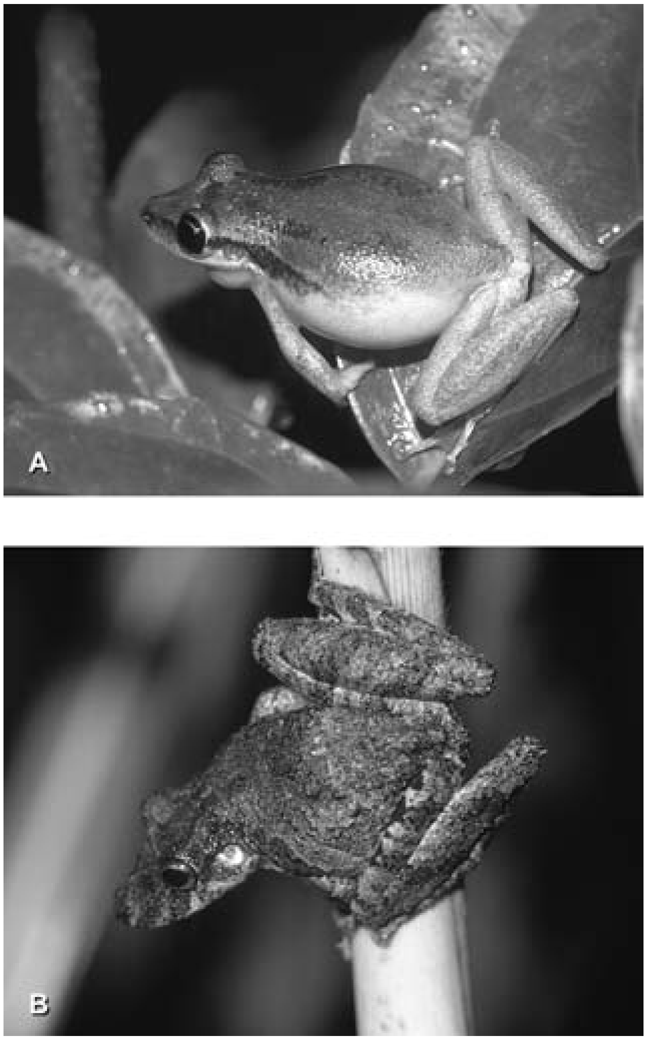

Fig. 5.17. Two Panamanian treefrogs with different calling behavior and different strategies of energy use. (A) *Scinax rubra* is an explosive breeder. Males call at high rates for only one or two nights after heavy rains and deplete intramuscular glycogen reserves very quickly. (B) *Scinax boulengeri* breeds continuously during the rainy season. Males call at low rates and deplete their energy reserves relatively slowly, even though they start out with lower concentrations of glycogen in their muscles. Photos by Kentwood D. Wells.

with high calling rates (Forester, Lykens, and Harrison 1989). If at least some of the variation in physiological traits that underlies variation in calling performance is heritable, then a female preference for high calling rate would result in selection for morphological and physiological traits that enable males to call at high rates.

Energy Substrates for Call Production

The enzymatic profiles of muscles involved in call production indicate that both lipids and carbohydrates are important sources of energy for calling frogs. In other vertebrates, sustained aerobic exercise generally is supported by a mixture of lipid and glycogen stored in the muscles. Glycogen provides energy at a faster rate than lipids, and therefore provides greater power output. Glycogen stores are more limited, however, and provide less energy per gram of storage product, so glycogen reserves are depleted much more rapidly. Lipids provide more energy per gram, so stores of lipids are depleted more slowly. Depletion of muscle glycogen reduces muscle performance, even when abundant lipid stores remain, so glycogen represents a short-term constraint on muscular activity (Holloszy and Booth 1976; Hochachka and Somero 1984; Guppy 1988; J.-M. Weber 1988). The relative importance of glycogen and lipids as substrates to support activity varies among species, with lipids being most important in animals that sustain high levels of activity over long periods of time. For example, highly aerobic mammals that are capable of long-distance running, such as dogs, rely much more on intramuscular lipid stores to support vigorous exercise than do less aerobic species that do not move rapidly over long distances, such as opossums (J.-M. Weber 1992). The same is true for acoustic insects. Species with high calling rates typically derive most of their energy for sound production from lipids, whereas those with low calling rates sometimes rely entirely on carbohydrates (Prestwich 1994; Prestwich and O'Sullivan 2005).

The laryngeal and trunk muscles of frogs are well supplied with lipid stores in the form of droplets closely associated with clusters of mitochondria (fig. 5.12; Eichelberg and Schneider 1973; Eichelberg and Obert 1976; Schneider 1977, 1986; R. Marsh and Taigen 1987; Ressel 1993; McLister, Stevens, and Bogart 1995). A comparative study of several Neotropical hylids and leptodactylids (fig. 5.18) showed that lipid content of trunk muscles is positively correlated with calling rate, and this appears to be true for frogs in general (Ressel 1996). One Neotropical hylid with a very low calling rate, *Agalychnis callidryas,* has virtually no lipid in its trunk muscles, and the same is true for two North American ranids that also have low calling rates, *Rana sylvatica* and *R. clamitans.* In contrast, male spring peepers (*Pseudacris crucifer*) have more lipid in their trunk muscles than is found in most other highly aerobic vertebrate muscles (Ressel 1993, 2001).

In species with abundant lipid reserves, changes in lipid content of trunk muscles generally are not detectable on a nightly basis. Of the seven Neotropical hylids and leptodactylids studied by Bevier (1997b), only *Phrynohyas venulosa* exhibited a significant reduction in trunk-muscle lipid stores after two to three hours of calling, and this species started with relatively small lipid stores. *Hyla microcephala,* which had initial lipid stores about three times as large, showed no change after two hours of calling. Spring peepers (*Pseudacris crucifer*) undergo a dramatic seasonal reduction in trunk-muscle lipid reserves. Males collected early

Table 5.6 Comparison of behavioral, morphological, and biochemical characteristics of two Neotropical hylid frogs

Characteristics	*Scinax boulengeri*	*Scinax rubra*
Behavioral characteristics		
Calling rate (calls/h)	474	2,064
Hours of calling/night	3	5
Morphological characteristics		
Body length (mm)	40	41
Body mass (g)	3.4	3.8
Trunk muscle (% body mass)	7	10
Trunk muscle mitochondria (% fiber volume)	15	21
Trunk muscle capillary length per fiber volume (mm)	774	1,389
Trunk muscle lipid (% fiber volume)	2.5	8.7
Biochemical characteristics		
Trunk muscle lipid (% dry tissue)	4.7	16.4
Trunk muscle glycogen (mg/g)	3.6	7.9
Trunk muscle CS activity (U/g)	47	98
Trunk muscle HOAD activity (U/g)	13	15

Source: Modified from Bevier (1997a).

Notes: Scinax boulengeri breeds continuously for much of the rainy season. *Scinax rubra* breeds opportunistically after heavy rains.

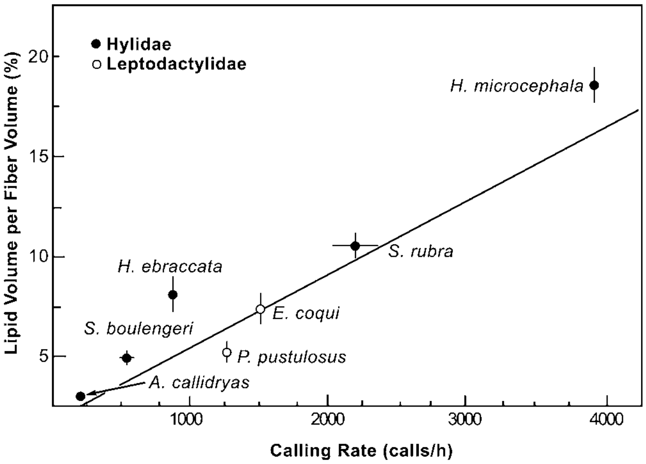

Fig. 5.18. Relationship of trunk muscle lipid reserves to calling rate in tropical frogs. Lipid volumes were estimated from transmission electron micrographs like those in fig. 5.12. Calling rates are estimated average calling rates at natural field temperatures. Genera as in fig. 5.14 and 5.15. After Ressel (1996).

in the season have larger reserves than any other species of frog that has been studied, but most of these reserves are gone by the end of the season (McKay 1989; Ressel 1993). Because this species breeds in cold weather, males do not begin feeding until relatively late in the breeding season (Wells and Bevier 1997). This is not true for *Hyla versicolor,* however. This species breeds in warmer weather and feeds throughout the breeding season, so it probably is less dependent on stored lipid reserves than are species that breed in cold weather (S. Walker 1989; Wells 2001a; see subsequent discussion of feeding). Less is known about depletion of energy substrates in laryngeal muscles. Eichelberg and Obert (1976) reported that lipid reserves in the laryngeal muscles of *Bombina bombina* were not significantly reduced by several hours of electrical stimulation, but were reduced after nearly two weeks of calling activity.

Both the trunk and laryngeal muscles of male frogs contain substantial quantities of glycogen (Schneider 1977; Bevier 1997b; Schwartz, Ressel, and Bevier 1995; Wells et al. 1995; Wells and Bevier 1997). Among Neotropical hylids and leptodactylids, initial trunk-muscle glycogen stores were positively correlated with both hourly calling rates and the total number of calls produced in an evening (Bevier 1997b). Rates of glycogen depletion also are correlated with calling rate. Species with relatively high calling rates, such as *Hyla microcephala, H. versicolor, Scinax rubra* and *Physalaemus pustulosus,* can deplete 50–60% of their trunk-muscle glycogen reserves after only two hours of calling (fig. 5.19). Species with lower calling rates, such as *Scinax boulengeri,* use up their trunk-muscle reserves more slowly (Bevier 1997b; Schwartz, Ressel, and Bevier 1995; Wells et al. 1995). In most of these species, liver glycogen reserves show little or no change after two hours of calling, suggesting that these reserves are not used to support call production.

The rapid depletion of glycogen reserves relative to lipid reserves might lead one to conclude that glycogen is a more important source of energy for call production. For many

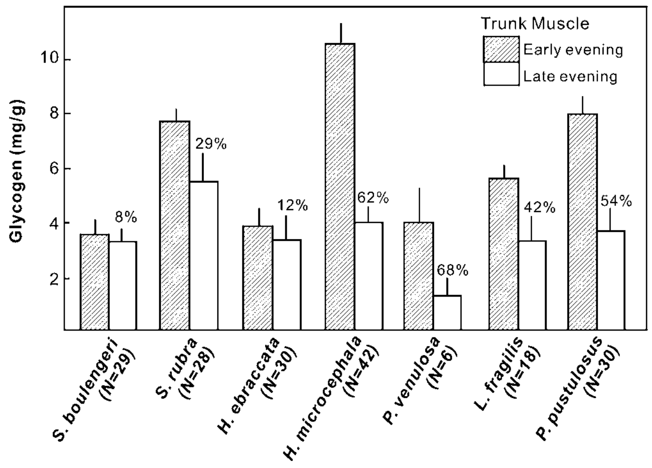

Fig. 5.19. Glycogen concentrations in trunk muscles of males for seven species of frogs from Panama. Bars show means ± 1 SE for individuals collected early in the evening and those collected after two to three hours of calling. Percentages show percentage decrease in glycogen concentration after calling. Genera as in fig. 5.14. After Bevier (1997b).

Table 5.7 Estimated contributions of carbohydrates and lipids to call production in frogs (%)

Species (source no.)	Carbohydrates	Lipids
Hyla arborea[a] (6)	69	31
H. microcephala[b] (2)	14	86
H. versicolor[b] (1)	25	75

species with high calling rates, however, this is not the case. Because lipids yield much more energy per gram of stored substrate, even a small amount of lipid can account for most of the energy used for call production. The relative importance of glycogen and lipids has been calculated for several species by measuring rates of glycogen depletion and calculating the amount of oxygen used to oxidize glycogen. The remaining oxygen consumed by a calling frog is used to oxidize lipid, so lipid utilization can be estimated by subtraction. Such calculations have shown that most frogs with relatively high calling rates derive 75–95% of their energy from lipids (table 5.7), even though glycogen reserves can be depleted on a single night. These values are mostly consistent with estimates derived from measurements of respiratory quotients (RQ = the ratio of CO_2 produced to O_2 consumed). Grafe (1997b) measured RQs for calling *Hyla versicolor* males and estimated that they derive at least 60% of their energy for calling from lipids. In *Hyperolius marmoratus,* RQs varied dramatically, depending on whether the frogs had recently fed. Calling males derived 37–89% of their energy from lipids, and they relied much more on stored lipids if they had not fed recently (Grafe 1996a). Grafe and Thein (2001) measured RQs for the European treefrog (*Hyla arborea*) and found that males derived nearly 70% of their energy for call production from carbohydrates, a result that is at odds with data for other frogs with high calling rates. Possibly the males used in the study had been feeding recently, resulting in a shift to greater use of carbohydrates, as in *Hyperolius marmoratus.*

Feeding and Strategies of Energy Use by Calling Frogs

For species that breed in warm weather, feeding probably is essential if males are to replace depleted energy reserves. Males either feed during hours when choruses are not active, or they leave a chorus periodically to feed. Males of summer breeding frogs in the temperate zone, such as *Rana clamitans* and *Hyla versicolor,* typically have food in their stomachs throughout the breeding season (Jenssen and Klimstra 1966; Wells et al. 1995; Wells 2001a). The foraging time of some calling males probably is limited by the amount of time devoted to calling or defending territories (see the following discussion). Daily food intake probably is converted mostly into glycogen and glucose, which can be utilized for calling within a few nights after a male has fed. This would explain the relatively low reliance on stored lipids for call production by *Hyperolius marmoratus* males that had recently fed.

Several investigators have experimentally supplemented the food of individual male frogs to determine whether food availability limits call production. For example, Sinsch (1988b) studied a high-altitude population of *Gastrotheca marsupiata* in Peru and found that males given supplemental feedings in the laboratory called at higher rates than did those that were not fed. In a study of *Physalaemus pustulosus* in Panama, A. Green (1990) did not find any effect of supplemental feeding on calling activity or the time required for males to return to a chorus. In contrast, Marler and Ryan (1996) found that males of this species given supplemental food were more likely to be calling during subsequent census periods than were males that were not fed. Unfortunately, neither of these studies quantified calling rates or total call production in males that were fed and not fed. Although *Physalaemus pustulosus* breeds more or less continuously throughout the rainy season in Panama, the most active choruses occur on nights after heavy rains (M. Ryan, 1985b). Males probably depend mainly on stored energy reserves to support calling. This species depletes a large proportion of its carbohydrate reserves on a single night of calling, but it apparently derives most of its energy for calling from stored lipids (Bevier 1997b). Feeding might enable males to conserve their lipid reserves by decreasing reliance on stored lipids, as shown for *Hyperolius* (Grafe 1996a), while having only a small effect on call output.

Another frog with a prolonged breeding season is *Hyla gratiosa,* a summer-breeding treefrog from the southeastern United States. Choruses are formed from March through August, and some males remain in choruses for a month or more. Median chorus tenure, however, is much shorter, only two to three days in most years; about 75% of males are present for less than a week. This pattern of chorus attendance suggests that males are energy-limited. Indeed, C. Murphy (1994a, b) found that males suffered reductions in body mass throughout their time in a chorus. Males that remained longer in the chorus were in better condition and lost mass more slowly than those that were present for only a few nights. Males in good condition also were more successful in acquiring mates, both because they were present on more nights, and because they were more likely to attract mates when they were present. Feeding during the breeding season was important for maintaining condition, and males that received supplemental food returned to the chorus more quickly and stayed longer than those that were not fed (C. Murphy 1994b).

In contrast, neither food intake nor body condition had much effect on the number of hours that a male *H. gratiosa* called on any given night (C. Murphy 1999). This suggests that many males probably stop calling well before they have exhausted their energy reserves, perhaps because females are unlikely to continue arriving at the pond. This is consistent with data for *Hyla versicolor* and for many tropical hylids, showing that most males still had significant reserves of glycogen available late in the evening when calling activity was winding down (Schwartz, Ressel, and Bevier 1995; Wells et al. 1995; Bevier 1997b). Food intake in these species probably is important mainly because it allows males to be active in a chorus on many nights, and male chorus attendance is the major determinant of mating success in many species (see chapter 8).

Two studies have examined the impact of supplemental feeding on ranid frogs with low calling rates and long chorus tenure. Judge and Brooks (2001) provided male bullfrogs (*Rana catesbeiana*) with a single meal (two chicken hearts) early in the breeding season. Feeding did not have any effect on chorus tenure or the length of time males occupied territories, but there was a tendency for males in better condition to have longer chorus tenure. Possibly the amount of supplemental food provided to the frogs was not sufficient to produce a significant change in their behavior. N. Gordon (2004) provided male green frogs (*R. clamitans*) with supplemental meals of insects throughout the breeding season. He did not find a significant effect on the amount of time males occupied territories or the vigor with which they responded to playbacks of calls. He did find that males that had been fed tended to move around the pond less than did those that had not been fed. This suggested that males responded to supplemental feeding mainly by reducing the time spent foraging rather than by increasing energy expenditure for territory defense.

Frogs that breed in cold weather face a special energetic challenge, because temperatures often are too low for their prey to be active or for frogs to digest food. Wood frogs (*Rana sylvatica*) and other early spring breeders do not feed at all (see discussion of "Energy Cycles of Males in Explosive Spring-Breeding Anurans"). Wood frogs lack significant lipid reserves, either in the trunk muscles (Ressel 1993) or in abdominal fat bodies (Wells and Bevier 1997). Consequently, they must rely entirely on glycogen reserves to support calling. At the beginning of the breeding season, trunk-muscle glycogen reserves of wood frogs are larger than are those of any other species of frog that has been studied. Despite a relatively low calling rate (table 5.2), these reserves are quickly depleted (fig. 5.20), and in some years, all trunk-muscle reserves probably are gone within a week (Wells and Bevier 1997). Nevertheless, wood frogs can afford to depend entirely on carbohydrates for calling because of their low calling rates and explosive breeding periods.

Spring peepers (*Pseudacris crucifer*) also begin breeding at temperatures too low for feeding, but in contrast to wood frogs, males collected early in the season have very little glycogen stored in either their trunk muscles or livers. Early-season males probably depend almost entirely on their enormous

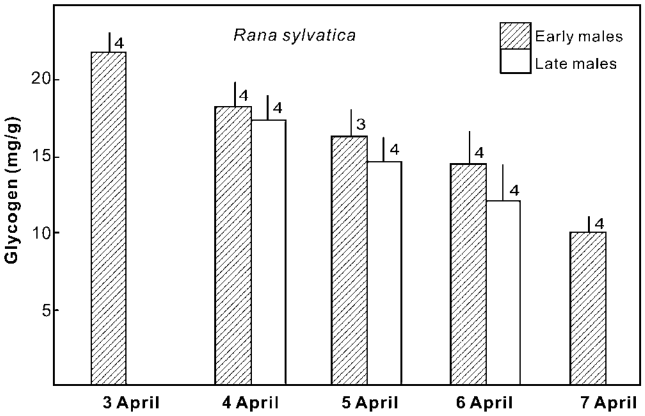

Fig. 5.20. Glycogen concentrations in trunk muscles of male wood frogs (*Rana sylvatica*) from Connecticut collected early in the evening and after 2 hours of calling. Bars show means + 1 SE. Numbers show sample sizes. After Wells and Bevier (1997).

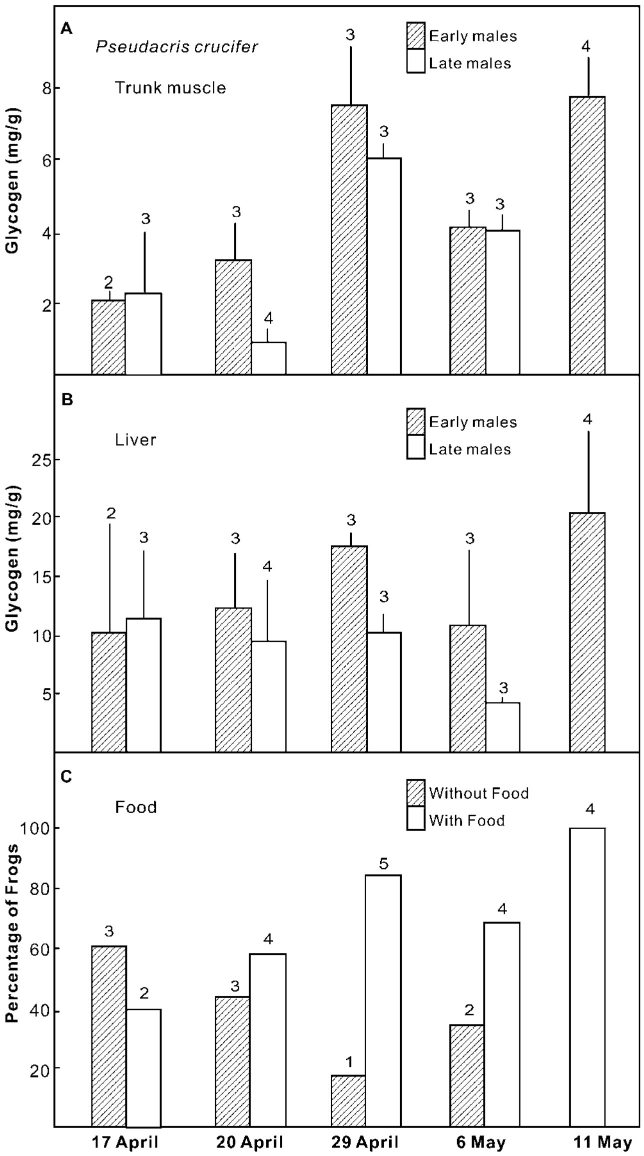

Fig. 5.21. Seasonal changes in (A) trunk-muscle glycogen concentration, (B) liver glycogen concentration, and (C) percentage of males with food in the digestive tract for calling male spring peepers (*Pseudacris crucifer*) in Connecticut. Bars show means + 1 SE. Numbers show sample sizes. After Wells and Bevier (1997).

trunk-muscle lipid reserves, and indeed, Wells and Bevier (1997) could not detect any decrease in glycogen reserves after two hours of calling on some nights. As the season progresses, and temperatures increase, calling rates and energy expenditure by male peepers increase (Wells, Taigen, and O'Brien 1996), probably resulting in an accelerating rate of lipid depletion. Insects also are more readily available, and males can partially compensate for lost energy reserves by feeding. Wells and Bevier (1997) found that the amount of food in the stomachs of males increased late in the season, and this was paralleled by an increase in trunk-muscle and liver glycogen reserves (fig. 5.21). It seems likely that late-season males shift to a greater dependence on carbohydrates for calling as their lipid reserves are depleted, much as *Hyperolius* males shift to using carbohydrates after feeding (Grafe 1996a).

Male frogs probably employ a range of energy use strategies during the breeding season similar to that described for breeding females in many kinds of animals. In the literature of life-history theory, animals often are classified either as capital breeders or income breeders (Bonnet, Bradshaw, and Shine 1998). Capital breeders depend on stored energy reserves to support breeding activities, whereas income breeders rely heavily on current food intake to support reproduction. It seems likely that many male frogs pursue a mixed strategy, relying both on stored energy reserves and food intake to support call production (Wells 2001a).

Table 5.8 summarizes the information on strategies of energy use currently available for two temperate-zone ranids and two hylids. Although this summary is somewhat speculative, it provides a useful framework for understanding strategies of energy use in other frogs. Two species that breed in cold weather, *Rana sylvatica* and *Pseudacris crucifer*, are primarily capital breeders, because they either do not feed at all, or begin feeding late in the breeding season. The stored energy substrates are different, however, with *R. sylvatica* relying entirely on glycogen reserves, and *P. crucifer* relying mostly on lipids. Two summer-breeding frogs, *Rana clamitans* and *Hyla versicolor*, are closer to the income breeder end of the spectrum, because both species are known to feed throughout the breeding season. The precise contribution of food intake to their reproductive energy budgets is not known. Despite the lack of effect of supplemental feeding on the territorial behavior of male green frogs studied by N. Gordon (2004), it seems likely that *R. clamitans* males are heavily dependent on food intake, because they have limited glycogen reserves and apparently do not use fat bodies to support call production (Wells 2001a).

Table 5.8 Hypothesized strategies of energy use in four species of temperate-zone frogs

	Source of energy			
Species	Lipids	Glycogen	Food	Energy-use strategy
Rana sylvatica		++++		Rely on stored glycogen
Pseudacris crucifer	++++	++	+	Mostly use stored lipids
Hyla versicolor	+++	++	++	Mixed strategy: stored lipids, glycogen, and food
Rana clamitans		+	++	Mostly rely on current food intake

Source: From Wells (2001).

Notes: The number of plus signs gives a qualitative estimate of the relative importance of each source of energy for call production. A blank cell indicates that a particular source does not contribute significantly to call production.

Hormones, Calling, and Energetic Constraints

Both the calling behavior of frogs and the physiological and morphological traits that support call production ultimately are under hormonal control. For example, both testosterone and arginine vasotocin (AVT) are known to stimulate calling behavior in frogs (Boyd 1994; Marler, Chu, and Wilczynski 1995; Solis and Penna 1997; Emerson and Boyd 1999; Burmeister, Somes, and Wilczynski 2001; Wilczynski and Chu 2001; Ten Eyck 2005). Androgens also affect the size and function of muscles involved in call production. For example, experimentally administered testosterone can increase the size of both laryngeal muscles (Kelley 1996) and trunk muscles (Emerson et al. 1999), and castration of males can decrease muscle size. These physiological responses are correlated with a greater expression of androgen receptors in the laryngeal and trunk muscles of males than in females (Kelley et al. 1989; Emerson et al. 1999). Testosterone also regulates seasonal changes in contractile properties of the trunk muscles involved in call production (Girgenrath and Marsh 2003).

Despite the obvious links between hormones and calling behavior, we know relatively little about how hormones affect the energetics of calling in frogs. Measurements of androgen and corticosteroid levels of calling males in natural choruses typically show wide variation both within and among species (Emerson and Hess 1996). Such variation appears to be related to variation in morphological and physiological traits that in turn lead to variation among individuals or among species in calling performance. Emerson (2001a) proposed a model that links levels of androgens and corticosteroid hormones to the energetics of call production. She hypothesized that seasonal development of trunk muscles involved in call production is under androgen control. High levels of testosterone are known to increase muscle mass and also alter contractile properties of muscle tissue in some vertebrates. As testosterone levels rise early in the breeding season, the mass of both trunk and heart ventricle muscle probably increases. As males begin calling, testosterone levels increase further in response to the calling of other males and their own calling behavior. At the same time, levels of corticosteroid hormones, which typically respond to stress, begin to rise as well. Some corticosteroid hormones, specifially glucocorticosteroids, can stimulate gluconeogenesis, thereby providing additional energy for call production. At very high levels, corticosteroid hormones counteract the effects of testosterone and AVT and inhibit reproductive behavior, perhaps causing males to stop calling and resume foraging. This could occur even before stored energy reserves are completely exhausted. Indeed, males of some species appear to stop calling well before energy reserves are completely gone (Wells et al. 1995).

The limited data available on hormone levels of frogs in natural choruses are consistent with this model. For example, there typically is a positive correlation between testosterone and corticosteroid hormone levels among calling individuals of the same species (Emerson and Hess 1996, 2001), even though very high levels of corticosteroids can inhibit calling (Marler and Ryan 1996; Burmeister, Somes, and Wilczynski 2001). In at least one species, *Pseudacris triseriata,* levels of both types of hormones increased during a single evening of calling and were positively correlated with each other (Emerson and Hess 2001).

Levels of these hormones also tend to be positively correlated among species, with the highest levels being found in species with high calling rates (Emerson and Hess 1996). In a detailed analysis of several species of Panamanian frogs previously studied by other workers, Emerson and Hess (2001) found that corticosteroid levels were positively correlated with both average calling rate and relative energetic investment in call production. *Hyla microcephala,* which has among the highest energetic investment in calling of any frog studied to date (Wells and Taigen 1989), had the highest hormone levels. *Scinax boulengeri,* which invests much less energy in call production (Bevier 1997a, b), had the lowest levels. *Physalaemus pustulosus* and *Hyla ebraccata* were intermediate. Thus, relative corticosteroid hormone levels not only were correlated with calling performance, but also with the expression of traits related to call production, including mitochondrial volume density (fig. 5.13 A), capillary density (fig. 5.13 B), citrate synthase activity (fig. 5.15), and intramuscular lipid stores (fig. 5.18).

Patterns of Energy Storage and Use

The energy substrates stored in trunk muscle are just one component of energy storage and use in amphibians. Other major energy storage sites include abdominal, cutaneous, and subcutaneous fat bodies, the tail (in urodeles), and the liver (a depot for storage of both glycogen and lipids; Hadjioloff 1930; Fitzpatrick 1976; G. Smith 1976; C. B. Jørgensen, Larsen, and Lofts 1979; Seale 1987; Wygoda, Garman, and Howard 1987; C. B. Jørgensen 1992b). Because of their relatively low maintenance energy requirements, amphibians can rapidly accumulate stored energy reserves during one part of the year for use at another time. They also can shift allocation of energy reserves between reproduction and growth according to seasonal demands and the availability of food, although not all species show a tradeoff between reproduction and growth (Lardner and Loman 2003).

Comparison of Energy Requirements of Males and Females

Maintenance requirements of males and females probably do not differ dramatically for most amphibians, but the energetic demands imposed on the two sexes by reproduction differ both qualitatively and quantitatively. For most species, the major cost of reproduction in females almost certainly is the production of eggs, although other activities such as searching for mates, nest building, brooding of eggs, and feeding tadpoles (in some dendrobatid frogs) add to reproductive costs. For males, the cost of sperm production probably is relatively small. Laboratory studies of males deprived of food have shown that moderate levels of starvation have little or no effect on spermatogenesis in urodeles (Ifft 1942) or anurans (Guha, Jørgensen, and Larsen 1980). Probably the major costs for males are associated with locating, attracting, courting, or fighting over females.

Only limited data are available on reproductive costs for males and females in urodeles. In a study of *Desmognathus ochrophaeus,* Fitzpatrick (1973a) estimated that egg production and brooding consumed about 48% of a female's total annual energy budget, with egg production accounting for 65% of all reproductive costs. The cost of courtship, which Fitzpatrick did not consider, is trivial by comparison (measured for the closely related *D. carolinensis* by Bennett and Houck 1983). Finkler and Cullum (2002) found that metabolic rates of gravid females of *Ambystoma texanum* were double those of males, and free glucose levels in the blood were higher in females as well. They concluded that females have considerably higher costs of reproduction than do males, although they did not measure metabolic rates during activity. In general, it seems likely that reproductive costs for male salamanders (fighting with other males, courtship, and spermatophore production) are small compared to those of females (Bennett and Houck 1983; Marks and Houck 1989).

Most attempts to compare reproductive energy budgets for male and female anurans have not been very precise, because most studies lacked critical data for either males or females. Presumably the high cost of calling in frogs means that reproduction consumes a greater proportion of a male's annual energy budget than it does in salamanders. Nevertheless, in some species, reproductive costs probably are higher for females than for males (Pough et al. 1992). In *Physalaemus pustulosus,* the energy content of eggs is approximately 4 kJ per clutch, while the cost to the female of beating the eggs into a foam nest was estimated to be only 3% as much (0.13 kJ; M. Ryan, Bartholomew, and Rand 1983). The number of clutches produced per year by this species is not known, so it is impossible to calculate the proportion of a female's yearly energy budget that goes into reproduction. Nevertheless, M. Ryan, Bartholomew, and Rand estimated that females that lay between one and 10 clutches per year expend about 1.2–12 times more energy on reproduction than males. More recent measurements of oxygen consumption by calling males in this species (Pough et al. 1992) and average calling rates in the field (Bevier 1995a) suggest that M. Ryan, Bartholomew, and Rand underestimated the cost of calling, perhaps by a factor of two, so their energy budgets probably need to be adjusted.

Grafe, Schmuck, and Linsenmair (1992) used laboratory measurements of oxygen consumption in calling males and egg production by females in *Hyperolius viridiflavus* to calculate total reproductive costs per season. They estimated that female expenditures were about two to three times those of males, but they lacked field data on seasonal variation in male calling effort and female egg production. Mac Nally (1981, 1984b) measured metabolic rates and changes in energy reserves in two species of *Crinia* and estimated that reproductive costs were similar for the two sexes (females apparently produce only a single clutch of eggs each year). He did not have measurements of oxygen consumption in calling frogs, so he used an estimate based on work with *Physalaemus* (Bucher, Ryan, and Bartholomew 1982), a risky procedure given the range of variation among species. His energy budget probably underestimated the cost of calling, because he assumed a five-fold increase in metabolic rate for calling males, much lower than that measured for most species studied to date. Woolbright (1985a) attempted to construct energy budgets for males and females of the Puerto Rican treefrog *Eleutherodactylus coqui.* He estimated that males expend more energy per season on reproduction than do females, but his conclusions must be considered tentative, because he did not have complete data on the costs of calling in males, seasonal and individual variation in male calling effort, or frequency of egg production by females.

Seasonal Cycles of Energy Allocation

Although information on annual expenditures for reproduction remains sketchy at best, it seems likely that for adult amphibians, reproduction is the single largest component of the annual energy budget, probably exceeding energetic investment in growth and routine activities. This does not mean that all amphibians are energetically stressed by their reproductive activities. If food is readily available, amphibians probably have little difficulty in replacing energy reserves depleted by reproduction. Furthermore, the degree to which reproductive activities themselves are limited by energetic constraints will depend on the timing of reproduction, the length of the breeding season, the nature of the mating system, and a variety of other environmental conditions. Limited data on changes in energy reserves throughout the year suggest that several distinct energy allocation patterns can be found among anurans. Few comparable data are available for urodeles.

Energy Cycles of Explosive Spring-Breeding Anurans

Some anurans from the Northern Hemisphere breed in early spring, often only a few days after emerging from their winter retreats. Breeding in these species tends to be explosive, with males remaining at breeding sites for only a few days (see chapter 8). These frogs must accumulate enough stored energy to survive the winter and carry them through the breeding season. In two early breeding European species, *Rana temporaria* and *Bufo bufo,* males usually do not feed at all during the breeding period and are unresponsive to prey that is placed in front of them (Juszczyk 1950; C. L. Smith 1950; Mazur 1967; Heusser 1968a, 1969c; Ashby 1969; Itämies and Koskela 1970; Blackith and Speight 1974; Pasanen and Koskela 1974; C. B. Jørgensen 1986, 1992b). In fact, individuals in some populations move to hidden retreats and become inactive for several weeks after the breeding period before beginning to feed in late spring and summer (Heusser 1968c; Ashby 1969). It seems likely that populations from far northern latitudes or high altitudes are particularly stressed energetically because cold temperatures often prevent the frogs from starting breeding activities until late spring. This leaves a relatively short postbreeding activity season in which individuals must replenish their depleted energy reserves before entering winter dormancy, which can last up to eight months in some regions (R. Savage 1961; Koskela and Pasanen 1974, 1975; M. Morton 1981; Beattie 1985; Terhivuo 1988; Elmberg and Lundberg 1991; Lardner and Loman 2003).

In these cold-weather breeders, stored energy reserves, including fat bodies (fig. 5.22), carcass lipids, and glycogen stores in the liver are at their lowest point during or immediately following the breeding period (C. L. Smith 1950; Mazur 1967; Krawczyk 1971; Pasanen and Koskela 1974; C. B. Jørgensen, Larsen, and Lofts 1979; M. Morton 1981; Guzik and Schimscheiner 1985; C. B. Jørgensen 1992b; Lu 2004). One might expect that frogs with very short breeding periods would not be subject to energetic constraints on their activities, but there is evidence of rapid depletion of energy reserves in several explosive-breeding species. Reductions in body mass of males during the breeding period have been reported in both *Rana temporaria* (A. Cooke 1981; Ryser 1989b) and *Bufo bufo* (Arak 1983c). In a population of *Rana temporaria* from northern Finland, males collected immediately after spawning had only half as much glycogen in their livers as those collected during the spawning period, and only a fourth as much as those collected immediately after emergence from winter dormancy (Pasanen and Koskela 1974). In another population from Britain, both males and females had virtually exhausted their liver glycogen stores and fat body lipids by the time breeding was completed (C. L. Smith 1950).

As discussed earlier, male wood frogs (*Rana sylvatica*) depleted trunk-muscle glycogen reserves after only a few days of calling. Liver glycogen reserves were not depleted, except at the end of the breeding season in a year when trunk-muscle reserves were very low (Wells and Bevier 1997). This species accumulates enormous stores of liver glycogen during the fall. During the winter, these reserves are converted to glucose, which is released in high concentrations into the blood stream and is used as a cryoprotectant to prevent intracellular fluids from freezing (see chapter 3). When the animals thaw, glucose is reconverted to glycogen and stored in the liver. However, repeated cycles of freezing and thawing can deplete liver glycogen reserves (K. Storey and J. Storey 1987; Lee and Costanzo 1993), in part because some glucose is lost through excretion (Layne, Lee, and Cutwa 1996). As a result, frogs entering breeding choruses probably have only a fraction of the liver glycogen reserves that they had the previous fall (Wells and Bevier 1997).

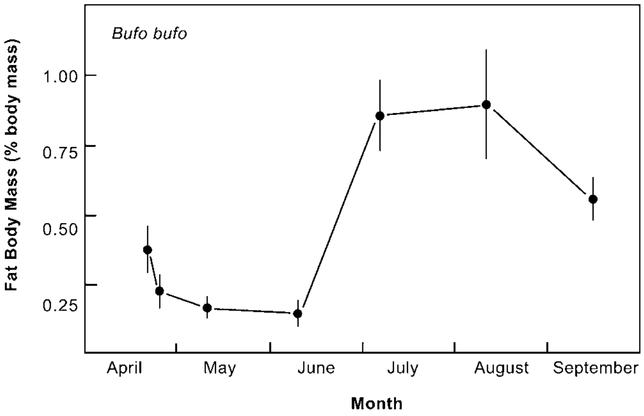

Fig. 5.22. Annual cycle of fat bodies in male common toads (*Bufo bufo*) from Denmark. Data show means ± 1 SE for males collected each month. Breeding occurred in April, immediately following emergence from winter dormancy. Plotted from data in Jørgensen, Larsen, and Lofts (1979).

Year-to-year variation in the duration of breeding activity in a given population can be affected by environmental conditions experienced months earlier. Because energy reserves are accumulated during summer and fall feeding periods, poor foraging conditions during these seasons reduce the energy reserves available for breeding. For example, Reading and Clarke (1995) found that toads (*Bufo bufo*) arrived at breeding ponds in unusually poor condition in a year following a hot, dry summer. Conditions immediately before breeding begins can be important as well. If winter and early spring temperatures are unusually warm, males probably arrive at breeding ponds with a substantial proportion of their energy reserves already exhausted (Ryser 1989b). In a 10-year study of a population of *Bufo bufo,* Reading and Clarke (1995) observed an increase in environmental temperatures in the month before breeding, and this was correlated with a decrease in body condition of both males and females at the breeding ponds. This was true even though breeding actually started earlier in the warmer years. Variation in the number of days that individual males spend in a chorus (Davies and Halliday 1979; Reading and Clarke 1983; R. D. Howard and Kluge 1985; Loman and Madsen 1986; Ryser 1989a; Elmberg 1990) also could be related to differences in stored energy reserves, but this has yet to be clearly established.

In early spring breeders, the breeding period is followed by an increase in feeding activity, probably in response to increasing temperatures and a greater availability of food. Feeding also is influenced by endogenous hormonal cycles (C. B. Jørgensen 1986, 1989, 1991; Jørgensen and Wind-Larsen 1987; Wind-Larsen and Jørgensen 1987). In *Rana temporaria,* the digestive tract actually undergoes a partial degeneration during winter dormancy, and this must be reversed before feeding can resume (Juszczyk, Obrzut, and Zamachowski 1966). Early in the feeding period, most of the ingested energy is allocated to growth and tissue repair, but by late summer, energy is increasingly shifted to stored reserves. A pattern found in a number of temperate-zone anurans is for lipid deposition in the carcass and fat bodies to peak in late summer or early autumn, well before the onset of winter dormancy. In contrast, deposition of glycogen reserves in both the liver and fat bodies usually takes place just before hibernation. In some species, glycogen reserves reach their peak even after the frogs become inactive (C. L. Smith 1950; Mizell 1965; Pasanen and Koskela 1974; Schlaghecke and Blüm 1978b; C. B. Jørgensen, Larsen, and Lofts 1979; Farrar and Dupré 1983; C. B. Jørgensen 1986, 1992a).

In environments where food resources are limited, energetic constraints probably are more severe for female anurans than for males, because allocation of energy to developing eggs competes with allocation to stored reserves that enable the animal to survive a period of dormancy. In early spring breeders, a new ovarian cycle of oocyte maturation usually does not begin until two to four months after spawning, when rebuilding of stored energy reserves is well underway (Gallien 1940; Ting and Boring 1940; C. L. Smith 1950; Mizell 1964; Jastrzebski 1968; Krawczyk 1971; Juszczyk and Zamachowski 1973; C. B. Jørgensen 1973a, b, 1975, 1991; Jørgensen, Larsen, and Lofts 1979). In regions where the activity season is very short, females often cannot acquire enough energy to breed every year and have a biennial or irregular reproductive cycle (Turner 1958; Licht 1975; Morton 1981). In many species, the process of vitellogenesis (provisioning of eggs with nutrients) is largely completed before winter dormancy (Su and Yu-lan 1963; C. B. Jørgensen 1973a, b, 1984a; Jørgensen, Hede, and Larsen 1978; Jorgensen, Larsen and Lofts 1979). In some species, the mass of the ovaries continues to increase during the winter (Lu 2004). C. B. Jørgensen, Larsen, and Lofts (1979) argued that this is due mainly to increases in fluid content and does not reflect transfer of energy from stored reserves to the eggs, whereas Lu (2004) argued that in *Rana chinensis,* the increase in ovarian mass is correlated with decreases in the mass of the liver and fat bodies and therefore represents actual transfer of energy reserves to the eggs.

Energy Cycles of Desert Anurans

Desert-dwelling anurans face many of the same energetic problems that confront early spring breeders, in that breeding often occurs immediately after emergence from dormancy. Furthermore, the frequency, seasonal occurrence, and duration of activity periods generally are less predictable for xeric amphibians than for early spring breeders, because the former respond to sporadic rainfall rather than regular seasonal changes in temperature (Bragg 1945, 1961, 1965; Main, Littlejohn, and Lee 1959; Slater and Main 1963; Mayhew 1965, 1968; Main 1968; Low 1976). Consequently, these animals must store sufficient energy to carry them through dormancy periods of uncertain duration and still have enough reserves to support breeding activities. Most of these species tend to be highly explosive breeders (Bragg 1965; Wells 1977a; B. K. Sullivan 1982b, 1985b; Woodward 1982c), but the energetic costs of reproductive behavior are unknown.

Some desert anurans have extraordinary abilities to survive for long periods without food. Spadefoot toads (*Scaphiopus* and *Spea*) in the southwestern United States sometimes go for a year or more without emerging from their burrows if rainfall is scarce (Bragg 1965; Mayhew 1965). Seymour (1973a) estimated that most individuals in a population of *Scaphiopus couchii* could survive at least nine months on the energy in their fat bodies alone, and some could survive up to two years by metabolizing other energy reserves. Even more remarkable are the survival abilities of water-holding frogs (*Cyclorana platycephala*) from the deserts of central Australia. Using data on stored energy reserves and metabolic rates of dormant frogs, Van Beurden (1980) estimated that all individuals in a population could survive at least 14 months of dormancy, about 20% could survive more than three years, and a few could survive up to nine years without food.

The time available for feeding is unpredictable for desert-dwelling species, so there is a premium on rapid acquisition of food to replenish depleted energy reserves. Couch's spadefoot toads (*Scaphiopus couchii*) can consume insects equivalent to 55% of their own body mass in one feeding. In Arizona, between 57 and 75% of food items in stomachs were winged termites, which emerged after the same heavy rains that triggered breeding by the spadefoot toads (Dimmit and Ruibal 1980). Termites comprised about half of the diet of *Spea multiplicata* as well. In an earlier study, Whitaker, Rubin, and Munsee (1977) reported that termites were the most important prey of *S. couchii* in both Texas and Arizona. Termites are an especially high quality food source because they are rich in lipids and contain relatively small amounts of indigestible material. Dimmitt and Ruibal (1980) estimated that only one or two meals of termites would be required to sustain *Scaphiopus couchii* through very long periods of dormancy in an extremely arid environment.

Most other spadefoot toads live in less arid habitats and do not consistently specialize on termites or other lipid-rich insects. Carabid beetles were the most important prey items for *Spea bombifrons* and *S. multiplicata* in Texas (A. M. Anderson, Haukos, and Anderson 1999a), and *S. bombifrons* from Colorado ate large numbers of these beetles as well (Whitaker, Rubin, and Munsee 1977). *Spea bombifrons* also ate many lepidopteran adults and larvae, and lepidopteran larvae were the most important prey items for *Spea hammondii* in Texas and *Scaphiopus holbrookii* in Indiana (Whitaker, Rubin, and Munsee 1977). In Florida, *S. holbrookii* ate mostly beetles and ants (Pearson 1955). European spadefoot toads (*Pelobates fuscus*) in Romania ate a wide variety of prey, including land snails, beetles, ants, and many other kinds of insects (Cogălniceanu et al. 1998). Much of the variation in diet composition reported in these studies probably is due to local variation in abundance of different kinds of insects, and does not necessarily reflect dietary specialization by particular species.

In contrast to many early spring breeding anurans that overwinter in cold habitats, some desert anurans and other species that are dormant at warmer temperatures continue to provision the eggs during dormancy, drawing on lipid reserves in fat bodies and the carcass (Berk 1938; F. Bush 1963; Seymour 1973a; D. Long 1987a, b). In *Spea multiplicata,* there was no increase in ovary mass or lipid content during dormancy, but individual follicles increased in size. These toads emerged from hibernacula well before breeding, and feeding during the prebreeding period apparently contributed to continued vitellogenic growth of eggs (D. Long, 1989).

Energy Cycles of Anurans with Prolonged Breeding Periods

In anurans with prolonged breeding seasons, there is considerable evidence that males are energetically stressed by their reproductive activities. Reductions in body mass, lipid reserves, and the mass of energy-storing organs over the course of a breeding season have been reported for males of many species, including *Pseudacris crucifer* (McKay 1989; Lance and Wells 1993; Ressel 1993), *Hyla gratiosa* (C. Murphy 1994a, b), *Rana clamitans* (Jenssen 1972; Wells 1978a), *Rana catesbeiana* (Byrne and White 1975), *Rana virgatipes* (Given 1988a), *Rana palustris* (Given 2005), *Rana epeirotica* (Tsiora and Kyriakopoulou-Sklavounou 2001), *Rana esculenta* (Schlaghecke and Blüm 1978a, b), *Rana ridibunda* (Loumbourdis and Kyriakopoulou-Sklavounou 1991), *Uperoleia laevigata* (J. Robertson 1986b), *Bufo canorus* (M. Morton 1981), *Bufo calamita* (Arak 1983c; Tejedo 1992c), *Bufo fowleri* (Given 2002), *Bufo rangeri* (Cherry 1993), two species of *Crinia* (Mac Nally 1981; Lemckert and Shine 1993), and *Pelobates fuscus* (Eggert and Guyétant 2003).

In *Rana clamitans,* the mass of the fat bodies and liver decrease during the breeding season (fig. 5.23 A, B), with the former being almost depleted by the end of the summer (Jenssen 1972). Reduction in liver mass probably is due in part to a depletion of liver glycogen reserves, and trunk-muscle glycogen reserves are gradually depleted as well (Wells and Bevier, unpublished data). Males take in less food during the breeding season than in spring or fall (fig. 5.23 C). This in turn probably results from the amount of time

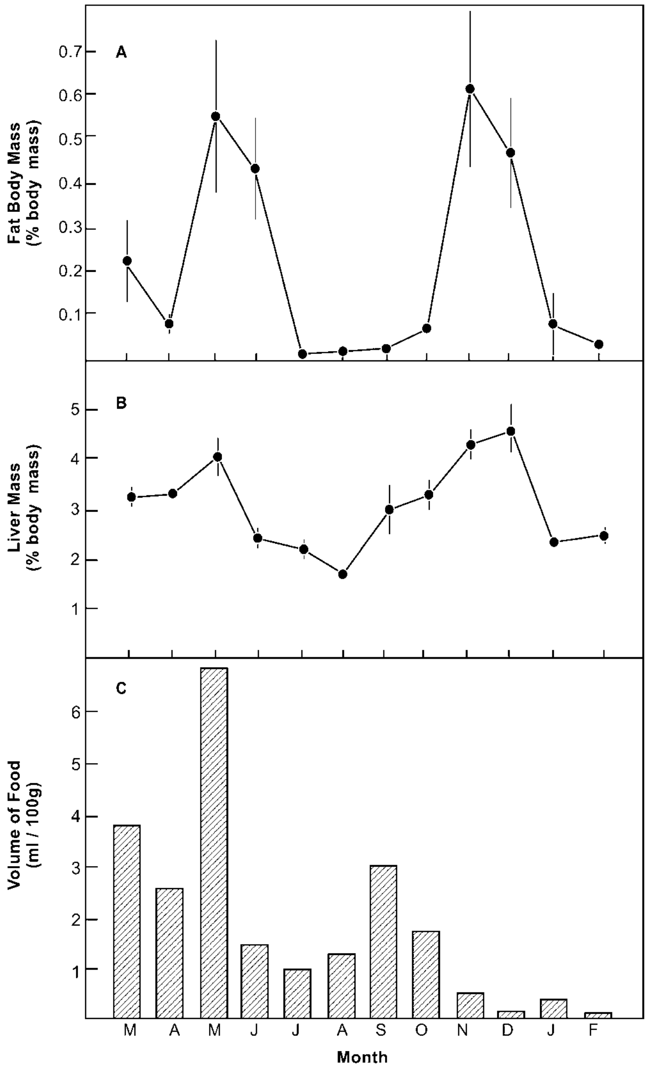

Fig. 5.23. Reproductive energetics of male North American green frogs (*Rana clamitans*), a species with a prolonged summer breeding season and territorial behavior. (A) Annual changes in mass of fat bodies. (B) Annual changes in mass of the liver. Data are shown as means ± 1 SE. (C) Mean volume of food in the stomach per 100 g of body mass for male frogs collected each month. Plotted from data in Jenssen (1972) for a population in southern Illinois.

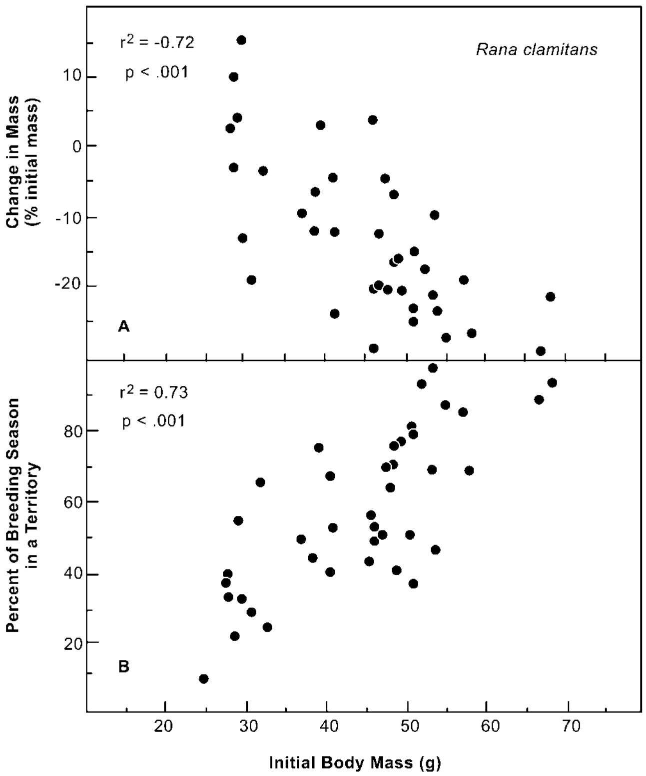

Fig. 5.24. Reproductive energetics of male North American green frogs (*Rana clamitans*). (A) Change in body mass as a function of initial body mass. (B) Percentage of the breeding season devoted to territorial defense as a function of initial body mass. Large males spent more time in territories and decreased more in body mass than did small males. Plotted from data in Wells (1976a) for a population in Ithaca, New York.

males invest in territorial defense. In one study (Wells 1976b, 1978a), large males suffered greater reductions in body mass than did small males (fig. 5.24 A), perhaps because they spent more time defending territories (fig. 5.24 B).

In contrast, Tejedo (1992c) reported that small *Bufo calamita* males lost mass at a faster rate than large males. Loss of mass was positively correlated with time spent in a chorus. Nevertheless, because large males had larger initial energy reserves, they remained in the chorus longer than did smaller males and achieved greater reproductive success. Somewhat similar results were obtained in a study of *Pelobates fuscus* in France. Males in good condition tended to arrive earlier and stay longer than those in poor condition, but suffered less total loss of mass (Eggert and Guyétant 2003). Cherry (1993) observed a steady reduction in body mass of breeding males in an African toad, *Bufo rangeri*, but males increased in mass when they left the chorus to feed. Loss of body mass increased as a function of calling rate.

In a summer-breeding frog from North America, *Rana virgatipes*, there was a direct tradeoff between calling rates of small males and growth rate during the breeding season, with some very active callers decreasing in mass, probably because of the combined effects of high energy expenditure and reduced feeding (Given 1988a). Calling also reduced feeding opportunities in a tropical frog from Puerto Rico, *Eleutherodactylus coqui.* Males seldom fed during peak calling times and obtained most of their food in the early morning hours (fig. 5.25). Consequently, food intake by calling males was substantially below that of noncalling males or females (Woolbright and Stewart 1987).

In females of temperate-zone anurans that breed during the summer, cycles of energy storage and use generally are similar to those of spring breeders, with the mass of energy-storing organs being greatest just before winter dormancy and reaching a minimum during or just after breeding. In contrast to early spring breeders, however, these species often emerge well before the breeding season begins and can replenish depleted energy reserves by feeding. In summer-breeding ranids, such as *Rana catesbeiana, R. clamitans, R. esculenta,* and *R. ridibunda,* vitellogenesis begins in the fall, but often is not completed until after spring emergence (Brenner 1969; Jenssen 1972; Byrne and White 1975; Rastogi et al. 1983; Kyriakopoulou-Sklavounou and Loumbourdis 1990). Furthermore, females that breed early in the season sometimes produce a second egg clutch later in the summer, with energy acquired by feeding during the breeding season (Wells 1976a, b; Emlen1977; Rastogi et al. 1983; R. D. Howard 1988a; Kyriakopoulou-Sklavounou and Loumbourdis 1990). Production of multiple egg clutches during summer breeding seasons also has been reported in a number of North American hylid frogs (Godwin and Roble 1983; Perrill and Daniel 1983; Ritke, Babb, and Ritke

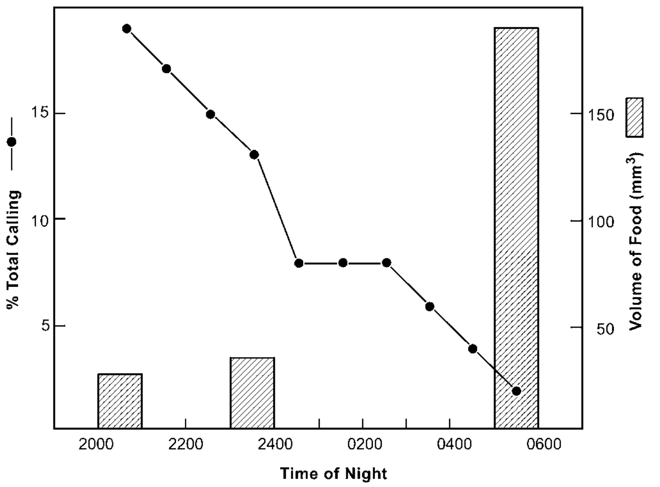

Fig. 5.25. Food intake of male *Eleutherodactylus coqui* from Puerto Rico in relation to calling behavior. Line shows proportion of total calling activity at different times of night for 14 males (plotted from data in Woolbright 1985b). Bars show volume of food in stomachs of male frogs collected at three different times of night (plotted from data in Woolbright and Stewart 1987). Males do most of their calling early in the evening and most of their feeding just before dawn.

1990) and a temperate-zone myobatrachid from Australia (Lemckert and Shine 1993). Females of these species probably also rely on feeding during the breeding season to provision their eggs (Ritke and Lessman 1994). Intervals between successive clutches often vary considerably among individual females, perhaps reflecting differences in foraging success (see table 7.15 in chapter 7).

In contrast to the ranid pattern, female cricket frogs (*Acris crepitans*) in Texas did not initiate ovarian development until after they emerged from winter dormancy, apparently utilizing stored lipids in fat bodies and replenishing them by feeding in the spring (D. Long 1987a). Still another pattern was found in *Bufo woodhousii,* which breeds opportunistically from spring through late summer. Ovarian development was initiated in the fall, but vitellogenesis occurred mainly during winter dormancy, drawing on stored energy reserves. Females generally spawned immediately after emergence, but retained some mature follicles throughout the summer, perhaps allowing them to deposit additional egg clutches during unpredictable periods of favorable weather (D. Long 1987a). A somewhat similar pattern was found in populations of *Bufo viridis* from Israel, which usually breed at the onset of winter rains, but also breed opportunistically at other times when water is available. Females feed throughout the year and can initiate vitellogenic growth of eggs at any time (C. B. Jørgensen 1984b).

In the tropics, anurans exhibit a variety of reproductive patterns, ranging from opportunistic breeding after heavy rains to continuous breeding during long rainy seasons (Crump 1974; Duellman and Trueb 1986; Donnelly 1989c; C. B. Jørgensen 1992b; Prado, Uetanabaro, and Haddad 2005; see also chapter 9). In many tropical species, ovarian cycles are asynchronous among females in a population (Church 1960a, b; Inger and Greenberg 1963; Berry 1964; Inger and Bacon 1968; C. B. Jørgensen, Shakuntala, and Vijayakumar 1986). Individual females sometimes lay several egg clutches each year (Senfft 1936; Chibon 1962; Pyburn 1966; Davidson and Hough1969; Crump 1974; Wells 1979, 1980a; Kluge 1981; K. Summers 1989; see table 10.5 in chapter 10 for examples). There is relatively little published information on patterns of energy storage and use in tropical anurans. It seems likely that continuous breeders in the tropics rely heavily on feeding during the breeding season to provision new egg clutches. In contrast, explosive or opportunistic species might be expected to rely at least in part on stored energy reserves. In several tropical species of *Bufo,* the size of fat bodies did not show a clear seasonal pattern. Nevertheless, fat bodies tended to be smallest in females with mature ovarian eggs or those that had just finished spawning, indicating that energy reserves are depleted during egg production (G. Alexander 1933; Church 1960a; Zug and Zug 1979; C. B. Jørgensen et al. 1986). In tropical anurans that breed in areas with pronounced wet and dry seasons, there does tend to be clear seasonal variation in fat body size. Fat bodies typically increase during periods of feeding, but decrease when eggs or sperm are being produced (Pancharatna and Saidapur 1985; Kanamadi et al. 1989; Kanamadi and Jirankali 1991, 1992). This pattern is not always seen in males, however. In some tropical species, variation in fat body size and testis size are not correlated (Saidapur, Kanamadi, and Bhuttewadkar 1989), perhaps because testicular activity is not necessarily directly related to the nutritional condition of males (Kanamadi and Saidapur 1988).

A comparative study of two populations of *Bufo marinus* in a wet and dry site in Venezuela revealed seasonal variation in fat body size, but the pattern differed at the two sites (Lampo and Medialdea 1996). At the wetter site, the toads were dry season breeders, laying eggs in pools along a river. Fat body size of females increased during the wet season. At the drier site, females did not show a clear peak of reproduction in any season, but fat body size did increase slightly in the wetter months. Males showed a similar pattern, but only at the dry site was fat body size inversely correlated with gonad size. In both sexes, fat body size was directly related to rainfall, which in turn was positively correlated with food intake. Toads at the wetter site allocated a larger proportion of their total body mass to fat bodies, indicating that they were more likely than those at the dry site to acquire energy in excess of that needed for reproduction.

In tropical India, frogs typically breed during monsoon rains, which occur either in a single period during the summer or in both summer and winter. In *Euphlyctis hexadactylus* from southern India, females with mature eggs were found throughout the year, but most breeding occurs in three seasonal peaks corresponding to rainy periods (Das 1996b). Fat body size in both males and females increased during the peak feeding months (the dry season), but declined sharply during breeding periods. Depleted fat reserves were rapidly replenished, increasing by up to 300% in about two months. In *Hoplobatrachus tigerinus,* there was only one peak of breeding during the summer monsoon rains (Girish and Saidapur 2000). Again, fat bodies increased during feeding periods and decreased in the breeding season. Supplemental feeding in the laboratory increased both the size of fat bodies and the number and size of ovarian eggs. Experimental removal of fat bodies did not diminish the number of eggs produced, but did result in smaller eggs. Removal of fat bodies from males resulted in regression of the testes (Kasinathan, Gunasing, and Basu 1978).

Energy Cycles of Urodeles

We know very little about seasonal energy cycles in male salamanders or how energy reserves might limit their reproductive activities, because there has not been much work on seasonal changes in energy stores. Changes in body mass tend to be a poor indicator of nutritional condition, because salamanders often take up substantial amounts of water when they first enter a pond (Aoto 1950; Verrell and Halliday 1985b; Hasumi and Iwasawa 1990). Species that breed during warm weather can feed at breeding sites (Verrell 1985a) and actually can increase in mass if they remain in ponds for long periods of time (Verrell and Halliday 1985b). On the other hand, Verrell, Halliday, and Griffiths (1986) found that male *Triturus vulgaris* showed substantial reductions in the mass of the liver and abdominal fat bodies during the summer breeding season, but replenished their reserves during the fall. How much of their stored energy is used for production of sperm and spermatophores, and how much for aggression and courtship, has yet to be determined, but males do appear to be under some energy stress. In another European salamandrid, *Chioglossa lusitanica,* the mass of the liver and tail decreased in males during the breeding period; both of these organs are important for energy storage (Sequeira, Ferrand, and Crespo 2003). Males of another salamander, *Amphiuma means,* exhibited reductions in fat body mass and carcass lipids during the breeding season (F. Rose 1967), but the reproductive behavior of this species is completely unknown.

Patterns of energy storage and use by female salamanders have not been studied extensively, although there is good information for *Desmognathus ochrophaeus* (Fitzpatrick 1973a, 1976). It is known that lipids stored in both fat bodies and the carcass are mobilized for vitellogenesis (Adams and Rae 1929; Tachi 1963; F. Rose 1967; Rose and Lewis 1968; Lewis and Rose 1969; Fitzpatrick 1973a; D. Scott and Fore 1995). Generally, lipid reserves of temperate-zone salamanders follow the same annual cycle as in anurans, reaching a low point at the end of the reproductive period and increasing until just before winter dormancy. The amount of energy stored as lipids varies with food intake, and this in turn can affect the probability that a female will reproduce in a given year and the number of eggs that she lays (D. Scott and Fore 1995). In some terrestrial salamanders, the tail is a particularly important energy storage organ, sometimes comprising up to 50% of an animal's biomass. In *Chioglossa lusitanica,* the tails of females decrease in mass during the breeding period (Sequeira, Ferrand, and Crespo 2003), and females with autotomized tails are less likely to produce eggs than those with intact tails (Arntzen 1981; see also Maiorana 1977).

The eggs laid by many plethodontid salamanders take weeks or even months to develop and hatch (Houck 1977a). In terrestrial species, the female often remains in close proximity to her eggs, protecting them from predators and providing them with moisture (Crump 1995b; see also chapter 11). This form of parental care can severely limit the foraging of females and lead to depletion of stored energy reserves. Because brooding is relatively prolonged, this can account for a significant fraction of a female's energy budget. Fitzpatrick (1973a) estimated that *Desmognathus ochrophaeus* females used about 16% of their annual energy budget for brooding eggs, mostly derived from stored lipids. The energetic demands of brooding can reduce growth rates as well, and in some species, brooding females decline in overall body condition (Ng and Wilbur 1995). Salamanders that brood their eggs for relatively short periods of time, or at low temperatures, probably incur a lower cost of brooding than those that brood eggs for several weeks during the summer (Kaplan and Crump 1978).

Summary and Conclusions

Amphibians have the lowest resting metabolic rates and lowest energy requirements of any terrestrial vertebrates. This low-energy lifestyle was once viewed as a handicap that prevented amphibians from exploiting the terrestrial environment as effectively as reptiles, birds, or mammals. Biologists now generally view the low energy requirements of amphibians as a feature that allows them to occupy niches not available to other vertebrates. Metabolic rates of amphibians are temperature-dependent, as they are in all ectotherms. Laboratory studies of thermal acclimation of metabolic rates have revealed a number of different types of response to acclimation at constant temperatures, ranging from complete metabolic compensation to a parallel effect of temperature change on metabolic rate. Many workers have tried to interpret the results of such experiments in terms of adaptations to increase metabolic efficiency or conserve energy, but the connection between laboratory-induced acclimation and acclimitization of metabolism under natural conditions is complex and difficult to evaluate.

Many amphibians rely on anaerobic metabolism to support short bursts of activity, such as rapidly escaping from a predator or lunging at prey. Anaerobic metabolism is less affected by environmental temperature than aerobic metabolism, although it is not completely independent of temperature. Anaerobic metabolism also makes energy available more quickly than aerobic metabolism, but can lead to inefficient use of energy substrates. Studies linking the ecology and behavior of amphibians with their metabolic physiology have revealed a considerable range of variation in metabolic strategies, especially among anurans. Species that engage in long periods of sustained activity, such as walking, swimming, or burrowing, generally have higher aerobic capacities and are less dependent on anaerobic metabolism than species that engage in short bursts of activity. Amphibians as a group have a relatively poor capacity for sustained, aerobically supported locomotion; the aerobic capacities of urodeles generally are lower than those of anurans, even though maximum aerobic speeds are not very different in these groups.

The limb muscles of amphibians that have high aerobic capacities for locomotion have morphological and biochemical characteristics that reflect their capacity for aerobically supported work. Although gross fiber types are not very different in different species of anurans, those with high aerobic capacities, such as toads (*Bufo*), have higher proportions of fast oxidative fibers than do species with lower aerobic capacities, such as frogs in the genus *Rana*. Activities of key enzymes involved in aerobic metabolism also are higher in species with high aerobic capacities. Some studies of individual variation in aerobic capacity, maximum aerobic speed, and sprint speed have revealed a correlation between one or more of these measures of performance capacity and leg muscle enzyme activities, whereas other studies have failed to show such a relationship. Correlation between physiological or behavioral performance variables and muscle biochemistry at the individual level appears to be more likely in species that support locomotion aerobically than in those that rely mainly on anaerobic metabolism.

A major shift in our understanding of amphibian metabolism occurred in the mid-1980s with the discovery that many species of frogs can achieve higher rates of aerobic metabolism while calling than they can during bouts of forced exercise in laboratory chambers. Previous workers had always considered the maximum metabolic rates measured during forced exercise to represent the maximum aerobic capacity of an animal. In some cases, metabolic rates of calling frogs are more than double the maximum aerobic capacity for locomotion. This is not necessarily true for all frogs, however, because nearly all measurements of O_2 consumption in calling frogs have been performed on species with relatively high calling rates. The ability of frogs to elevate their metabolism as much as 25 times resting rates became less puzzling with the discovery that the muscles involved in call production are fundamentally different in morphology and biochemistry from those used in locomotion. This is especially true for species with very high calling rates, which have trunk and laryngeal muscles composed of more aerobic fiber types than leg muscles, with much higher concentrations of mitochondria, higher capillary densities, and higher activities of enzymes involved in aerobic metabolism. Recent studies have revealed a wide range of variation in morphological and biochemical characteristics of call-producing muscles, even within the same family of anurans. Species that call at very low rates have muscles that lack many of the features that enhance muscle aerobic capacity, and in some cases, these muscles are not very different from the leg muscles of the same species.

The way in which anurans allocate their energy reserves for call production and other reproductive activities also varies considerably. Anurans with very high calling rates depend heavily on stored lipid reserves to support call production, because available carbohydrate reserves are not sufficient to support calling at high rates for more than a few hours. Some species, such as the spring peeper (*Pseudacris crucifer*) and some tropical hylids, have higher concentrations of lipids in their trunk muscles than are found in most other lipid-rich vertebrate muscle. Stores of lipids are closely associated with the mitochondria, which provide the machinery for aerobic work. Frogs that call at low rates lack extensive intramuscular lipid reserves and apparently depend almost entirely on carbohydrates to support call production. In this respect, the variation in energy-use strategies in calling frogs parallels that of singing insects and exercising mammals.

Annual patterns of energy storage and use by male anurans also vary among species and are related to temporal patterns of reproduction, the availability of females, and the temperature at which males are active. Many frogs and toads that breed in early spring must depend on stored energy reserves to support call production and other reproductive activities, because they emerge from hibernation and move to breeding sites before food is readily available. Some species, such as wood frogs (*Rana sylvatica*), lack extensive lipid reserves and rapidly deplete stored carbohydrate reserves during an explosive breeding period. Frogs with prolonged breeding seasons and relatively low calling rates, such as summer-breeding ranids, appear to deplete energy reserves much more slowly, and they can supplement energy reserves by feeding. Individual males often are present for a substantial proportion of the breeding season. In contrast, frogs with prolonged breeding seasons and high calling rates, such as many hylid treefrogs, deplete energy reserves relatively rapidly, and chorus tenure of individual males often is very short. Desert anurans resemble early spring breeders in that they move to breeding ponds immediately after emerging from dormancy and must rely mainly on stored energy reserves to support reproductive activities. Because favorable conditions for feeding are relatively brief, desert anurans often feed voraciously immediately after breeding and sometimes specialize on lipid-rich prey, such as termites.

Much less is known about patterns of energy use in urodeles. Costs of reproduction, including aggression, courtship, and production of spermatophores, have been measured in only one species of plethodontid salamander, and these appear to be very low compared to the cost of calling in frogs. Newts in the family Salamandridae engage in prolonged, vigorous courtship that is more likely to be energetically costly, but direct measurements of such costs have not been made. Annual patterns of energy use in temperate zone urodeles resemble those of anurans, with energy reserves being depleted during the breeding season and rebuilt before winter dormancy. In some species, however, mating and egg-laying seasons are separated, and courtship takes place both before and after winter hibernation. Females of many plethodontid salamanders remain with their eggs throughout development, which can be prolonged, and the energetic costs of brooding and lost opportunities for feeding can represent a substantial portion of a female's annual energy budget.

The basic features of the metabolism and energetics of amphibians are now well understood, but many details remain to be investigated. For example, there has never been a rigorous, phylogenetically controlled comparison of metabolic rates of anurans from tropical and temperate-zone regions, nor has the temperature sensitivity of metabolism in tropical and temperate-zone species been investigated in detail. One would expect temperate-zone species to exhibit lower temperature sensitivity, especially at low temperatures, because they are more likely to encounter a wide range of temperatures on a daily or seasonal basis. Some low-elevation tropical species have been shown to have lower resting metabolic rates at low temperatures than high-elevation species in the same genera, but the effect was even greater for activity metabolism. Low-elevation species were incapacitated at temperatures commonly experienced by high-elevation forms. Similarly, temperate-zone frogs such as spring peepers (*Pseudacris crucifer*) are active and call at temperatures below the lower lethal limits for some tropical hylids. The capacity for activity at low temperatures is assumed to be a derived trait in hylids (Hedges 1986), and it would be interesting to examine the evolution of physiological traits related to temperature sensitivity in more detail. These might include changes in muscle enzyme activities, the composition of isozymes present in the muscles, or changes in muscle contractile properties.

Ecological correlates of variation in exercise physiology also need to be reexamined, especially in anurans, which are more diverse in their locomotor behavior and foraging ecology than other amphibians. Studies like that of Taigen et al. (1982) revealed a relationship between aerobic capacity and broadly defined ecological and behavioral categories such as foraging mode and burrowing behavior. There is evidence from studies of groups of closely related species, such as dendrobatid frogs, that anurans actually exhibit a continuum of activity strategies correlated with a similar range of variation in metabolic characteristics. There is a need for more detailed, phylogenetically controlled comparative studies that actually quantify behavioral and ecological variables that can be related to metabolic physiology. Investigators also need to pay closer attention to individual variation in behavioral performance and how this is related to variation in physiological traits (Bennett 1987).

Studies of reproductive energetics offer a rich opportunity to examine possible physiological constraints on behavioral performance that directly affects individual fitness. Energetically expensive activities such as calling are more likely to push individual animals to their physiological limits, rather than relatively low-level activities such as foraging, so differences in physiological capacities probably lead to differences in mating success. Although we now have a reasonably good understanding of the cost of calling in some hylids, leptodactylids, and hyperoliids with high calling rates, it is important not to draw sweeping conclusions about the potential cost of calling in all frogs from this limited data set. All of the species for which we have actual measurements of metabolism during calling represent a phylogentically restricted set of species with rather similar breeding ecology. We have some evidence indicating that the cost of calling in other frogs, such as ranids, is much lower than in species with high calling rates, leading to very different strategies of energy allocation. The calling energetics of archeobatrachian frogs has scarcely been investigated, and we know very little about the vast array of tropical forest frogs with unusual reproductive modes. We also need much more detailed information on the natural range of variation in hourly calling rates, nightly calling effort, and seasonal chorus tenure in frogs, so that accurate estimates of total energy expenditures can be made. Until such information is available, it will be impossible to construct reliable annual energy budgets for these species.

Chapter 6 Movements and Orientation

The solitary pool has drawn to itself the entire toad population of the surrounding country. . . . Each toad has his own home or hermitage somewhere in that area, where he spends the greater portion of the summer season. . . . When spring returns he sets out on his annual pilgrimage of a mile or two . . . until he arrives at the sacred pool.

The music and revels over, the toads vanish, each one taking his own road, long and hard to travel, to his own solitary home. Their homing instinct . . . is practically infallible.
—W. H. Hudson, *The Book of a Naturalist* (1919)

One problem with trying to understand the ecology and behavior of amphibians is the difficulty of relating to the spatial scale on which these animals operate. A person walking through a forest inhabited by terrestrial salamanders is much like Gulliver in the land of the Lilliputians. A single stride can encompass the entire home range of a salamander, and several strides will carry the person beyond the area covered by a salamander in a lifetime of movement. Indeed, amphibians almost certainly are the most sedentary of terrestrial vertebrates. A comparison of amphibians to other vertebrates weighing less than 20 g reveals that home ranges of amphibians are 250–10,000 times smaller than those of birds, 125–2,000 times smaller than those of mammals, and 2–500 times smaller than those of small insectivorous lizards (table 6.1). These differences probably are conservative estimates. For reasons that will be discussed, published figures on amphibian home range sizes probably exaggerate the extent of their daily movements. Furthermore, the way in which amphibians utilize their home ranges differs considerably from the behavior of other vertebrates. A bird can traverse its entire home range every few minutes, a small mammal can do so in a few hours, and a lizard in a few days or weeks. An amphibian, on the other hand, probably spends much of its time in a very limited area and makes only occasional movements to other parts of the home range. In addition, the home range of a bird or arboreal lizard often has a substantial vertical component, whereas the home ranges of most amphibians are essentially two-dimensional.

Many aspects of the ecology and behavior of animals are affected by their capacity for movement. Sedentary animals do not have the option of making long-distance movements to escape from periodic changes in weather, and they often are forced to obtain food or mates from a relatively limited area. Daily, seasonal, and lifetime movements affect nearly every other aspect of an animal's behavior and ecology (Swingland and Greenwood 1983), including foraging ecology and energetics (chapter 5), territorial behavior (chapters 8, 9), mating systems (chapters 8, 9), responses to predators (chapter 14), and interactions with other species (chapter 15). Patterns of movement, especially dispersal, affect the dynamics of populations (Gill 1978a, b; Sinsch 1992c; Miaud et al. 1993; Sinsch and Seidel 1995), their genetic structure, (Shields 1982; Breden 1987; Thornhill 1993; Scribner et al. 2001) and the evolution of life history strategies (chapter 10; Horn 1983; Horn and Rubenstein 1984). Conservation decisions also depend on detailed information on pat-

Table 6.1 Approximate home range sizes of small terrestrial vertebrates (< 20 g)

Group	*No. of species*	Home range size (m^2) Range	Median	Source
Birds	34	1,000–44,000	10,000	Schoener, 1968
Mammals	9	500–8,100	2,500	Harestad and Bunnell 1979; Eisenberg 1981
Lizards

terns of movement within and between habitats (Langton 1989; Reh and Seitz 1990; Dodd 1996; Dodd and Cade 1998; Gibbs 1998a; Hitchings and Beebee 1998; Baker and Halliday 1999; see also chapter 16).

Types of Movement

Any type of movement carries potential costs for amphibians, including energetic costs, exposure to predation, and exposure to drought or other unfavorable climatic conditions. Consequently, amphibians move only when absolutely necessary. All animal movement is related in some way to acquisition of resources, including food, mates, and shelter from extreme environmental conditions. Some amphibians make repeated short movements away from a central location, such as a diurnal retreat site, while others wander more widely between resource patches. Some also make long distance movements, usually between habitat patches that are used in different seasons. Many amphibians are largely sedentary or even remain underground for much of the year, restricting their movements to certain seasons, when they move to breeding or hibernation sites.

Movements that are directly related to the acquisition of resources such as food, mates, or retreat sites that tend to keep an animal within a home range have been termed station keeping (Dingle 1996). Foraging is one type of station keeping, as is territorial defense of all or part of the home range. Any movement outside of a home to explore new resource patches is termed ranging behavior. Ranging behavior includes occasional forays outside of an established home range by adults, as well as movements of juveniles away from natal areas. Movements of juvenile amphibians away from breeding ponds often have been described as dispersal movements. However, many of these juveniles eventually will return to their natal ponds to breed, so only those that move permanently to new ponds can be considered dispersers (Breden 1987). The rest move some distance from their natal ponds, perhaps searching for new breeding sites, but eventually return without permanently shifting their locations.

The term dispersal often has been used to distinguish one-way movements from bidirectional movement, often called migration. Dingle (1996) defined migration as a specialized kind of movement that is not directly responsive to resources. Typical features of migration include the following: movement that is persistent and of greater duration than during station keeping or ranging; movement that takes place along relatively straight-line paths; temporary suppression of responses to resources that normally terminate movement, such as food; the occurrence of activity patterns related to departure and arrival; and allocation of energy reserves specifically to support migration. Although many migratory animals exhibit bidirectional movement, not all migration is bidirectional. Compared to other terrestrial vertebrates, especially birds and mammals, amphibians are not highly migratory animals. Even the longest migrations of amphibians between winter or summer locations and breeding ponds seldom exceed a few hundred meters.

Local Movements and Home Range

Methods for Studying Amphibian Movements

Most amphibians are difficult subjects for studies of movement patterns because of their secretive habits. Continuous observation of marked individuals usually is not feasible, because amphibians often spend much of their time under cover or underground. The most common method for studying movements of amphibians is to mark the animals, release them, and recapture them at variable intervals. A variety of methods has been used to mark and identify amphibians, including toe-clipping, marking with various sorts of waistbands and tags, tattooing, heat branding, freeze branding, marking with silver nitrate, marking with fluorescent powders, skin autografts, and mapping of individual color patterns (Ferner 1979; Donnelly et al. 1994; Kuhn 1994b).

Toe clipping is by far the most common method, because it is the least expensive and easiest method for fieldwork. Some investigators have reported that toe clipping can slightly increase mortality (Clarke 1972) or lead to infected toes (Golay and Durrer 1994), but other studies have not found these detrimental effects (van Gelder and Strijbosch 1996; Lüddecke and Amézquita 1999). Davis and Ovaska (2001) found that toe clipped salamanders (*Plethodon vehiculum*) gained less mass in the field than did unmarked salamanders or those marked with fluorescent paint. There also appeared to be slightly higher mortality among toe-clipped individuals. Some investigators have suggested that toe clipping is responsible for the relatively low recapture rates obtained in many studies (Nishikawa and Service 1988). Nishikawa also argued that toe clipping could cause animals to move farther than they would normally (Nishikawa 1985), but Davis and Ovaska (2001) did not find any effect of marking method on patterns of movement in *P. vehiculum*. The disadvantage of all mark-recapture techniques that have been used in studies of movement is that animals often disappear for weeks or months at a time, then reappear near the original capture site. The apparent movement of the animal is very small, but its actual movements in the intervening period are unknown.

Various techniques have been used for fine-scale studies of individual movement. One is to label animals with small radioactive wires and then locate them on successive days with a detection device (Karlstrom 1957; Breckenridge and Tester 1961; Barbour et al. 1969; Madison and Shoop 1970; Kramer 1973, 1974; Clarke 1974a; Ashton 1975; Ashton and Ashton 1978; Semlitsch 1981b; Kleeberger and Werner 1982). This allows the investigator to obtain many sightings of each individual, thereby providing accurate estimates of day-to-day movements. This method is most useful for small-bodied species with relatively small home ranges (Ashton 1994). It is of limited use for species that spend much of their time deep in subterranean burrows. It also does not uniquely identify individuals, so other identifying marks are required. Unfortunately, the animals sometimes suffer injury from the radioactive wires (Ashton 1975; Semlitsch 1981a), and permission to use radioactive materials can be hard to obtain. The technique also is fairly expensive and has not been widely used in recent years. A technique developed more recently is to mark individuals with tiny implanted passive integrated transponders (PITs) containing computer chips that produce unique identification numbers when activated with a special reading device (Camper and Dixon1988; Sinsch 1992d; Fasola, Barbieri, and Canova 1993). This is an expensive technique, but it allows repeated identification of individuals without a lot of handling. A disadvantage of this technique for studying movements is that the tags can only be detected at close range.

Several investigators have used fluorescent powders of different colors to mark amphibians for long-term or short-term studies of movements. When these are applied to the skin under pressure, they can produce marks that are visible under ultraviolet light and last for more than a year (Nishikawa and Service 1988; Davis and Ovaska 2001). Nishikawa (1990) used this technique to make detailed studies of plethodontid salamanders moving around on the surface at night. Other workers have simply sprinkled fluorescent powders onto the backs of amphibians to monitor nightly movements over relatively short periods of time (Woolbright 1985b; Ovaska 1992). This method is most useful for animals that are readily visible on the forest floor or on vegetation at night, because it allows them to be identified without disturbance. Windmiller (1996) attached strips of yarn dipped in fluorescent powder to the backs of frogs and was able to monitor movements of up to 150 m by following trails of powder left on the ground. He also experimented with capsules filled with luminescent fluid that were attached to the backs of animals and were visible for up to 80 m.

In a study of box turtle movements, Stickel (1950) equipped animals with spools of thread that unwound as the animal moved, leaving a record of its path. This technique has subsequently been used with some success in studies of anuran movements (Dole 1965a, b, 1968, 1972a, c; Tracy and Dole 1969b; Grubb 1970; Neill and Grubb 1971; Sinsch 1987a, c, 1988b, c; Duellman and Lizana 1994; Seebacher and Alford 1999; Tozetti and Toledo 2005). This method provides information on movements over relatively short intervals, but it is impractical for small-bodied species.

Radio tracking has been widely used to study movements of mammals, birds, and reptiles, but until relatively recently, most transmitters were too large to be implanted in or carried by any but the largest amphibians. Transmitters now have been sufficiently miniaturized to be used with many kinds of amphibians. They have been used successfully with toads (*Bufo;* Nuland and Claus 1981; van Gelder et al. 1986; Sinsch 1992b, c; Oldham and Swan 1992; Denton and Beebee 1993a; Kusano, Maruyama, and Kaneko 1995; Seebacher and Alford 1999; Miaud, Sanuy, and Avrillier 2000; Schwarzkopf and Alford 2002; Muths 2003; Bartelt, Peterson, and Klaver 2004), ranid frogs (Fiorito et al. 1994; Spieler and Linsenmair 1998; Lamoureux and Madison 1999; Matthews and Pope 1999; Richter et al. 2001; Bulger, Scott, and Seymour 2003), small rhacophorid frogs (Fukuyama, Kusano, and Nakane 1988; Kusano 1998), hellbenders (*Cryptobranchus;* Stouffer et al. 1983; Gates et al. 1985), ambystomatid salamanders (Madison and Farrand 1998), and newts (Jehle and Arntzen 2000). The transmitters are mounted on a harness or waistband, surgically implanted, or ingested by the animals. Unfortunately, there is considerable potential for either external or implanted transmitters to cause injury even to relatively large species of amphibians (Weick et al. 2005).

Patterns of Movement

Many amphibians exhibit considerable fidelity to limited areas of suitable habitat, although they sometimes move between habitats at different seasons. Individuals have been found in the same home ranges for up to five years in *Scaphiopus holbrookii* (Pearson 1955, 1957), seven years in *Sala-*

mandra salamandra (Joly 1968; Rebelo and Leclair 2003b) and *Plethodon kentucki* (Marvin 2001), and nine years in *Bufo bufo* (Heusser 1968d). Similar fidelity to hibernation sites has been observed in *S. salamandra,* with some individuals hibernating in the same cave for 20 years (Feldmann 1987). Some Manitoba toads (*Bufo hemiophrys*) turned up in the same mounds on a Minnesota prairie every winter for up to six years (Kelleher and Tester 1969). These same toads exhibited very little fidelity to summer home ranges, perhaps because they lived in relatively uniform habitat at that season (Breckenridge and Tester 1961).

Routine movements during activity seasons usually are quite limited, with distances between recapture points averaging less than 10 m for terrestrial salamanders (table 6.2) and less than 15 m for terrestrial anurans (table 6.3). Even the large aquatic salamander *Cryptobranchus alleganiensis* generally moved only 10–30 m between recaptures (Hillis and Bellis 1971; Nickerson and Mays 1973b), although they sometimes moved 1–2 km over a period of months (Gates et al. 1985). Both *Siren lacertina* and *Amphiuma means* in Florida showed similar sedentary patterns of behavior, with no movements of more than 10 m being observed for either species (Sorensen 2004). Nevertheless, recapture rates for these species were extremely low, so the possibility of long-distance movements cannot be ruled out. Daily movements within a home range probably are considerably shorter for most species. Comparisons of movement distances based on mean values can be misleading, because distributions of movement distances usually are negatively skewed (fig. 6.1), with many short movements and only a few long ones (Stebbins 1954b; Bellis 1965; Hillis and Bellis 1971; Wells and Wells 1976). Consequently, median movement distances often are lower than means and provide a better estimate of typical movement (tables 6.2, 6.3).

Amphibians sometimes make brief excursions outside their normal home ranges, possibly in search of mates or better quality home sites. Such excursions usually occur in rainy weather and range from less than 100 m in terrestrial salamanders (Barbour et al. 1969; Wells and Wells 1976; Staub, Brown, and Wake 1995) to several hundred meters in anurans (Raney 1940; Willis, Moyle, and Baskett 1956; Turner 1959, 1960a; Breckenridge and Tester 1961; Bellis 1965; Dole 1965b; Heusser 1968d; Duellman and Lizana 1994; Kam and Chen 2000; Frétey et al. 2004). Long movements often are most apparent with long recapture intervals, so mean movement distance sometimes is positively correlated with mean recapture interval (Ingram and Raney 1943; Turner 1959; Bellis 1965; Hollenbeck 1974; Wells and Wells 1976; Duellman and Lizana 1994). Including these occasional long movements in calculations of home range size (see the following discussion) can lead to serious overestimates of the area in which an animal carries out its daily activities. On the other hand, many studies of movement patterns, especially for terrestrial salamanders, have been conducted on plots that were too small for very long movements to be detected (Staub, Brown, and Wake 1995). Ignoring such movements could result in an underestimate of the amount of habitat that is familiar to an individual animal.

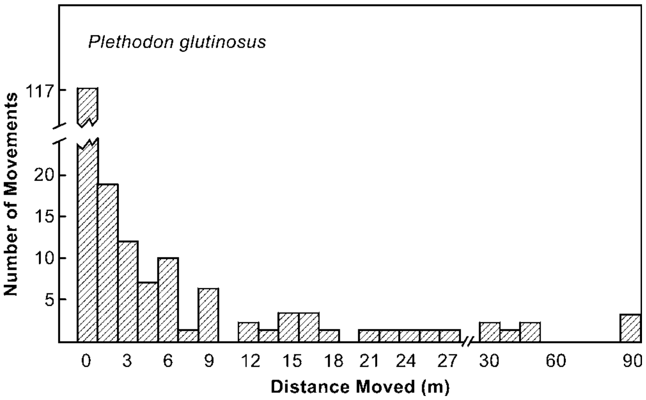

Fig. 6.1. Distribution of distances between recaptures for a population of slimy salamanders (*Plethodon glutinosus*) in North Carolina. The pattern of movement is typical of many amphibians, with many short movements and relatively few long ones. After Wells and Wells (1976).

Continuous monitoring of marked individuals throughout their activity periods provides much more useful information on short-term patterns of movement than do mark-recapture studies, particularly in relation to foraging behavior and daily energy budgets (see chapter 5). Unfortunately, such studies are rather tedious and have been attempted for only a few species. One of the most detailed studies of movements in salamanders is Nishikawa's (1990) study of *Plethodon teyahalee* and *P. metcalfi* in the southern Appalachian Mountains. This is a very wet region, but the salamanders were extremely sedentary. Even when visible on the surface, they moved very little. Individuals of *P. teyahalee* that were sighted more than once on the same night did not move more than about one meter between sightings, which was similar to the average distance between recaptures on different nights. *Plethodon metcalfi* was even more sedentary, with individuals moving less than 0.2 m per night, even though individuals of this species actually utilized larger home ranges over a period of several months. In both species, individuals were not active on the surface every night, and many of those that were visible were seen sitting at the entrances to retreat holes. Individuals sometimes used several different retreat holes, but particular holes were never used by more than one salamander. The sedentary behavior of these salamanders, which probably is typical of most terrestrial plethodontids, indicates that they are mainly sit-and-wait foragers.

Short-term movements of anurans have been studied in somewhat more detail. Dole (1965b) observed individual leopard frogs (*Rana pipiens*) for up to 6.5 hours at a time and

found that almost half did not move at all. Some marked individuals remained virtually immobile for more than 24 hours. Clearly this species is quite sedentary on a day-to-day basis, even though some individuals utilize a relatively large home range over a period of several months. Similarly, chorus frogs (*Pseudacris triseriata*) tagged with radioactive wires averaged only 3.5 m of movement per day, but were capable of moving up to 42 m in less than 24 hours (Kramer 1973). Freda and Gonzalez (1986) followed the movements of eight individuals of *Hyla andersonii* and reported that most individuals moved less than 20 m per day and remained within 70 m of a breeding pond; the longest daily movement was about 100 m. In a study of *Pseudacris cadaverina,* a tree frog that lives in rocky canyons in California, R. T. Harris (1975) found that adults spent most of the day sitting on rocks near a stream. In late afternoon, they moved an average of 3 m to the water's edge, where they foraged for insects or engaged in breeding activities until returning to the same diurnal resting sites. These frogs appear to remain within a few meters of one segment of a stream for most of their lives. A high degree of site fidelity and very limited daily movement also is characteristic of several ranid frogs living along tropical and subtropical forest streams (Inger 1969; Kam and Chen 2000).

Movements of terrestrial anurans that are not closely associated with water have not been studied in as much detail, but several species also exhibit a high degree of site fidelity. Woolbright (1985b) studied nightly movements of the Puerto Rican frog *Eleutherodactylus coqui* in the understory of a tropical forest by monitoring marked individuals every 15 minutes. He found that most individuals traveled only 3–5 m per night, usually moving from a diurnal retreat site to a nighttime foraging station at dusk and returning to the retreat at dawn. This low rate of movement is associated with a very low number of prey capture attempts each night (Taigen and Pough 1985). Ovaska (1992) found *Eleutherodactylus johnstonei* in Barbados to be equally sedentary, with individuals moving only 3–4 m per night. Another very sedentary species is *Ceratophrys cornuta,* a large forest-floor frog from Peru. Most individuals moved less than 2 m per night, and many did not move at all (Duellman and Lizana 1994).

All of the anuran species discussed previously are sit-and-wait predators that are expected to be relatively sedentary. In contrast, an actively foraging Panamanian frog, *Dendrobates auratus,* averaged about 160 m of movement (6,000 body lengths) in a 12-hour activity period and made 400–500 attempts to capture prey (Taigen and Pough 1985). This species probably uses a much larger proportion of its home range each day than do species that sit and wait for their prey. Other dendrobatids in the genus *Colostethus* have much lower rates of movement each day, but still are considerably more active than sedentary species such as *Eleutherodactylus coqui* or *Rana pipiens.* Similarly, *Bufo marinus,* an active forager, moves at a faster rate and uses a much larger area each night than does *Leptodactylus ocellatus,* a sit-and-wait predator living in the same habitat (Strüssmann et al. 1984). In Australia, where *Bufo marinus* has been introduced, individuals sometimes moved up to 100 m per night in wet weather and often ended up in diurnal shelters 30–40 m from their previous shelter sites (Seebacher and Alford 1999). At least some individuals of this species appear to be nomadic, wandering over wide areas with little evidence of a fixed home range (Schwarzkopf and Alford 2002).

One aspect of amphibian behavior that has received little attention is vertical movement into trees and other vegetation. Some terrestrial plethodontid salamanders regularly climb into low vegetation on rainy nights, giving them access to insect prey not readily available in the leaf litter and possibly aiding in orientation (Hairston 1949; Madison 1972; Jaeger 1978). Pacific giant salamanders (*Dicamptodon*) have been observed climbing into bushes and trees as high as 1.5 m above the ground (Stebbins 1954a). It is well known that many tree frogs move high into trees after the breeding season and occasionally are heard calling from the tops of trees, but there have been very few attempts to follow the vertical movements of individuals on a daily basis. Stewart (1985) reported that juveniles and females of *Eleutherodactylus coqui* regularly climbed high into the forest canopy to feed at dusk and "parachuted" to the ground at dawn. Males generally remained lower in the vegetation at established calling sites. A reverse pattern was observed in *Hyla rosenbergi* during the breeding season. At dusk, males rapidly descended from diurnal retreat sites to nests on the ground, where they remained throughout the night (Kluge 1981). An unusual example of arboreal behavior was reported in a population of *Bufo valliceps* living in a public park in Austin, Texas. These toads usually are considered to be strictly terrestrial, but Neill and Grubb (1971) observed toads climbing as high as 5 m into live oak trees and repeatedly using tree holes as retreat sites. Several species of European anurans (*Bufo bufo, Rana temporaria, Alytes obstetricans*) have been observed climbing into oak trees, apparently seeking moisture in wet moss growing on the bark (Gosá 2003).

Sizes of Home Ranges

Several methods have been used to estimate home range sizes for amphibians. Most investigators have used procedures developed by mammalogists in the 1940s. The most common technique is to draw a convex polygon around all recapture points for each individual (Mohr 1947), or to construct a polygon that encloses the smallest possible area, even if it is not convex (the minimum area polygon method;

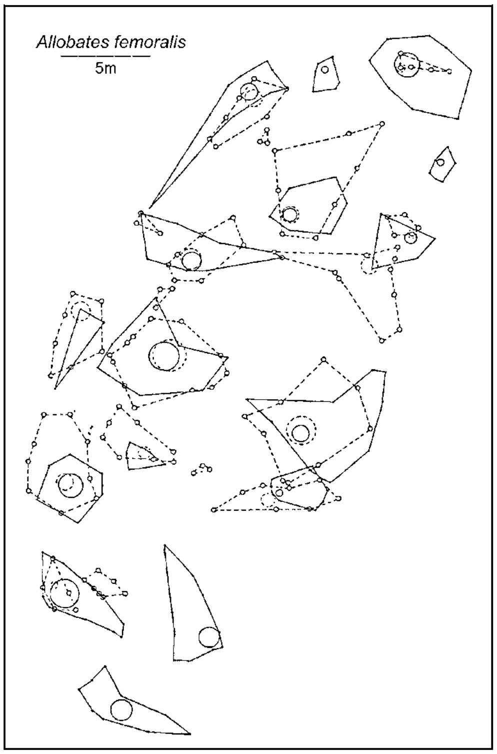

Fig. 6.2. Example of polygonal home range boundaries plotted for individual frogs. This figure shows the boundaries of territories defended by males of the dendrobatid frog *Allobates femoralis* in Amazonian Peru. Solid and dashed lines show territory boundaries in two different years. Circles indicate the most frequently used calling sites in those years. After Roithmair (1992).

fig. 6.2). These methods are quite sensitive to number of recaptures, with estimates of home range size generally increasing as the number of recaptures increases (Barbour et al. 1969; Jennrich and Turner 1969; D. Anderson 1982; B. Rose 1982). Polygon area methods tend to exaggerate the importance of occasional long movements. They probably are most accurate for species that travel over much of the home range each day, and least accurate for sit-and-wait predators or species that spend much of their time near retreat sites and make only brief long-distance excursions.

Inger (1969) reported home ranges of several species of *Bufo* and *Rana* as linear transects along tropical streams. This approach is appropriate for frogs that spend all of their lives within a few meters of a stream, but are difficult to compare with estimates of the areas of two-dimensional home ranges of other species. Some authors have determined the size of a circle or ellipse enclosing some arbitrary proportion of all recapture points (Pearson 1955; Madison 1969). This technique has the disadvantage of seriously distorting home range size if the home range deviates significantly from a circular or elliptical shape (Jennrich and Turner 1969; B. Rose 1982). Home range size also can be expressed as a Mean Activity Radius (Hayne 1949; Currie and Bellis 1969; Hillis and Bellis 1971; Holomuzki 1982; Kleeberger and Werner 1982; Kleeberger 1985). The geometric center of all recapture points is determined and the distance from that point to each recapture point is measured. The Mean Activity Radius is the average of these measurements and can be used to calculate the area of a circular home range (e.g., Hillis and Bellis 1971; Nishikawa 1985). This procedure has the advantage of reducing the impact of very long movements. Unfortunately, the statistical center of activity often bears little relationship to the physical activity center of the animal in the field, especially if the animal's movements are asymmetrically distributed around a choice feeding perch or retreat site (e.g., Pearson 1955). There also are various statistical methods that estimate home range use from the distribution of capture points or fixes using radio tracking (e.g., Muths 2003). Often these methods yield larger estimates of home range size than polygon area methods (Clarke 1974a; Healy 1975; Holomuzki 1982; Kleeberger and Werner 1982; Nishikawa 1985), although this is not consistently true (e.g., Watson, McAllister, and Pierce 2003). Unfortunately, there is no way to make statistical comparisons of data obtained by different methods. The data summarized in tables 6.4 and 6.5 include only estimates derived from the minimum area polygon method.

Detailed studies of amphibian home ranges have been done mainly on North American, European, and a few Neotropical species (tables 6.4, 6.5). Home range sizes vary considerably both within and among species. Most authors have presented mean home range sizes, but not medians. In a few cases in which both could be calculated (Hansen 1957; Barbour et al. 1969; Madison and Shoop 1970; Kramer 1974; Ashton 1975), the median was smaller, suggesting that the median would provide a better estimate of typical home range size than the mean.

Given the variability in home range size estimates, few generalizations are possible. Small plethodontid salamanders that center their activities around retreat sites such as logs or burrows tend to have very small home ranges (table 6.4), but the extent of their movements in underground burrows is unknown. Terrestrial salamandrids are more active foragers than plethodontids and tend to have larger home ranges (Joly 1963, 1968; Healey 1975). In the case of *Salamandra,* this probably relates to a much larger body size, whereas red efts (*Notophthalmus viridescens*) are about the same size as small *Plethodon,* but have home ranges up to 20 times larger.

Among anurans, there is no clear relationship between either body size or habitat and home range size, although very small terrestrial dendrobatids, leptodactylids, and leiopelmatids tend to have the smallest home ranges, whereas larger toads and semiaquatic ranids have the largest (table 6.5). The dendrobatid data are not strictly comparable to the

other species, however, because they are based on sizes of territories defended by males. Foraging mode probably has a greater impact on home range size than body size, with active foragers likely to have larger home ranges than sit-and-wait predators of a similar size. Body size and foraging mode tend to be confounded (sit-and-wait predators usually are larger than active foragers), and all of these variables are further confounded by differences in phylogeny. This makes it difficult to do a really sophisticated comparative analysis. It is clear that most anurans spend their lives in quite restricted areas. Even species that make periodic migrations to aquatic breeding sites often return to the same terrestrial

Table 6.5 Estimated home range sizes for anurans

Species (source no.)	N_i	Habitat	Duration of study	Home range size (m^2) Range	Mean
Bufonidae					
Atelopus oxyrhynchus (8)	57	Tropical forest	13 mths		41
Bufo bufo (14)	48	Pine forest	2 mths	490–3,420	1,900
B. fowleri (7)	3	Golf course	< 1 mth	103–1,245	750
B. japonicus (20)	15	Temple garden	5 mths		220
B. marinus (11)	13	Clearings	1 mth		168

[c] Minimum convex polygon for radio-tracked adults around drying pools.

home ranges each year (Martof 1953a; Turner 1960a; Bellis 1965; Dole 1965b; Heusser 1968d, 1969c; Clarke 1974a; Dole 1974; Yano 1978; Okuno 1985; Fukuyama, Kusano, and Nakane 1988; Kusano 1998).

The factors influencing home range size are unknown for most amphibian species, but presumably availability of suitable shelter sites and abundance of food are important factors. In one of the few experimental studies conducted to date, Kleeberger (1985) examined factors affecting home range size in *Desmognathus monticola* by manipulating both salamander density and the number of cover objects. He found that home range size increased at high population densities, perhaps because of competition for food. Salamanders from high-density plots generally had less food in their stomachs than did those from control plots. When cover objects, or both cover objects and salamanders, were added to plots, there was no effect on home range size. Apparently, as population density increased, individuals wandered more widely in search of food or shelter. Spieler and Linsenmair (1998) observed enormous variation in the size of individual home ranges of a ranid frog (*Hoplobatrachus occipitalis*) in a West African savanna. Frogs inhabiting a sandy riverbank with abundant bushes that were used for shelter sites had much smaller home ranges than did those on more open, rocky riverbanks. These authors speculated that differences in quality and abundance of diurnal retreat sites and prey were responsible for the difference in home range size, but they did not present quantitative data to support their argument.

Migrations of Adult Amphibians

Movements to and from Breeding Ponds

Although many terrestrial salamanders and anurans remain in the same areas year round, some amphibians make seasonal migrations between hibernation sites or terrestrial home ranges and aquatic breeding sites. There is a considerable literature on the timing of breeding migrations in relation to time of day, temperature, and rainfall (reviewed in Salthe and Mecham 1974). Most amphibians migrate in wet weather, a pattern to be expected in animals that face severe problems of evaporative water loss (see chapter 2). Migrations of winter and early spring breeders often are strongly influenced by temperature as well, but temperature usually has little effect on patterns of activity in tropical or summer-breeding amphibians (Blanchard 1930; Baldauf 1952; Packer 1960; Oldham 1966; Heusser 1968d; Hurlbert 1969; Fitzgerald and Bider 1974a, b; Gibbons and Bennett 1974; Douglas 1979; Semlitsch 1981b, 1983a, 1985a; Wisniewski et al. 1981; Gittens 1983a; Harrison et al. 1983; Griffiths 1984; Petranka 1984d; Semlitsch and Pechmann 1985; Beneski, Zalisko, and Larsen 1986; Pechmann and Semlitsch 1986; Aichinger 1987a; Sinsch 1988c, 1992c; Donnelly and Guyer 1994; Palis 1998; Spieler and Linsenmair 1998). Most breeding migrations take place at night (Heusser 1968d; Sinsch 1988c; Semlitsch and Pechmann 1985; Pechmann and Semlitsch 1986; Spieler and Linsenmair 1998), and even a bright full moon can reduce activity in some species (Fitzgerald and Bider 1974b). Once a migration has been initiated, however, some amphibians continue to move toward ponds or summer home ranges during daylight hours (Gittins 1983b; Kusano, Fukuyama, and Miyashita 1995).

Information on the distances traveled by adult amphibians to breeding sites is scarce. This is mainly because marked individuals are seldom recaptured away from breeding areas even with frequent and intensive searching. There are scattered reports of adult amphibians being found several hundred meters to several kilometers from the nearest breeding area (Fitch 1958; Landreth and Christensen 1971; Degani and Warburg 1978; Franz, Dodd, and Jones 1988; Dodd, 1996). Displacement studies have shown that some species, such as *Taricha rivularis,* are capable of moving many kilometers, although they probably do not move such long distances on their own (Twitty, Grant, and Anderson 1964; Twitty 1966). One of the most impressive migrations reported so far was observed in a mixed population *Rana lessonae* and *R. esculenta* (a hybridogenetic species) that breeds in a lake on the border of Austria and Hungary. Some individuals moved up to 15 km from breeding sites to hibernation sites in peat fens at the southern end of the lake. Tunner (1992) speculated that this was an ancient hibernation site for these frogs, and that migration distances gradually increased with a northward expansion of the lake in the last few thousand years. In a population of *Hoplobatrachus occipitalis* in a West African savanna, a few individuals moved as much as 6 km from home ranges along a river to flooded areas of the savanna that were used for reproduction. Some frogs moved more than a kilometer on a single night (Spieler and Linsenmair 1998).

The limited data available suggest that migrations of most amphibians are much shorter (Glandt 1986). Some of the best information comes from Heusser's (1968d, 1969c) studies of *Bufo bufo* in Europe. He found that most toads have summer home ranges 500–1,500 m from the breeding pond, with a few individuals moving as much as 3 km. The toads often took the same routes between the pond and their summer home ranges each year. Studies of other populations of the same species yielded similar migration distances, with most individuals occupying home ranges within 1,600 m of their breeding ponds (Blab 1978; Sinsch 1988c). Many individuals of this species begin moving from summer home ranges toward breeding ponds in the fall and hibernate in

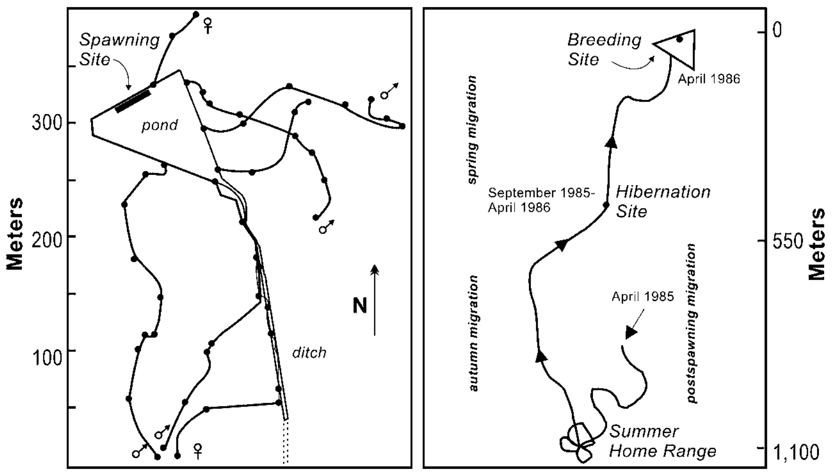

Fig. 6.3. Migration behavior of common toads (*Bufo bufo*) in Germany. (A) Paths taken by seven individual toads to a breeding pond in spring. After Sinsch (1988c). (B) Seasonal movements of a single male toad between the summer home range, hibernation site, and breeding pond. After Sinsch (1990).

sites closer to the ponds, so the actual migration distances in the spring are much shorter (Heusser 1968d; Sinsch 1988c, 1989b; fig. 6.3). In a population of the same species in the Austrian Alps, individuals moved 130–1,000 m from breeding ponds, but some also moved nearly 400 m up steep, rocky slopes to reach suitable patches of habitat above the breeding ponds (Sztatecsny and Schabetsberger 2005).

Other toads also migrate a few hundred meters to breeding ponds. Most male natterjack toads (*Bufo calamita*) in a population in Germany remained within 400 m of their breeding sites, but females moved much greater distances, sometimes up to 3 km (Sinsch 1989b, 1992b, c). In a population of the same species in a more arid agricultural region of Spain, individuals moved to sites within 1,000 m of the breeding site, but cumulative movement paths were as long as 4.4 km (Miaud, Sanuy, and Avrillier 2000). American toads (*B. americanus*) usually migrate less than 500 m (Blair 1943; Oldham 1966), and Japanese toads (*B. japonicus*) living in developed areas usually have home ranges within 200 m of breeding ponds (Yano 1978; Okuno 1986; Kusano, Fukuyama, and Miyashita 1995). In a population of *Bufo boreas* in Colorado, most males remained within 500 m of the breeding pond, but some females moved two to three times as far (Muths 2003), a pattern similar to that observed in *Bufo calamita*. The same pattern was seen in a population of *B. boreas* in Idaho, with males moving less than 600 m from breeding sites on average, whereas females averaged over 1100 m of movement (Bartelt, Peterson, and Klaver 2004).

A radio tracking study of *Rana luteiventris* in the mountains of Idaho revealed considerable variation in patterns of movement among different habitats (Pilliod, Peterson, and Ritson 2002). Many individuals remained at breeding sites throughout the summer, long after breeding had ceased, but others moved considerable distances to separate summer habitats. Males were more likely than females to remain in the breeding habitat, and those that did move usually were found within 400 m of the breeding pond, whereas females moved up to 1,033 m from breeding ponds. Similar variation in movement patterns was reported for populations of *Rana draytonii* in California coastal forests and grasslands. Some individuals moved as much as 500 m from breeding sites, either ponds or streams, whereas most remained within 130 m of the breeding area (Bulger, Scott, and Seymour 2003). There was no evidence of a sexual difference in movement in this study.

The reason for shorter movements by males of some species is not entirely clear. Muths (2003) attributed the larger home ranges and longer movements of female boreal toads (*Bufo boreas*) to greater energetic requirements of females compared to males, but there are several possible alternative explanations for this pattern. Often there is strong selection on males to arrive early at breeding ponds (see chapter 8), and remaining close to breeding sites would facilitate rapid return when breeding resumes the next year. This sort of sexual dimorphism in behavior also could reflect differences in locomotor capacities of males and females. In most anurans, including *Bufo calamita, B. boreas,* and *Rana luteiventris,* females are larger than males, and large frogs tend to move farther than small ones (Pilliod, Peterson, and Ritson 2002). Nevertheless, males of all of these species occasionally make considerably longer movements.

Many other anurans have home ranges within a few hundred meters of breeding sites, and often less than 100 m (Martof 1953a; H. Moore 1954; Delzell 1958; Turner 1960a; Kramer 1973; Hollenbeck 1974; Blab 1978; Niekisch 1982;

Freda and Gonzalez 1986; Glandt 1986; Büchs 1987; Hellbernd 1987; Fiorito et al. 1994; Kusano 1998; Richter et al. 2001). In general, one might expect individuals moving toward breeding ponds to move faster and in a more directed manner than those moving away from the pond at the end of the breeding season, especially for explosive early-spring breeders. Few data are available to test this hypothesis, however, mainly because anurans are much more likely to be tracked while leaving ponds than while approaching them. Migrating toads have been observed moving at speeds of about 30 m per hour, or 200–250 m per night (Oldham 1966; Gittins, Parker, and Slater 1980; van Gelder, Aarts, and Staal 1986). Those with home ranges closest to breeding ponds probably could complete the journey in a single night, whereas others might require five or six nights. Movements by *Rana luteiventris* in Idaho were considerably faster, up to 160 m/h, or more than 700 m/day (Pilliod et al. 2003).

Ambystomatid salamanders tagged with radioactive wires or equipped with radio transmitters generally moved less than 250 m from breeding ponds to small mammal burrows and other retreat sites used for much of the year (Williams 1973; Douglas and Monroe 1981; Semlitsch 1981b; Kleeberger and Werner 1983; Madison and Farrand 1998; Faccio 2003; Regosin, Windmiller, and Reed 2003). Most adults in a population of *Hynobius nebulosus* in Japan settled in home ranges less than 100 m from the breeding pond (Kusano and Miyashita 1984). Females of *Salamandra salamandra,* a viviparous species, moved similar distances from their summer home ranges to deposit larvae in the water (Joly 1968). European newts (*Triturus*) sometimes have terrestrial retreat sites only 5–10 m from breeding ponds, although movements of up to 400 m have been recorded (Blab 1978; Dolmen 1981b; Griffiths 1984; Glandt 1986; Jehle and Arntzen 2000). Some striped newts (*Notophthalmus perstriatus*) in a Florida population moved at least 500 m from a breeding pond, although most moved shorter distances (S. Johnson 2003).

Breeding Site Fidelity

Many amphibians exhibit strong fidelity to particular breeding sites, although occasional movements of 0.5–2 km between breeding sites have been reported (Raney 1940; Blair 1943; Turner 1960a; Miaud, Joly, and Castanet 1993; Sinsch and Seidel 1995). Adult amphibians seldom move between breeding sites within a breeding season, and they often are recaptured in the same pond or stream year after year (Jameson 1957b; Twitty 1959, 1961, 1966; Heusser 1958a, 1960, 1969c; Oldham 1966, 1967; Whitford and Vinegar 1966; Joly and Miaud 1989; Berven and Grudzien 1990; Reading, Loman, and Madsen 1991; Sinsch 1992b, c; Sinsch and Seidel 1995; Lüddecke 1996; Sjögren Gulve 1998b; Kusano, Maruyama, and Kaneko 1999; Pilliod, Peterson, and Ritson 2002; Vasconcelos and Calhoun 2004; Greenberg and Tanner 2005). Some amphibians will return to the same site for several years even after the breeding habitat has been destroyed (Jungfer 1943; P. Anderson 1954; Heusser 1960, 1964, 1969c; McMillan 1963; Shoop 1968). Nevertheless, Schlupp and Podloucky (1994) were able to experimentally shift the fidelity of European common toads (*Bufo bufo*) to a new breeding pond by blocking access to their old pond and transferring them to the new one. After four years, less than 15% of the migration was directed toward the old site, and in later years, less than 1% of the toads moved in that direction.

There is some variation in the degree of site fidelity among species. Griffiths (1984), Joly and Miaud (1989), and Perret et al. (2003) all reported that most adults of European newts (*Triturus*) were captured in only one pond, but some moved between ponds that were relatively close together. Gill (1978a, b) followed the movements of more than 8,500 red-spotted newts (*Notophthalmus viridescens*) and never found an adult that changed breeding ponds, even though some ponds were only a few hundred meters apart and were connected by waterways. A long-term study of *Taricha rivularis* showed that individuals returned to the same 50-yard (46 m) stretch of stream every year and were never recaptured in adjacent steams (Packer 1963b; Twitty 1959, 1961, 1966). Many newts continued to turn up in their home stream segments eleven years after being marked (Twitty, Grant, and Anderson 1967). In a study of *Ambystoma maculatum* in Maine, adults were 100% faithful to their breeding ponds (Vasconcelos and Calhoun 2004).

Berven and Grudzien (1990) marked hundreds of wood frogs (*Rana sylvatica*) in montane ponds in Virginia over a seven year period and found that all adults were completely faithful to the first ponds in which they bred, even though some ponds were only 250–1,000 m apart. Another study of the same species in Maine found that 98% of males and 88% of females were faithful to their breeding ponds (Vasconcelos and Calhoun 2004). Movement of breeding adults between ponds in a population of *Hyla chrysoscelis* was less than 2%, except when one pond dried up (Ritke, Babb, and Ritke 1991). Movement of adult Fowler's toads (*Bufo fowleri*) to new breeding areas was less than 17% in an area with many small ponds separated by sand dunes (Breden 1988). Male natterjack toads (*Bufo calamita*) breeding in areas with networks of small pools showed great fidelity (98%) to specific breeding areas, but were less faithful to individual breeding pools (about 67%). Some males used as many as four different pools in a single breeding season (Sinsch and Seidel 1995). Females showed less site fidelity and sometimes used breeding sites up to 3 km apart in different years (Sinsch 1992c). Some movement between breeding sites within a breeding season also was reported for a population of *B. calamita* in Spain (Miaud, Sanuy, and Avrillier 2000). D. Marsh (2001) studied movements of *Physalaemus pustulosus* in Panama in plots supplied with small artificial pools. Individuals readily moved between pools, which were only five m apart, but seldom moved between plots, which were 200 m apart. These frogs probably do not regularly move between natural breeding ponds that are 200 m apart (D. Marsh, Fegraus, and Harrison 1999).

Okuno (1984) marked about 1,500 Japanese toads (*Bufo japonicus*) at several ponds on a university campus over a period of eight years. Only 25 of these toads changed breeding sites, and nearly all of these moved from the largest pond to smaller ponds with lower density breeding populations. All of the ponds were within 150 m of one another. The degree of site fidelity in various species undoubtedly depends in part on the availability of alternative breeding sites in the area. A comparison of several studies of toads revealed that breeding site fidelity was very high (95–97%) for populations with fewer than four breeding ponds within normal migratory distances, but lower (24–73%) for populations with 6–15 ponds available (Sinsch 1992a). Both *Bufo boreas* and *Rana cascadae* exhibit strong site fidelity to specific breeding sites, even within the same lake. These species often breed in isolated alcoves surrounded by steep cliffs that effectively isolate breeding sites from each other (Olson 1992).

Movements to Overwintering Sites

Many amphibians that hibernate in terrestrial sites probably spend the winter in sites within their normal home ranges. Some species, however, make regular movements to special hibernation sites. The movements of European common toads (*Bufo bufo*) from summer home ranges to terrestrial hibernation sites closer to their breeding ponds has already been mentioned (Sinsch 1988c). Some amphibians that hibernate in or near water move from summer home ranges to different habitats that provide better conditions for hibernation. For example, a population of green frogs (*Rana clamitans*) in upstate New York moved from permanent ponds, where they spent the summer, to hibernation sites along seeps and streams, where flowing water provided sites that were well supplied with oxygen and unlikely to freeze (Lamoureux and Madison 1999). Movement distances were extremely variable, ranging from 80 to 560 m. In the mountains of California, a population of mountain yellow-legged frogs (*Rana muscosa*) was widely distributed in a system of lakes in the summer. In September, some frogs moved more than 450 m to just a few of these lakes, where they spent the winter in underwater crevices along the lakeshore (Matthews and Pope 1999). Similar migrations to deep lake overwintering sites also have been observed in *Rana luteiventris* in the mountains of Idaho (Pilliod, Peterson, and Ritson 2002; see chapter 3 for a more detailed discussion of hibernation).

Movements of Juveniles

Data on movements of metamorphosed young from breeding sites are meager. Because mortality rates are very high for juveniles, hundreds or even thousands of individuals must be marked if any are to be recaptured. Furthermore, juveniles tend to disperse in many directions, although they may exhibit preferences for particular terrestrial habitats near breeding sites (e.g., Vasconcelos and Calhoun 2004). It is nearly impossible for investigators to check all possible sites for marked individuals. Consequently, data on movements often are limited to the first few weeks after metamorphosis. If marked juveniles are recaptured at all, they usually are found within 500 m of their natal ponds (Jameson 1956a; Schroeder 1976; Roble 1979; Semlitsch 1981b; Pilliod, Peterson, and Ritson 2002; Vasconcelos and Calhoun 2004). Sometimes a few individuals have been recaptured up to 5 km away (Blair 1953; Dole 1971; Schroeder 1976; Turner 1960a; Gill 1978a; Płytycz and Bigaj 1984; Breden 1987).

There is a general assumption in the literature that most amphibians return to the ponds or streams where they hatched to breed (that is, they exhibit natal philopatry). Indeed, it has been suggested that adult amphibians locate breeding areas by retracing routes followed during dispersal as juveniles (Anderson, in Twitty 1961; D. Ferguson and Landreth 1966). Nevertheless, clear evidence for natal philopatry in amphibians is scarce. In his long-term study of movements in *Taricha rivularis,* Twitty (1966) never marked juveniles dispersing from streams. He did find that hybrid newts reared in tanks and released as larvae into limited areas of a stream tended to return to the same areas as breeding adults. Gill (1978a, b) proposed that the terrestrial eft of the red-spotted newt (*Notophthalmus viridescens*) is a dispersal stage that allows for long-distance migration to new breeding sites. He hypothesized that selection should favor dispersal because of variability and unpredictability in the quality of breeding habitats. Early data supported the hypothesis, because many unknown adults entered his ponds to breed. Subsequent data, however, revealed that the eft stage is much longer (six years or more) than previously suspected. When individuals originally identified as dispersing juveniles finally began moving into breeding ponds, Gill (personal communication) found that nearly 70% of those recaptured returned to their natal ponds, and most of the others moved into the next nearest pond. These data suggest that long-distance dispersal is less important in this species than originally thought. Only about 10% of all juveniles were recaptured as adults, however, so it is possible that some moved longer distances to new breeding areas.

Blair (1953) reported that only 7% of 357 *Bufo valliceps* marked as juveniles were recaptured as adults at their natal pond. Only one other individual was recaptured at all (in another pond), so it is not clear whether the remaining individuals died or dispersed to more distant sites. Spencer (1964) marked over 5,000 juvenile chorus frogs (*Pseudacris triseriata*) in a mountainous region and did not find any movement between breeding sites, some of which were less than 1 km apart. The longest movement by a juvenile frog was only 690 m, and most moved less than 300 m from their natal ponds. In contrast, 18% of 5,000 juvenile wood frogs (*Rana sylvatica*) marked in montane ponds were subsequently recaptured as breeding adults in different ponds (Berven and Grudzien 1990). Breden (1987) found even higher rates of dispersal (27%) by juvenile Fowler's toads (*Bufo fowleri*), but breeding pools were closer together than in the other studies. Juveniles of *Bombina variegata* in Poland were more likely to move to new breeding areas than were adults, although most individuals returned to their natal pond (Płytycz and Bigaj 1984).

Kneitz (1998) presented some of the most detailed information on dispersal of juvenile anurans. He studied populations of anurans in an agricultural landscape in Germany, where a number of ponds were in close proximity to one another, but often separated by relatively inhospitable habitat. He marked several thousand juveniles of three ranid frogs (*Rana temporaria, R. dalmatina, R. esculenta*) and one toad (*Bufo bufo*). Between 80 and 98% of recaptured individuals returned to their natal ponds, and most of the rest dispersed to the next nearest pond. Pool frogs (*Rana lessonae*) in Sweden exhibited less natal philopatry, with about 65% of recaptured juveniles returning to the natal pond. The rest moved to another pond about 270 m away (Sjögren-Gulve 1998b).

It seems likely that juvenile dispersal is more common than is adult dispersal in many aquatic-breeding amphibians. If juveniles move more or less randomly through terrestrial habitat in search of suitable breeding habitat, dispersal distances may be greater for species that take several years to reach sexual maturity than for those that mature early, simply because they have more time to wander from their natal ponds (Palo et al. 2004). Genetic studies of several species have suggested that females often disperse farther than do males, and in these cases, females usually mature at a later age (Austin et al. 2003; Palo et al. 2004). In addition, there may be other reasons for sex-biased dispersal, such as inbreeding avoidance or selection on males to find suitable breeding ponds as early as possible.

Colonization of New Habitats

If all juvenile and adult amphibians were completely faithful to one breeding pond, then they never would colonize new habitats. Yet such colonization clearly does occur on a regular basis. Some amphibians occur in metapopulations in which many local breeding sites contribute recruits to the overall population, and local extinction is balanced by immigration from other ponds (Gill 1978b; Laan and Verboom 1990; Sjögren 1991a; Olson 1992; Sinsch 1992c; Miaud, Joly, and Castanet 1993; Sjögren Gulve 1994; Sinsch and Seidel 1995). The high degree of philopatry exhibited by adults and juveniles of most amphibian species studied to date probably is due, in part, to a focus on relatively large, isolated breeding sites that are easily encompassed by drift fences.

Amphibians that use more ephemeral habitats are harder to study, but are much more likely to move between breeding sites, because the location of suitable breeding areas changes from year to year. For example, the Neotropical túngara frog (*Physalaemus pustulosus*) breeds in all sorts of temporary water, from rain puddles and water-filled animal footprints to drainage ditches and road ruts. Frogs are readily attracted to shallow pans of water placed on the forest floor (Rand 1983), and even flooded lawns are rapidly colonized by breeding pairs. D. M. Marsh, Fegraus, and Harrison (1999) placed small artificial pools at distances up to 200 m from existing breeding pools on Barro Colorado Island in Panama. They found that ponds close to existing breeding sites were colonized more quickly than were those at greater distances, and more egg masses were deposited in the nearby ponds. They could not determine, however, whether ponds were colonized mostly by dispersing juveniles just starting to breed, or by adults that moved between ponds. In a second set of experiments, D. M. Marsh, Rand, and Ryan (2000) placed artificial ponds in groups of three, with distances of 0–50 m between ponds in a group. Adult male túngara frogs showed strong fidelity to one breeding pond when the ponds were widely spaced, but moved extensively between ponds when they were close together (fig. 6.4). Many other tropical frogs breed in ephemeral habitats ranging from small rock pools to water-filled seed pods (Crump 1974; Gascon 1991, 1992b; Caldwell 1993; Spieler and Linsenmair 1997; see also chapter 10), and these must be colonized by dispersing adults. Even the highly aquatic frog *Pipa arrabali* will colonize small basins placed on the forest floor (Gascon 1992c).

A number of investigators have constructed larger ponds in suitable habitats, and these usually were colonized by a variety of amphibians within a few years (Wilbur and Travis 1984; Laan and Verboom 1990; Resetarits and Wilbur 1989, 1991; Arntzen and Teunis 1993; Banks, Beebee, and Denton 1993; Gressler 1997). Indeed, the construction of new breed-

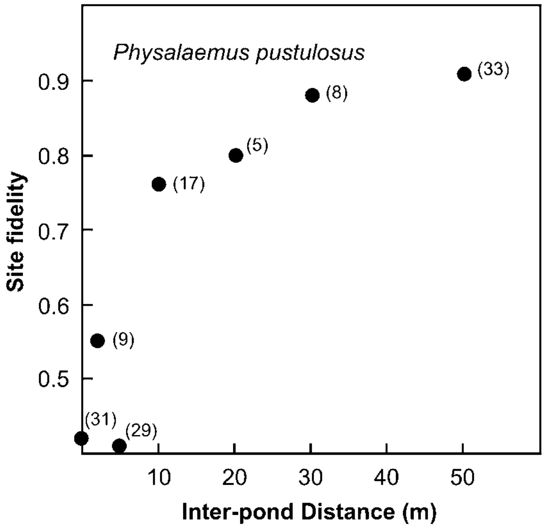

Fig. 6.4. Effects of interpond distance on site fidelity of male túngara frogs (*Physalaemus pustulosus*) in Panama. Site fidelity was measured as the probability of a male being recaptured at the previous capture site. Numbers in parentheses show number of recaptures of males at each distance. After D. Marsh, Rand, and Ryan (2000).

ing ponds that are subsequently colonized by existing populations has been a major focus of wetland restoration and amphibian conservation efforts, both in Europe and North America (Thielcke et al. 1985; Pauley and Barron 1995; Beebee 1996; Lehtinen and Galatowitsch 2001; Pechmann et al. 2001). Colonization of new ponds depends not only on the suitability of the ponds as breeding habitats for various species, but also on proximity to established breeding areas, the degree of isolation by unsuitable habitat, and the dispersal abilities of different species (Laan and Verboom 1990; Vos and Chardon 1998; Baker and Halliday 1999; Lehtinen, Galatowitsch, and Tester 1999; Babbitt and Tanner 2000; see subsequent further discussion and chapter 16).

Some amphibians can be considered pioneering species that specialize in invading newly opened habitats. These species can be expected to exhibit greater dispersal tendencies than those that breed in more stable habitats. Pioneering species typically lay large numbers of small eggs, often have short larval periods, and their larvae tend to do poorly in competition with species adapted to more permanent water (see also chapters 10, 13, and 15). Many anurans that breed in temporary ponds exhibit life-history characteristics of pioneering species, but this is more pronounced in some species than in others. For example, many toads (*Bufo*) tend to breed in newly formed ephemeral habitats, but some species show greater tendencies to use such habitats than do others. The European natterjack toad (*Bufo calamita*) is more of a pioneering species than is the common toad (*B. bufo*), with which it shares much of its range. Natterjack toads favor shallow, newly formed, nutrient-poor ponds in sandy regions, and their tadpoles do poorly in more mature, nutrient-rich ponds with abundant populations of predators and competitors (Beebee and Griffin 1977; Beebee 1979b, c, 1983; Banks and Beebee 1986b, 1987a, b, 1988; Griffiths 1991; Griffiths, Edgar, and Wong 1991; Tejedo 1991). The low site fidelity of female natterjack toads presumably facilitates movement into new habitats, although movement of adults between habitat patches appears to be insufficient to account for recolonization of breeding sites after local extinction events (Sinsch 1989b, 1992b). This suggests that dispersal by juveniles also is important in colonization of new breeding sites. Sinsch (1997) found that juvenile natterjack toads dispersed up to two km from their natal ponds within a few weeks. He recaptured only nine tagged individuals, all males, as breeding adults. All of these individuals returned to their natal pond to breed, but this could have been due to the destruction of other nearby breeding ponds.

Another pioneering species is the Neotropical toad *Bufo marinus*. In its native habitats in Central and South America, this species breeds in various kinds of temporary water (Zug and Zug 1979). It was introduced into Queensland, Australia in the 1930s to control sugar cane beetles. It has since dispersed over much of northern Australia and southward to New South Wales, increasing its range by as much as 35 km per year (Van Beurden and Grigg 1980; Easteal 1981; Sabath, Boughton, and Easteal 1981; Easteal et al. 1985; Freeland and Martin 1985; Easteal and Floyd 1986). Transport by humans has been responsible for some of this range expansion, but much of it probably has been due to dispersal of thousands of juveniles from their natal ponds to new breeding sites. Sinsch (1990) cited data on the rate of range expansion given by Freeland and Martin (1985) as evidence that juvenile toads can disperse as much as 35 km per year, but these authors did not present data on juvenile dispersal. Instead, they estimated rates of range expansion from questionnaires distributed to the public. They did report anecdotal evidence that sexually immature toads tended to turn up in new localities before any breeding activity had been reported.

Some amphibians that are not strictly pioneering species nevertheless occupy a wide range of habitats, from relatively ephemeral to more permanent ponds. Many of these species probably are capable of long-distance dispersal, either as juveniles or adults, and this ensures rapid colonization of new breeding sites. For example, the European tree frog (*Hyla arborea*) is widely distributed over much of the continent. In Sweden, Edenhamn (1996) did not find any relationship between degree of pond isolation and the use of ponds for breeding by this species, but Vos and Stumpel (1995) did find an effect of pond isolation in a more fragmented landscape. Juveniles of this species have been recaptured up to 12 km from their natal ponds (Stumpel and

Hanekamp 1986), suggesting an ability to disperse over long distances, but the proportion of long-distance dispersers in a population is unknown.

Movement and the Genetic Structure of Populations

The genetic structure of populations is governed by current gene flow between populations, selection acting on local populations, and historical events such as expansion and contraction of species' ranges, extinction of local populations, and genetic bottlenecks brought about by small population size (Driscoll 1998; Barber 1999). Gene flow between local populations of amphibians is regulated by dispersal of juveniles and adults between breeding sites. Natal philopatry, coupled with a lack of movement between breeding sites by adults, can lead to increased inbreeding within local populations and a corresponding reduction in genetic variation. It also can lead to genetic differentiation between populations, especially if selection pressures differ between localities. In contrast, movement among populations tends to reduce local genetic differentiation (Merritt et al. 1984; Breden 1987; Berven and Grudzien 1990; Waldman and McKinnon 1993).

Information on adult movements alone is not sufficient to predict patterns of gene flow, because many species that exhibit philopatry as adults often show more extensive movement in the juvenile stage (Shields 1982). Unfortunately, juvenile dispersal has not always been considered in studies of genetic variation. For example, Inger, Voris, and Voris (1974) examined electrophoretic variation in a number of rainforest anurans from Malaysia. They predicted that species in which adults remain in fixed home ranges along streams and do not move to separate breeding sites would show less genetic variation than species that aggregate to breed, because restricted movement would lead to increased inbreeding. This would be true only if juvenile frogs return as adults to breed near their birthplaces. It is equally plausible that juveniles move some distance before finding suitable unoccupied home sites. In fact, they found that patterns of genetic variation in several ranids and bufonids did not support the prediction of low gene flow in streamside species.

Genetic Variation among Populations

Surveys of anuran populations almost always show some genetic differentiation among populations. Many of these studies involve comparisons of samples from widely separated localities (e.g., Case, Haneline, and Smith 1975; Matthews 1975; Platz 1976; Dunlap and Platz 1981; Easteal 1985; Barber 1999; E. Hoffman, Schueler, and Blouin 2004). Some studies have revealed significant genetic differences among populations only a short distance apart, even when overall genetic similarity among populations is high (Cory 1962; Tordoff, Pettus, and Matthews 1976; Case 1978; Hedgecock 1978; Green 1984; Waldman, Rice, and Honeycutt 1992; Waldman and McKinnon 1993; Scribner et al. 2001; Lampert et al. 2003; Jehle et al. 2005). These data suggest that movement between breeding sites by both juveniles and adults is limited, although some genetic differences could be due to strong local selective pressures that counteract the effects of migration between demes (e.g., Tordoff 1980). Genetic differentiation among populations is likely to be greatest for populations separated by major barriers, such as rivers and mountain ridges (Lougheed et al. 1999; Lampert et al. 2003; Funk et al. 2005). Some amphibians also exhibit a clear correlation between genetic differentiation and distance between populations (e.g., E. Hoffman, Schueler, and Blouin 2004), especially in subdivided habitats (Monsen and Blouin 2003, 2004; Funk et al. 2005).

Genetic structuring sometimes can occur in the absence of obvious habitat barriers to dispersal, especially if individuals have inherently low tendencies to disperse from natal areas. For example, Driscoll (1998) found a high degree of genetic differentiation among populations of two Australian myobatrachid frogs, *Geocrinia lutea* and *G. rosea,* only 1–4 km apart. Genetic differentiation was not related to habitat features such as forest type, the presence of dry ridges, or rivers. Driscoll hypothesized that repeated expansion and contraction of ranges, coupled with very small population size, was responsible for the pattern of genetic structuring in these populations. Once isolated populations were established, there was little or no movement between nearby populations, and hence little or no gene flow. In two closely related species, *G. alba* and *G. vitellina,* there was virtually no dispersal between local populations, although data were available only for adult males. Genetic neighborhoods were very small, less than 40 m in diameter, and were limited to single breeding sites (Driscoll 1997, 1999a). By comparison, Berven and Grudzien (1990) estimated a genetic neighborhood averaging 1.26 km for *Rana sylvatica,* an area that encompassed several different breeding sites. For populations of *Bufo bufo* in England, there is considerable gene flow among ponds less than two km apart, whereas those separated by greater distances show more genetic differentiation (Scribner et al. 2001).

Some amphibian populations exhibit surprisingly low levels of genetic differentiation, despite apparent barriers to dispersal or long distances between populations. Genetic differentiation was low among low-elevation populations of Columbia spotted frogs (*Rana luteiventris*) separated by relatively long distances, whereas genetic differentiation was greater in high-elevation populations (Funk et al. 2005). Populations of *Rana temporaria* and *Bufo bufo* occur on very small, rocky islands in the Baltic Sea, on the coast of Finland. Despite the presence of salt water between the islands, Seppä and Laurila (1999) found little evidence of inbreeding in island populations. Genetic differentiation among islands was small, and most of that was due to variation among groups of islands. Toads have been seen swimming in the sea, and frogs were reported as prey of sea gulls (Kilpi and Byholm 1995). These observations, along with the genetic evidence, suggest that dispersal between islands is relatively common. A study of water frogs (*Rana saharica*) in Morocco also revealed low levels of genetic differentiation among populations, most of which are separated by inhospitable desert (Buckley et al. 1996). In this case, frequent dispersal between local populations seems unlikely. The lack of genetic differentiation is more likely a result of repeated expansion and contraction of local populations during cycles of wetter and drier climates over the last two million years. Recent expansion of the Sahara probably has increased the fragmentation of populations, but these events probably were too recent for substantial genetic differences to appear.

In contrast to these frogs, most populations of salamanders exhibit high levels of genetic differentiation among local populations. Plethodontid salamanders in particular often show greater genetic differentiation among local populations than do most other terrestrial vertebrates (Highton and Webster 1976; Highton 1977; Feder, Wurst, and Wake 1978; Larson and Highton 1978; Duncan and Highton 1979; Tilley et al. 1978; Tilley and Schwerdtfeger 1981; Jacobs 1987; D. Wake 1997). This is especially true of Central American plethodontids, which exhibit high levels of genetic variation within populations, but also remarkably high levels of differentiation between nearby populations (García-París et al. 2000). As discussed at the beginning of this chapter, plethodontid salamanders have some of the lowest rates of movement and smallest home ranges of any terrestrial vertebrates, and this low vagility undoubtedly contributes to low gene flow and high levels of genetic differentiation among local populations. One result has been a proliferation of closely related species in both North America and Central America.

Genetic Variation within Populations

Several studies have revealed unexpectedly low levels of heterozygosity within breeding populations of amphibians (Tabachnick and Underhill 1972; Guttman and Wilson 1973; Case, Haneline, and Smith 1975; Tabachnick 1977; Hedgecock 1978; Christein, Guttman, and D. H. Taylor 1979; Nevo and Yang 1979; Merritt et al. 1984; Reh and Seitz 1990; Sjögren 1991b; Scribner et al. 2001). There are several possible reasons for this: (1) spatial or social structuring within breeding populations that results in frequent matings of close relatives; (2) selection against heterozygotes; (3) reduced genetic variation during the initial founding of isolated populations; (4) a lack of adult or juvenile dispersal between breeding sites; (5) periodic population declines, resulting in small effective population size; or (6) local extinctions that produce genetic bottlenecks, as sites are recolonized from a single source population.

Substructuring of breeding populations seems unlikely for most species. Two studies of *Bufo americanus* found little evidence for frequent matings among close relatives (Christein, Guttman, and Taylor 1979; Waldman, Rice, and Honeycutt 1992). Waldman, Rice, and Honeycutt (1992) even suggested that female toads might recognize and avoid mating with close male relatives, perhaps from differences in call structure. They reported a significant correlation between genetic relatedness of male toads, as determined by DNA fingerprints, and degree of similarity in temporal features of calls. Unfortunately, they did not present correlation coefficients, but most such relationships appear to be relatively weak. For females to use information from call structure to avoid mating with close relatives, they would need to have a genetic template for call perception that would allow them to identify potential brothers. Waldman (2001) presented results of playback experiments indicating that females can discriminate between the calls of closely related and distantly related males. He hypothesized that females might possess a genetic template for call production that would allow them to recognize the calls of related males, but direct evidence for such a template is currently lacking.

The possibility of selection against heterozygotes often has been inferred from patterns of genetic variation (e.g., Guttman and Wilson 1973; Waldman and McKinnon 1993), but direct evidence for such selection is scarce. Most such evidence consists of interspecific correlations between levels of heterozygosity and environmental variables that are thought to be characteristic of fluctuating or constant environments. For example, Nevo and his colleagues conducted broad-scale electrophoretic surveys of amphibian populations and searched the literature for additional information on genetic variability. They found considerable variation in levels of heterozygosity among families and among species within families (Nevo, Dessauer, and Chauang 1974; Dessauer, Nevo, and Chuang 1975; Nevo 1976a, b; Nevo and Yang 1979, 1982; Nevo, Beiles, and Ben-Shlomo 1984; Nevo and Beiles 1991). They attributed most of this variation to ecological variables—specifically, to differing selective pressures in constant and variable environments.

Nevo and Beiles (1991) reported that terrestrial amphibians (some of which breed in water) exhibited the highest levels of heterozygosity, followed by arboreal, aquatic, fossorial, and subterranean species. They argued that terrestrial and arboreal environments are more variable than aquatic or subterranean environments, and that high levels of heterozygosity represent adaptations to this environmental variation. They also reported that tropical amphibians exhibited higher levels of heterozygosity than did temperate-zone species, despite the fact that many biologists tend to view the tropics as a more equable environment than the temperate zone. They discounted the importance of demographic variables in determining levels of heterozygosity, although they did report that species living in isolated populations or those with a patchy distribution generally exhibited less heterozygosity than those with more widely distributed populations.

The analysis of Nevo and Beiles (1991) provides an unparalleled compilation of data on genetic variation in amphibian populations, but their ecological interpretations of the data are problematic for several reasons. First, they failed to take phylogenetic history into account. Five of the six groups with the highest levels of heterozygosity were anuran families, whereas the three with the lowest levels of heterozygosity were urodele families. Urodeles and anurans were combined in a single analysis, with some families represented by many congeneric species that are ecologically similar (e.g., *Plethodon, Rana, Bufo*), perhaps because of shared ancestry. Other families were represented by only a few species. By using individual species as independent data points in multiple regression analyses, sample sizes were greatly inflated, increasing the probability that significant trends will be apparent (Brooks and McClennan 1991; Harvey and Pagel 1991). In addition, some of the ecological comparisons were biased by heavy representation of certain clades in the analysis. For example, 85% of the tropical species were plethodontid salamanders, all members of a single tribe, the Bolitoglossini. Thus, the comparison of tropical and temperate-zone species is largely a comparison between these salamanders and a variety of other amphibians with diverse life histories and ecology.

Several demographic features of populations related to dispersal probably are closely correlated with the broad ecological categories used in Nevo and Beiles's study. For example, species that were classified as fossorial were mostly desert-dwelling spadefoot toads, which emerge to breed in temporary ponds. Because their ability to move long distances probably is limited by the aridity of their environment, one might expect relatively little dispersal between populations. In addition, local breeding pools often fail to produce any juveniles, so recruits into the population probably come from a small subset of breeding adults. Both of these factors are likely to reduce heterozygosity, and pelobatids as a group had the lowest levels of heterozygosity of any anuran family. Anurans that breed in well-established ponds, such as many ranids, are likely to exhibit greater breeding site fidelity and natal philopatry than are species that breed mostly in temporary water, such as many toads (*Bufo*). Indeed, ranids as a group exhibited lower levels of heterozygosity than did bufonids. Other differences were unexplained. For example, rhacophorid tree frogs had higher levels of heterozygosity than did hylid tree frogs with very similar ecology. Some of these differences probably were related to variation in dispersal patterns of the particular populations used in the analysis.

Other studies have shown that the combined effects of small population size, lack of movement among populations, and periodic local extinction can lead to reduction in heterozygosity within populations and increased genetic differentiation among populations. For example, very low levels of heterozygosity also were reported for local populations of *Rana lessonae* in an area of Sweden not greatly affected by human development (Sjögren 1991a). These frogs reproduced in a network of small pools, many in close proximity to one another. Each pool supported a rather small breeding population, and reproductive failure, usually due to cold weather, was common. In some years, all pools in the area failed to produce metamorphosing frogs, leading to dramatic reductions in recruitment into the breeding population in subsequent years. Migration between pools occurred, but at low levels, and extinction of local populations was frequent. The repeated bottlenecks created by small population sizes, low rates of migration between populations, and periodic extinction probably account for the low level of genetic variation (Sjögren 1991a, b).

Patterns of Movement and Amphibian Conservation

Information about patterns of movement between terrestrial habitats and aquatic breeding sites, as well as dispersal between breeding sites, is essential for making decisions about protection of critical habitats for threatened or endangered species of amphibians. The importance of dispersal for conservation is discussed in more detail in chapter 16, so only a few points will be mentioned briefly here. One concern is the effect of man-made barriers to dispersal, such as roads, on the genetic structure of populations. High levels of inbreeding and low heterozygosity do not always result in reduced fitness of individuals (Sjögren 1991a), but artificial isolation of populations by roads and other forms of human land use could reduce effective population sizes and increase the effects of inbreeding depression on reproductive success (Waldman and McKinnon 1993; Scribner et al. 2001). For example, Reh and Seitz (1990) studied the genetic structure of populations of *Rana temporaria* in an area of Germany that was highly dissected by roads and agricultural land. All local populations exhibited low levels of heterozygosity, probably because of increased inbreeding.

Heterozygosity decreased with increasing isolation of populations and was especially low for a population that was completely surrounded by roads. Other studies also have shown decreased levels of genetic variation within populations and increased differentiation among populations of anurans isolated by urban development (Hitchings and Beebee 1997, 1998). In *Bufo bufo,* decreased heterozygosity was correlated with an increase in developmental abnormalities in tadpoles and a decrease in tadpole survival, but these effects were not seen in *Rana temporaria.* Negative effects of decreased heterozygosity can be particularly severe under stressful conditions, such as unusually cold winters or very hot, dry summers (Samollow and Soule 1983).

The effects of low levels of genetic variation, combined with small population sizes, also can make such artificially isolated populations especially vulnerable to extinction. Subsequent recolonization becomes impossible because of a lack of suitable dispersal corridors (Laan and Verboom 1990). Not all fragmented populations exhibit genetic effects of isolation, however. For example, a comparison of populations of red-backed salamanders (*Plethodon cinereus*) in a fragmented suburban landscape and undisturbed forest revealed relatively small differences in the degree of genetic differentiation between populations (Gibbs 1998c). Probably this is due to the large population sizes and very low rates of movement in natural populations of this salamander. Even relatively isolated populations probably can persist for a long time in patches of suitable habitat, with few genetic effects. Such isolated populations could be vulnerable to extinction, however, if events such as prolonged drought reduce populations below viable numbers and immigration is prevented because of habitat barriers.

Roads not only prevent movement between populations, but also can have a direct effect on population size, simply because amphibians are killed when attempting to cross them, especially during migrations to and from breeding areas (Fischer 1969; Karthaus 1985; Kuhn 1987; Cooke 1988, 1995; Fahrig et al. 1995; Hels and Buchwald 2001). Two approaches have been widely adopted in Europe, and to a lesser extent in North America, to alleviate this problem (see chapter 16). The first is the construction of various types of tunnels under roads along known migration routes of amphibians (Langton 1989). The second approach is the construction of substitute breeding ponds to intercept amphibians before they cross over roads. Such ponds often are readily colonized by amphibians, although not necessarily by exactly the same assemblage of species found in natural breeding ponds (Podloucky 1989; Schlupp et al. 1989). Migrating amphibians also can be redirected to new breeding ponds by blocking access to old ones (Schlupp and Podloucky 1994). An important consideration is the proximity of suitable terrestrial habitats or dispersal corridors that would allow amphibians access to newly constructed ponds. Use of ponds as breeding sites by amphibians often decreases when ponds are far removed from wooded habitats used for summer home ranges or hibernation (Loman 1988; Wederkinch 1988; Laan and Verboom 1990; Baker and Halliday 1999).

Homing Behavior

If amphibians make regular movements between breeding sites and terrestrial habitats, or occasional excursions out of their normal home ranges, they must have some means of finding their way home again (Sinsch 1992a). Indeed, many amphibians can find their way back to a breeding pond or home range after being experimentally displaced (tables 6.6, 6.7). Studies of homing behavior are useful in determining the ability of individuals to make long distance migrations to and from breeding sites, and as a means of investigating mechanisms of orientation. The methods used to study homing vary considerably. Some studies have involved rather haphazard displacements of individuals at different distances, with little attempt to quantify homing success as a function of displacement distance. Many investigators have failed to include proper controls (animals marked and released at their home sites), so it is impossible to compare recapture rates of displaced animals with rates expected for animals that are not displaced. In some studies (e.g., Madison 1969), recapture rates actually were higher for animals released at a new site than for those released at home. Presumably this is because displaced animals immediately headed for home on the surface, while nondisplaced animals disappeared into retreat sites in their home ranges. Barthalmus and Savidge (1974) suggested that the time required for individuals to return home as a function of displacement distance would provide a better measure of homing performance than the proportion of animals homing, but few workers have used this method.

Homing by Urodeles

Homing to nests by displaced females has been reported for several species of plethodontids (table 6.6), but displacement distances in these studies were very short. F. Rose (1966) found that the number of females of *Desmognathus auriculatus* homing successfully from a 6 m displacement was very low (8%), perhaps because these animals were released outside of their familiar foraging ranges. Other studies of terrestrial plethodontids have shown that many individuals can home from locations up to 30 m from their home ranges (table 6.6), a distance considerably greater than that covered in normal daily movements (table 6.3).

(*continued*)

Several species exhibited poor homing performance when displaced 60–300 m (table 6.6).

Joly and Miaud (1989) collected groups of alpine newts (*Triturus alpestris*) from three breeding ponds that were 25–150 m apart. The animals were released at four different sites that were either 30 or 100 m from the ponds. Most individuals that were recaptured returned to their native ponds, but a higher percentage returned from short-distance displacements. Individuals displaced 30 m to a wooded site returned to their ponds within two weeks, but those displaced the same distance into a pasture took up to seven weeks to return. Those displaced 100 m into either woods or pasture

Notes: Data are combined for males, females, and juveniles, except for homing to nests, which are for females only. Both the percentage of individuals recaptured and the percentage of animals that exhibited a homing response are reported whenever possible. All recaptures were made in the same season except as indicated. A distance of zero indicates control animals released at the home site. BP = breeding pond; HR = home range; HS = home site; HZ = home zone in stream; NE = nest with eggs.

also took up to seven weeks. An even longer delay was observed by Gill (1979) after he moved adult red spotted newts (*Notophthalmus viridescens*) from one breeding pond to another 400 m away. Many of the newts remained in the new pond for the rest of that breeding season. About a third of the animals were recaptured a year later, and 65% of these (21% of those displaced) had moved back to the original pond. These animals probably delayed their return because the cost in lost breeding opportunities outweighed any advantage of returning in the same season.

The most impressive homing ability exhibited by any amphibian is that of the newt *Taricha rivularis,* studied for many years by Victor Twitty and his colleagues in California. In initial studies, newts were displaced about 1,600 m to a new location in their home stream. Over a five year period, about 64% of the animals were recaptured, and nearly 90% of those returned to their home segments of the stream (Twitty, Grant, and Anderson 1964; Twitty 1966). In subsequent experiments, newts were displaced to different streams, either in an adjacent valley, or in an area separated from the home stream by several ridges. The longest displacement was about five miles (8 km). In only two years, 44% of the animals were recaptured, with about 41% of these returning to the home stream (table 6.6; Twitty 1966). Records of animals recaptured in drift fences placed along ridge tops indicated that the animals moved overland on a relatively straight compass course to reach their home stream. Homeward bound individuals had to pass through a third stream which was ideal newt habitat, but few of them established residence there. Since these newts generally do not wander far from their home stream segments (Twitty, Grant, and Anderson 1967), there is no doubt that they were able to return home even when released in completely unfamiliar areas.

Homing by Anurans

There have been a number of anecdotal reports of individual anurans being displaced and returning to their home sites (e.g., Durham and Bennett 1963), but quantitative data are scarce. Most studies have involved displacements of less than 300 m, with the highest percentages of successful homing obtained from individuals displaced from breeding ponds (table 6.7; Jameson 1957b; Oldham 1966, 1967; Lüddecke 1996; Holenweg Peter 2001). Presumably return rates were high in these species because animals were strongly motivated to return to the breeding area. One of the few detailed studies of homing from longer distances is Bogert's (1947) work on *Bufo terrestris.* He found that homing success decreased with displacement distance (table 6.7), although the tendency for animals to establish home ranges at the release sites also depended on the suitability of the habitat in the area. In a two week study of homing by *Rana esculenta, R. ridibunda,* and *R. lessonae,* frogs were displaced up to 225 m from their home ponds (Holenweg Peter 2001). Overall, slightly less than half were recaptured, of which 90% were back in the home ponds. Homing performance declined dramatically at distances of more than 75 m, and none of the frogs released more than 150 m from the home pond returned (table 6.7). Adult mountain yellow-legged frogs (*Rana muscosa*) that were moved 144–630 m to new ponds showed

a mixed response, with about half moving back to or toward their original capture sites and the rest remaining at the new release site (Matthews 2003).

Gonser and Woolbright (1995) displaced male *Eleutherodactylus coqui* 20–100 m from their calling sites in a Puerto Rican rainforest. These are terrestrial breeders, so they do not move to ponds, but they exhibit considerable fidelity to calling sites. Nearly all males returned to their home sites after displacements of 20 m, more than half returned from 40 m, but only a quarter returned from 100 m (table 6.7). The time required for the frogs to return home increased with displacement distance as well, from an average of four nights at 20 m to nearly 13 nights at 100 m.

The ability of anurans to return home from displacements exceeding 2 km has not been investigated in detail, but a few studies have examined accuracy of initial homeward orientation at different distances. Dole (1968) displaced leopard frogs (*Rana pipiens*) up to 10.5 km from their home ranges. Although he did not report the number of frogs that returned home, he did find that nearly all frogs displaced 200–800 m moved in a homeward direction, while the orientation of frogs displaced 3.2–10.5 km was random. Furthermore, those displaced shorter distances averaged more than twice as much movement per rainy night as those displaced longer distances, suggesting that some frogs in the latter group accepted the release site and established new home ranges. Sinsch (1987a, c) reported that toads (*Bufo bufo*) displaced up to 250 m showed strong initial home-

ward orientation, whereas those displaced 500 or 1,000 m were much less accurate. However, seven of ten toads that were displaced 3 km from one breeding pond to a point within 200 m of another pond showed a strong tendency to move toward their home pond.

The Adaptive Significance of Homing

Several hypotheses have been proposed to explain the evolution of homing abilities in amphibians. For species such as *Taricha rivularis* and *Bufo bufo,* which spend most of their lives on land and return to the water to breed, homing allows the animals to reliably locate a suitable breeding site and then return to a familiar summer home range (Twitty 1966; Heusser 1968d). For species that live along streams, an ability to home allows individuals to return to a familiar area after being accidentally displaced by floods or other chance events. For example, dendrobatid frogs of the genus *Colostethus* live on boulders in tropical streams that are transformed from little more than seepage areas during the dry season to raging torrents during the wet season. It is not uncommon for frogs to be knocked into the water during fights and be washed several meters downstream, but they apparently return to their home sites with little difficulty (Wells 1980a). During dry periods, males abandon their territories and move into streambeds; some individuals return to their former territories in the next rainy season.

Still another possibility is that homing allows individuals to make forays outside of their normal home ranges to search for better feeding areas or retreat sites, but to return if good quality habitat is not found. The tendency for many amphibians to make occasional long-distance movements and then turn up in their old home ranges has already been mentioned. Phillips (1987) suggested that for aquatic breeders such as *Notophthalmus,* the evolution of homing is related to dispersal. Juveniles leaving their home ponds can explore the surrounding area for suitable breeding sites, but an ability to home gives them the option of returning to the natal pond if alternative sites are not available. Probably no single hypothesis will suffice to explain the evolution of homing ability in all amphibians. An ability to return home at least over short distances probably is a general characteristic of most amphibians, and indeed, most vertebrates; the precise advantage derived from the behavior will depend on the ecology and life history of each species.

Orientation

The information presented so far shows that many amphibians remain in a relatively restricted area for most of their lives, evidently becoming very familiar with their own home ranges. Occasionally they make long excursions into new areas to feed or reproduce and are able to find their way home from distances ranging from several hundred meters to several kilometers. Individuals of some species clearly can home from distances that greatly exceed any natural movements the animals normally make. The remainder of this chapter considers the sensory mechanisms that allow amphibians to find their way home during natural wanderings or after displacement to unfamiliar terrain.

Two types of orientation seem to be most important in guiding the movements of amphibians. The first is piloting, the ability to steer a course using familiar landmarks (Adler 1976; Papi 1990; Sinsch 1990, 1991b, 1992a). Piloting probably is the principal means of orientation used by amphibians for daily movements within their normal home ranges. Many individuals commonly return to the same retreat site, burrow, or feeding station every day, sometimes for many years in succession. Presumably an animal learns the characteristics of the local area and uses visual or chemical cues to relocate its home site after relatively short-distance movements.

Amphibians also are capable of compass orientation without local landmarks. A compass sense is important in maintaining a proper orientation relative to features in the environment, even when these are not visible to the animal. For example, many amphibians are found near the shores of ponds and streams and often escape predators by jumping directly into the water or into surrounding vegetation. When placed in a featureless arena open only to the sky, these animals usually orient as if they were moving perpendicular to their home shore, rather than orienting in a true homeward direction (fig. 6.5; Adler 1970, 1976). This behavior, termed *Y-axis orientation* (D. Ferguson and Landreth 1966), has provided a useful tool for investigating sensory mechanisms of orientation. Animals can be trained to a shoreline in a laboratory tank and then tested for orientation after experimental manipulation of external cues or sense organs.

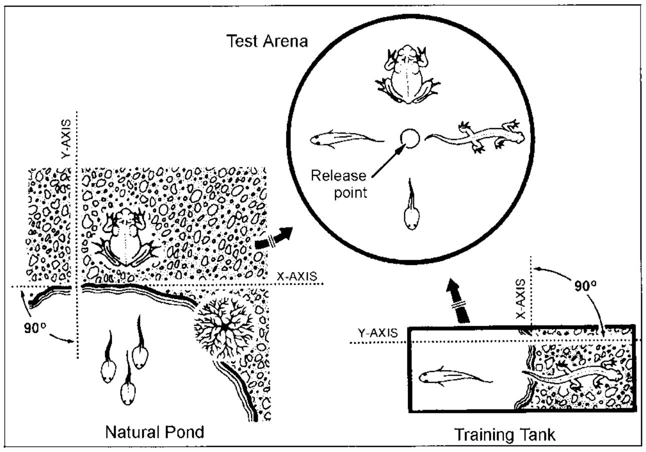

Fig. 6.5. Diagram of compass orientation in aquatic and terrestrial vertebrates. When toads and tadpoles collected near a shore are placed in a test arena under a clear sky, they orient along an axis parallel to their natural Y-axis. The toad orients toward land, whereas the tadpoles orient toward water. When a salamander is trained to a shoreline in a training tank and then placed in the test arena, it orients parallel to the trained Y-axis in a shoreward direction. A fish trained to the same shoreline would orient toward water. After Adler (1976).

Amphibians probably also use a compass sense for orientation during movements to and from breeding sites or during occasional excursions out of their normal home ranges. For example, amphibians collected at drift fences around breeding ponds tend to enter and leave a pond at approximately the same point (Shoop 1965, 1968; Shoop and Doty 1972; Williams 1973; L. Hardy and Raymond 1980; Douglas and Monroe 1981; Stenhouse 1985b; Beneski, Zalisko, and Larsen 1986; Phillips and Sexton 1989; Dodd and Cade 1998; Palis 1998). This could be evidence of orientation along a fixed compass axis. However, in many cases, the animals also could be responding to local environmental cues, or they might use such cues in conjunction with a compass sense. Studies of European frogs have shown consistent orientation toward particular types of habitats by both juveniles and adults leaving breeding ponds (Sjögren-Gulve 1998b). Different species showed somewhat different patterns of orientation, with each tending to orient toward habitats typically used by that species (Sjögren-Gulve 1998a). Experiments with North American wood frogs (*Rana sylvatica*) and spotted salamanders (*Ambystoma maculatum*) showed that juveniles and adults exhibited strong orientation toward forest habitats and away from clear-cut areas and open areas near power lines (deMaynadier and Hunter 1999). Similar results were obtained in a study of European newts (*Triturus cristatus* and *T. vulgaris;* Malmgren 2002). The fact that juveniles emerging from ponds showed the same orientation preferences as adults in these studies suggests that individuals are responding to local environmental cues, since the juveniles have not previously moved along any particular compass axis. It is possible that juveniles use local environmental cues to initially learn the direction of suitable habitats, but then rely in part on compass information to return to a pond in subsequent years. A similar multistage process of orientation has been proposed for juvenile sea turtles leaving the beaches where they hatch (Lohmann et al. 1997).

There is evidence for consistent compass orientation among adult amphibians moving to and from breeding ponds. Data on movements of salamanders tagged with radioactive wires indicate that most individuals follow a straight-line course when moving from breeding ponds to summer home ranges and simply reverse course to return to the pond the following year (Williams 1973; Semlitsch 1981b, 1983a). Although animals could follow a fixed dispersal path by learning local landmarks, evidence from several anuran species indicates that migrating individuals will maintain their original compass headings even when placed in arenas that obscure local landmarks (Tracy and Dole 1969a; Dole 1972c).

A third type of orientation is true navigation, the ability to orient in the absence of familiar local cues. Navigation requires some type of compass sense. It also requires that the animal be able to determine where it is relative to the goal; that is, it must have a "map sense." Map information could be acquired if an animal integrates information about the distance and direction of its displacement from home and uses this to orient in the opposite direction from its net direction of displacement ("route-based" information). Alternatively, an animal might be able to detect gradients of environmental cues that vary predictablly in different directions and derive a bicoordinate "map" from this information (Phillips 1987; Rodda and Phillips 1992; Fischer et al. 2001).

The sensory basis of orientation can be investigated either by manipulating environmental stimuli and testing the responses of intact animals to these cues, or by eliminating one or more sensory modes and testing an animal's ability to orient without them. Many amphibians probably use several sensory modes and several types of environmental cues for orientation. This redundancy makes it difficult to determine precisely which mechanisms are most important in the natural environment. Experimental manipulation can reveal whether a given environmental cue or sensory system is essential for orientation, but it does not necessarily indicate the relative importance of different cues for orientation in intact animals. By eliminating one sensory mode or altering one cue at a time, investigators often are left with a list of cues that the animal can detect, but none that appears absolutely essential for successful orientation.

Orientation to Local Environmental Cues

Many amphibians behave as if they can use local landmarks for orientation. For example, frogs often return to exactly the same feeding perch or spot on the shore of a pond night after night, even after relatively long excursions (e.g., Dole 1965b). Male green frogs (*Rana clamitans*) appear to recognize natural features such as clumps of vegetation or rows of bullrushes as boundaries of defended territories (Wells 1977b). Fire salamanders (*Salamandra salamandra*) displaced from their home sites do not return home on a straight-line course, but instead make a series of short movements between natural landmarks such as logs or trees (fig. 6.6; Joly 1963, 1968; Plasa 1979). Despite the obvious importance of visual landmarks for orientation, only Plasa (1979) has done controlled laboratory experiments to test the ability of amphibians to orient using such cues. Salamanders were trained to a home box in an arena with the entrance to the box marked with a variety of striped patterns or a group of small blocks. When the location of the landmarks was switched, the salamanders oriented toward the learned pattern, not in the actual compass direction of the home box.

A number of other types of local orientation cues have been proposed for amphibians. Several early workers suggested that amphibians might locate breeding sites by following humidity gradients (hygrotaxis) or by moving downhill (geotaxis; B. Cummings 1912; Czeloth 1930). Several other studies showed that these cues have little influence on orientation when animals are in a familiar area, but become important when they are in unfamiliar surroundings (Chapman and Chapman 1958; Savage 1961; Oldham 1966, 1967; Twitty 1966; Heusser 1964, 1969c). Omland (1998) found that red-spotted newts (*Notophthalmus viridescens*) tend to orient downhill (geotaxis) when placed in unfamiliar surroundings, presumably because moving downhill generally leads them to water. Adult newts were collected during spring migrations and placed in an apparatus that allowed the slope angle to be varied. They exhibited a strong downhill orientation. In contrast, terrestrial juveniles (efts) did not orient downhill and showed no tendency to move toward ponds. His results are consistent with laboratory studies of magnetic orientation in newts that revealed a high degree of sensitivity to the slope of the test arena, requiring careful leveling of the test apparatus (Phillips and Borland 1994; Deutschlander, Phillips, and Borland 2000).

Although some amphibians use rivulets, streambeds, or other depressions as migration routes (Hurlbert 1969; Hershey and Forester 1980), others appear to move along relatively straight compass courses unrelated to topographic features (Douglas and Monroe 1981; Pilliod, Peterson, and Ritson 2002). A number of investigators have suggested that amphibians have a kinesthetic sense that enables them to remember a path by sensing changes in topography through movements of muscles and joints (Buytendijk 1918; Eibl-Eibesfeldt 1950; Twitty 1959). There is evidence for a kinesthetic sense in newts (Endler 1970) and frogs (Adler 1980), but this probably is more important for making minor corrections in a travel path after avoiding obstacles than for orientation over long distances. Orientation to flowing currents of water (rheotaxis) has been reported in the cave-dwelling salamander (*Proteus anguinus*) and a surface-dwelling relative, *Necturus maculosus* (Durand and Parzefall 1987), as

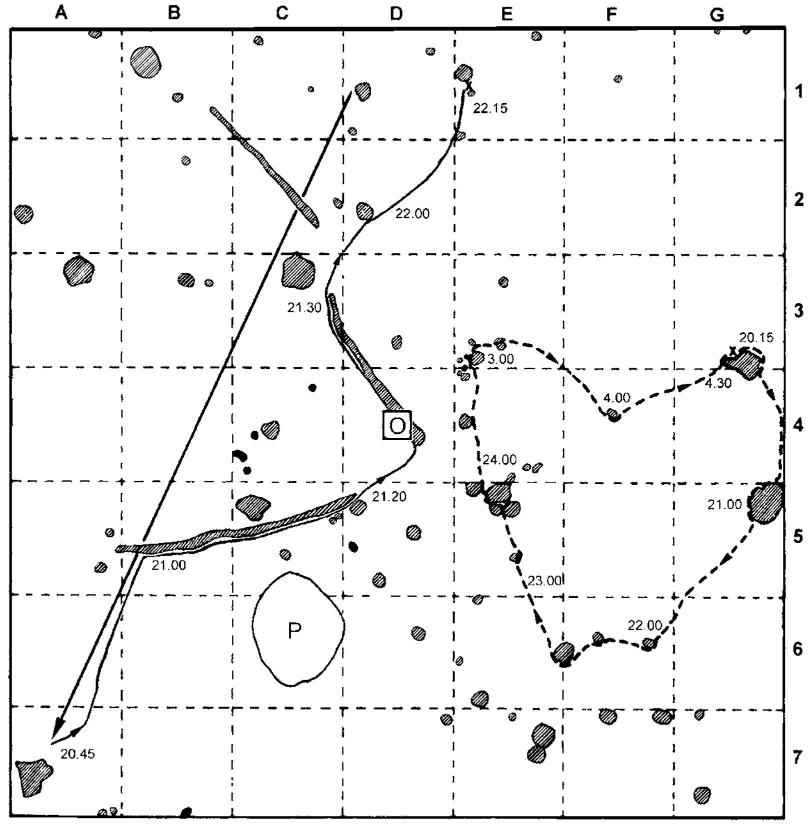

Fig. 6.6. Map of movements of adult fire salamanders (*Salamandra salamandra*) in Germany during natural wanderings (dashed line) on a single night and after linear displacement (long arrow) from a home range. These salamanders appear to use natural landmarks such as trees and logs to orient during normal movements and when finding their way home after displacement. Shaded areas are trees and logs. O = observation platform. P = pond. Numbers show the times of night. Each square in the grid is 2 m. After Plasa (1979).

well as *Triturus vulgaris* (Dolmen 1981b). The biological role of this type of orientation is unclear.

Olfactory Orientation

Local habitat features such as breeding ponds, hibernation sites, or diurnal retreat sites probably have unique chemical signatures that could be used by amphibians for orientation, although the distance at which such cues can be detected is not known for most species. Several lines of evidence suggest that olfactory cues are important for orientation in some anurans and urodeles, but the available data must be interpreted cautiously. Savage (1935b, 1961) provided indirect evidence for olfactory orientation toward breeding ponds by *Rana temporaria*. He found that migration from hibernacula north of a breeding site took place mainly when the wind was blowing from the south across the ponds. He suggested that the odor of algae in the water was important in guiding the movements of migrating frogs. He did not have any experimental evidence that the animals actually were detecting these odors, and studies of other species have failed to detect a relationship between wind direction and migration or the ability to return home after displacement (Eibl-Eibesfeldt 1950; Moore 1954; Heusser 1964, 1969c; Dole 1968). Sinsch (1987c) reported that wind blowing from the direction of home ponds improved the directional orientation of toads (*Bufo bufo*), but orientation was not eliminated when wind was blowing away from the ponds.

Several investigators have used various types of experimental chambers (olfactometers) to present amphibians with a choice of odors from different sources. Early work on *Triturus* by Czeloth (1930) and *Bufo bufo* by W. Jungfer (1943) showed that adults would move toward the odor of a breeding site in a wind tunnel. Martof (1962b) gave *Pseudacris triseriata* adults a choice between the odor of a breeding pond and leaf litter from a forest; the frogs preferred the pond odor. *Pseudacris crucifer* tested in a similar manner did not show a preference for home pond odors. Grubb (1973a, c, 1975) later demonstrated that some anurans preferred the odors of their own breeding areas to those of other bodies of water, including other suitable breeding ponds. Not all test groups showed this discrimination, perhaps because of chance similarity in the odors of different ponds. Grubb (1973b) did not find evidence of olfactory orientation in *Hyla chrysoscelis* or *Scaphiopus hurterii,* but attributed this to differences in the motivation of the test animals rather than an inability to discriminate odors. Metamorphosing juveniles of *Rana lessonae* preferred natal pond odors to odors of tap water or unfamiliar ponds, and exposure to artificial chemical odorants during larval development resulted in a preference for those odors in juveniles (Ogurtsov and Bastakov, 2001). Forester and Wisnieski (1991) reported that *Dendrobates pumilio,* a terrestrial breeder, preferred odors emanating from their own cages to those coming from a blank cage, and they preferred the odor of bromeliads, which normally were placed in their cages, to unfamiliar mint plants. Whether olfactory orientation plays a significant role in the biology of this species in the field is open to question, because these diurnal frogs are very visually oriented in their foraging and social behavior.

Relatively few experimental studies of this type have been done with salamanders, which is surprising, given the importance of chemical senses in the lives of these animals (see chapter 9). A test with *Plethodon metcalfi* failed to demonstrate an ability to discriminate the odor of leaf litter collected in an animal's home area from that collected elsewhere, although other evidence suggested that olfaction might be important in the orientation of this species (Madison 1972). McGregor and Teska (1989) used paper towels impregnated with material from different ponds to test a preference for home pond cues in spotted salamanders (*Ambystoma maculatum*). They scored a choice by determining the relative amount of time the animals spent on marked towels on either side of a test chamber. The salamanders exhibited a strong preference for home pond substrates. The design of this experiment does not clearly distinguish the chemical sense involved in detecting home pond odors (olfactory or vomeronasal system), and it does not necessarily show that the salamanders are capable of detecting airborne odors of ponds at a distance.

Joly and Miaud (1993) presented evidence for olfactory orientation in European newts (*Triturus alpestris*) moving to breeding ponds. Newts were captured while migrating to a breeding pond from different directions. When they were transferred to arenas on the opposite sides of the pond, they showed strong orientation toward the pond. When the pond was covered with a tarpaulin to reduce odor emissions, the newts changed their orientation and moved away from the pond. In laboratory olfactometer experiments, the newts showed a preference for odors emanating from water collected in their own breeding ponds.

Olfactometer tests have the advantage of allowing the investigator to determine preferences for particular odors in animals that have not been traumatized by surgery. Without information about the distance over which odors can be detected in the field, however, they do not necessarily demonstrate an important role for olfaction in orientation. Other workers have surgically impaired visual or olfactory systems in experimental animals to determine whether olfactory cues can be used for homing orientation. The effects of these experimental treatments often appear to be quite traumatic for the animals, and they often exhibit much less movement than control animals (e.g., Sinsch 1987c). Often animals subjected to these treatments eventually find their way home, but in fewer numbers than for control animals, and the time required to make the trip usually is much greater. This could be due to impaired sensory abilities, distress caused by the treatments, reduced survivorship during homing, or a combination of all three.

In several species, including *Bufo boreas, Rana clamitans, Notophthalmus viridescens,* and *Taricha rivularis,* homing ability or homeward orientation was significantly reduced in blinded animals, and in two species, *Salamandra salamandra* and *Bufo spinulosus,* it was eliminated. In many other species, the homing performance of blinded animals was as good as that of normal individuals (table 6.9). In *Bufo bufo,* animals with their eyes covered with tape showed initial homeward orientation as good as that of control animals, but their paths of movement toward home were less straight (Sinsch 1987c). Experiments with blinded animals suggested that olfaction was important for orientation. Unfortunately, many of these studies were done before the possibility of extraocular photoreception or magnetic orientation was recognized, so depriving animals of sight alone does not provide definitive evidence of olfactory orientation.

Many of the same workers also tested the orientation of animals rendered anosmic through surgical severing of the olfactory nerves, perfusing the nostrils with formalin or other chemicals, or blocking the nares with wax or vaseline. Among anurans, only *Bufo boreas* appeared to be completely disoriented when rendered anosmic, although the homing orientation of anosmic *B. bufo* and *R. clamitans* was significantly impaired (table 6.9). Other anurans showed little or no reduction in homing orientation. This suggests that animals simply switch to olfaction or extraocular photoreception if vision is impaired, and to visual cues if olfaction is eliminated. In two studies of toads (*Bufo valliceps* and *B. bufo*), animals rendered both blind and anosmic were completely disoriented (Grubb1970; Sinsch 1987c).

In contrast to the results with anurans, most studies of urodeles have shown that homing ability is reduced or eliminated in anosmic individuals (table 6.9), suggesting a more important role for olfaction in this group. This is to be expected, given the dominant role of chemical senses in the foraging and social behavior of these animals (see chapters

1 and 11). Most homing studies of salamanders have involved relatively short displacements (< 30 m) from home ranges or breeding sites, so it is conceivable that animals could pick up odor cues from the home area. A notable exception was *Salamandra salamandra,* which was fully capable of homing when nostrils were blocked with Vaseline (Plasa 1979). This species finds prey mainly by visual detection, so it probably relies heavily on visual cues for orientation as well (Himstedt 1994).

The results with *Taricha rivularis* are somewhat puzzling. Anosmic newts were displaced up to 3.2 km (2 miles) to another stream. Very few found their way home, even though both normal and blinded newts homed from the same release point. Most of those that did home were found to have regenerated olfactory tracts (Twitty 1966; Grant, Anderson, and Twitty 1968). These experiments seemed to provide strong evidence for the use of olfaction in homing orientation. Nevertheless, it is hard to imagine how newts could detect odors unique to a particular stream at such great distances, and all of Twitty's (1966) experiments designed to test odor discrimination in this species failed. Alternative interpretations are that survival of anosmic newts was greatly reduced because of an inability to find food or locate moist retreat sites (Twitty 1966), or that the surgery also damaged extraocular photoreceptors important for celestial orientation (Adler 1976) or magnetic receptors (Phillips and Borland 1994). Overall, the available data suggest a role for olfaction in enabling urodeles and perhaps some anurans to find their way home when they are in a familiar area, but its importance for long distance homing is questionable.

Acoustic Orientation

There has been considerable debate about the importance of vocalizations in guiding the movements of anurans to breeding sites. Many authors have assumed that both females and late-arriving males are attracted to the sound of a chorus (Salthe and Mecham 1974), but males and females of many species find their way to breeding sites before chorusing begins (Heusser 1958a, 1960, 1964, 1969c; Savage 1961; Oldham 1966, 1967; Wells 1979). In fact, European toads (*Bufo bufo*) apparently begin moving from their summer home ranges toward breeding ponds in the fall, and overwinter only a few hundred meters away (Heusser 1968d, 1969c). In experiments with *Bufo americanus* and *Rana clamitans,* Oldham (1966, 1967) found that males from the local area oriented toward familiar breeding sites independent of the sound of a natural or tape-recorded chorus, whereas foreign individuals placed in an arena showed some orientation to broadcast calls. Several other studies have shown that migrating individuals placed in an arena can be diverted from their original compass course by the sound of a chorus. Usually this occurs only when other orientation cues are absent (D. Ferguson and Landreth 1966; Landreth and Ferguson 1966; Tracy and Dole 1969a; Landreth and Christensen 1971). Sinsch (1992b) reported that displaced females of *Bufo calamita* often oriented toward the nearest pond with calling males, whereas males usually oriented toward their home ponds. This suggests that for females, finding a mate quickly is more important than breeding in a particular pond, and is consistent with the much lower level of site fidelity of females compared to males in this species. It is possible that species that breed opportunistically in temporary water are more likely to be attracted to the sound of a chorus than those that breed year after year in the same location.

A surprising example of interorder acoustic orientation was reported by Diego-Rasilla and Luengo (2004). They found that marbled newts (*Triturus marmoratus*) oriented toward playbacks of the calls of natterjack toads (*Bufo calamita*), which often breed in the same ponds, but not to those of green toads (*B. viridis*), which are not sympatric with these newts. Because salamanders lack external ears, they traditionally have been considered deaf to airborne sounds while on land (Wever 1985). Recently, however, Hetherington (2001) found that the lateral body wall of salamanders with lungs, including newts, vibrate in response to airborne sounds, providing a possible extratympanic route for sound transmission similar to that of some frogs that lack external ears (see chapter 7).

Celestial Orientation

Orientation using celestial cues, particularly the position of the sun, appears to be of primary importance for many amphibians (D. Ferguson 1966, 1971). Celestial cues provide amphibians with a means of compass orientation that is independent of local environmental cues. Most tests have been done on aquatic or semiaquatic species from North America. It is not clear how important this type of orientation is for species that spend all of their lives in forested habitats with little exposure to celestial cues (although these species could use polarized light for orientation—see the following discussion). Most studies have focused on Y-axis orientation. Animals are collected along a natural shoreline, or trained to a shoreline in an arena. The animals are then placed in an aquatic or terrestrial arena that provides a view of the sky, but positioned so that all cues from the home site are excluded. A positive response is scored if an animal moves in a compass direction perpendicular to the shoreline at the home site or training arena. Most species tested to date exhibit Y-axis orientation under a clear sky with the sun visible, but show random orientation under overcast conditions (table 6.8). Several anuran species and one species of newt also can orient along a Y-axis when the moon is

Notes: All animals were tested in aquatic or terrestrial arenas with only the sky visible. Blanks indicate conditions under which animals were not tested. "Dark" indicates a night with complete cloud cover, or a test conducted when the moon and stars were not visible. "Yes" indicates that animals showed orientation. "No" indicates no orientation. Most of these studies were not designed to eliminate the possibility of magnetic orientation.

visible, and a few species show Y-axis orientation when only stars are visible. One study of marbled newts (*Triturus marmoratus*) found similar results in tests for orientation toward a home pond (Diego-Rasilla and Luengo 2002). Species tested under an overcast night sky, or on dark nights when the moon and stars are not visible, invariably display random orientation. In a similar set of experiments, alpine newts (*Triturus alpestris*) showed homeward orientation under a clear night sky, but not when the sky was obscured. In this species, orientation under a clear sky was disrupted by alteration of the magnetic field (see the following discussion; Diego-Rasilla 2003).

When amphibians are collected during migration to a breeding pond and tested in an arena some distance away, they typically maintain their original compass course but do not necessarily orient in the true direction of the breeding pond. This suggests that the mechanism of orientation to breeding sites is similar to Y-axis orientation; that is, the animals move on a fixed compass course until they intersect the shoreline. Tests with migrating animals generally have yielded the same results as tests of animals showing Y-axis orientation to a shoreline. Orientation is maintained under clear day or night conditions when the sun or moon is visible, but orientation sometimes is disrupted when the sky is dark or overcast (D. Ferguson and Landreth 1966; Landreth and Ferguson 1967c; Tracy and Dole 1969a; Landreth and Christensen 1971). On the other hand, Sinsch (1987c) found that European toads (*Bufo bufo*) released under an overcast sky oriented toward breeding ponds nearly as well as those released under a clear sky. This species normally migrates during overcast or rainy weather, when celestial cues are obscured.

These experiments provide strong circumstantial evidence that celestial bodies, particularly the sun, provide cues essential for orientation when only the sky is visible. To use celestial cues for compass orientation, an animal not only must be able to determine the position of the sun or the moon, but also must have a built-in time sense to compensate for the apparent movement of these bodies in the sky. For example, if an animal maintains a fixed compass course, its angle of movement relative to the sun will depend on the time of day, so it must know local time to orient correctly (fig. 6.7). An animal moving south in the northern hemisphere would move at an angle to the right of the sun in the morning, but would move on a course to the left of the sun in the afternoon. If the animal's photoperiod is delayed by six hours, the animal will behave as if the afternoon sun were in the morning position and shift its course 90° in a clockwise direction. Similarly, a six-hour advance in the photoperiod will result in a 90° shift in a counterclockwise direction (Adler 1976).

Several lines of evidence show conclusively that amphibians do have an internal clock synchronized to local solar time. First, animals can maintain the correct orientation in an arena independent of time of day (D. Ferguson, Landreth, and McKeown 1967). Second, orientation usually is disrupted if animals are held for several days in the dark (D. Ferguson, Landreth, and Turnipseed 1965; Ferguson, Landreth, and McKeown 1967; Landreth and Ferguson 1967c), indicating that the animals' biological clocks must be reset periodically by exposure to celestial cues. Experiments with *Acris gryllus* showed that exposure to the sun is essential for maintaining synchrony with local time. Animals exposed only to a night sky in a training arena failed to orient to the trained shoreline when tested during the day, but instead continued to orient on the Y-axis of their home shore. In contrast, animals trained under a day sky learned to orient to the new shore (D. Taylor and Ferguson 1969). Finally, all species that have been phase-shifted through altered photoperiods have shown the predicted change in directional orientation (fig. 6.8; D. Ferguson, Landreth, and McKeown 1967; Landreth and Ferguson 1967c; Gorman and Ferguson 1970; D. Taylor and Ferguson 1970; D. Taylor 1972; Justis and Taylor 1976).

The evidence for a lunar or stellar compass sense in amphibians is less convincing than for a solar compass. Be-

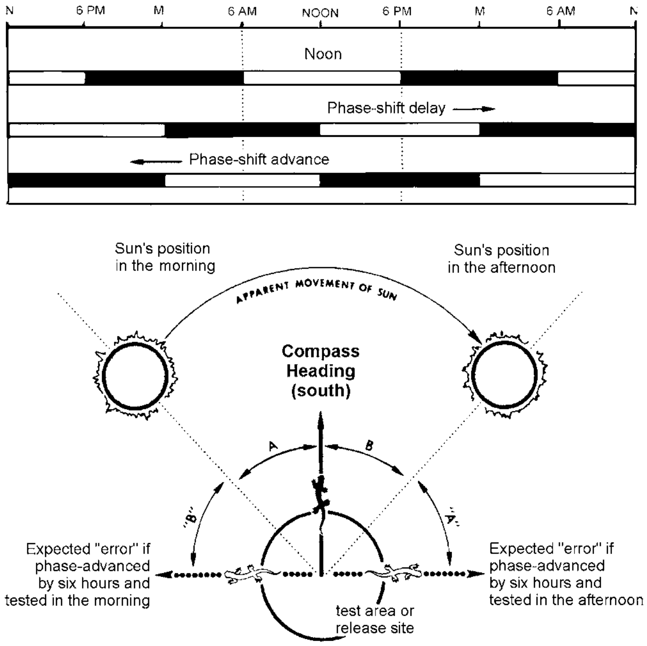

Fig. 6.7. The effect of clock-shifting on the orientation of a salamander in a North Temperate location. By changing the photoperiod, animals can be subjected to a six-hour delay phase-shift or a six-hour advance phase-shift (see diagram at top). Animals trained under a normal photoperiod are expected to orient in the correct compass direction (south). Those subjected to phase-shifting are expected to orient in a direction 90° to the right or left of the correct direction, depending on the nature of the phase-shift. Orientation errors are clockwise in phase-delayed animals and counterclockwise in phase-advanced animals. After Adler (1976).

Taylor (1972).

cause lunar time is not synchronized with solar time, use of a moon compass would require two separate internal clocks (Able 1980). Although several species are reported to show orientation when the moon is visible (table 6.8), the dispersion of individuals in the arena generally is much greater than in daytime tests, suggesting that orientation is less precise at night (D. Ferguson, Landreth, and Turnipseed 1965; Ferguson, Landreth, and McKeown 1967; D. Ferguson and Landreth 1966; Landreth and Ferguson 1966; D. Ferguson et al. 1968; Tracy 1971). There is some indication that animals that tend to move mostly at night, such as juvenile bullfrogs (*Rana catesbeiana*), can orient more accurately under a night sky than primarily diurnal species such as *Bufo fowleri* (D. Ferguson et al. 1968; McKeown 1968), but rigorous statistical comparisons have not been made. There have not been any experiments clearly demonstrating the existence of a lunar clock in amphibians, so the importance of lunar orientation remains unclear. Of seven species tested for orientation under stars alone, only four showed evidence of Y-axis orientation (table 6.8). Again, the responses of individuals tested under stars are not very consistent, and there is a tendency toward bidirectional orientation along the Y-axis in some species (D. Ferguson, Landreth, and Turnipseed 1965; Ferguson, Landreth, and McKeown 1967; D. Ferguson and Landreth 1966; McKeown 1968). The reason for this bidirectionality is not known.

Seasonal and motivational changes can influence orientation responses. For example, D. Ferguson et al. (1968) found that adult bullfrogs (*Rana catesbeiana*) showed Y-axis orientation during a spring breeding season, but the response disappeared in mid-summer after breeding had subsided. However, animals tested in the fall again showed an oriented response. One explanation for this change is that frogs on their summer home ranges learn particular escape routes relative to local features of the environment. When placed in an arena, the frogs often attempt to escape by moving in a preferred direction, rather than on a fixed compass course relative to the shore (D. Ferguson et al. 1968). This interpretation is supported by data showing that individual *Rana* and *Bufo* exhibit consistent differences in their directional orientation in an experimental arena (Adler 1980; Adler and Taylor 1981).

In species that breed in water but return to land as adults, Y-axis orientation is maintained throughout life, but the direction of orientation changes with ontogeny. This was studied in detail by McKeown (1968), who worked with *Bufo fowleri, Gastrophryne carolinensis, Rana catesbeiana,* and *R. clamitans.* He found that Y-axis orientation was well developed in tadpoles once they reached the free-swimming stage. Young tadpoles generally oriented in a direction that would take them toward deep water at the home pond or training tank. Once the tadpoles developed legs and began to emerge from the water, there was a brief period when Y-axis orientation appeared to be random, but eventually the directional preference shifted toward the shallow water end of the Y-axis. Metamorphosed juveniles showed clear orientation toward shallow water when tested in an aquatic arena, suggesting a tendency to disperse away from the breeding pond. When tested on land, some juveniles oriented in a landward direction, while others tended to moved in a direction that would take them back to water. The latter response may have been an attempt to escape from desiccating conditions. Subsequent studies with aquatic larvae and terrestrial juveniles of both anurans and urodeles have produced similar results (D. Ferguson et al. 1968; Goodyear and Altig 1971; Tracy 1971; Dole 1972a, 1973; D.Taylor 1972; Tomson and Ferguson 1972).

Extraocular Photoreception and Orientation by Polarized Light

A number of studies have shown that blinded amphibians can find their way home after displacement (table 6.9). Originally this was seen as evidence that olfactory cues are important for orientation (see the following discussion). Subsequent work showed that many amphibians have photoreceptors other than their eyes that are used for orientation (Adler 1970, 1976). The importance of extraocular photoreceptors

was first suggested by the work of Landreth and Ferguson (1967c) with *Taricha granulosa*. They found that blinded newts tested in arenas where olfactory cues were not available showed Y-axis orientation similar to that of normal animals. They also found that blinded newts displaced about 230 m from breeding ponds in view of the sun showed accurate homeward orientation, whereas many normal newts displaced under cloud cover or in light-tight containers were disoriented. Finally, blinded newts could orient in a trained direction relative to an artificial light source in the laboratory, but individuals lacking an optic tectum could not.

The principal site of extraocular photoreception in amphibians is the pineal complex, located on the dorsal surface of the diencephalon (fig. 6.9). In anurans, an extension of the diencephalon known as the frontal organ, or pineal end organ, lies in the dermis on the top of the head and probably is the principal extraocular photoreceptor. Urodeles and caecilians lack the frontal organ, but the pineal body itself is sensitive to light transmitted through the skull, as it is in anurans (Eakin 1973; Adler 1976).

The importance of extraocular photoreceptors for orientation has now been demonstrated for several amphibians, including *Acris gryllus* (D. Taylor and Ferguson 1970), *Rana catesbeiana* tadpoles (Justis and Taylor 1976), and *Ambystoma tigrinum* (D. Taylor 1972; Taylor and Adler 1978). In a typical series of experiments, D. Taylor and Ferguson (1970) found that blinded cricket frogs failed to orient properly when the top of the head was covered with opaque plastic, but they could orient when the head was uncovered. Animals with intact eyes could orient properly even with the top of the skull covered. Similar results were obtained with both adult and larval tiger salamanders (D. Taylor 1972). Subsequent work by D. Taylor and Adler (1978) showed that removal of the pineal body in blinded

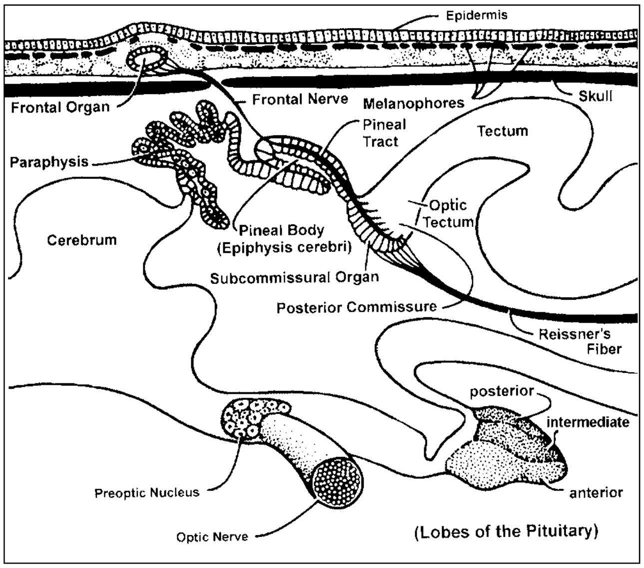

Fig. 6.9. Anatomy of pineal complex in a frog (*Rana*), showing the extra-optic photoreceptor (frontal organ) and its connections to the pineal tract and other parts of the brain. Salamanders and caecilians lack the frontal organ, but otherwise are similar to frogs. After Adler (1976).

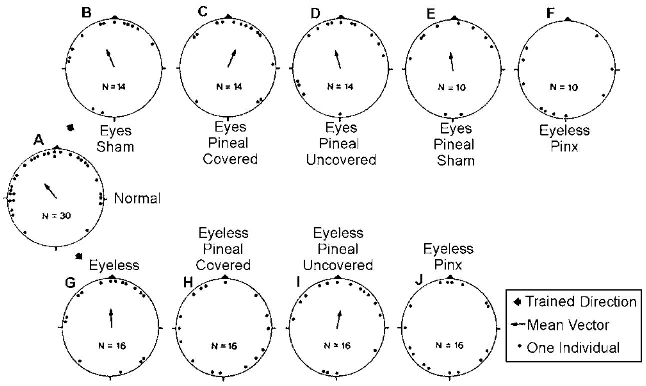

Fig. 6.10. Orientation of normal, eyeless, and pinealectomized (pinx) tiger salamanders (*Ambystoma tigrinum*). Thirty normal animals were tested and then divided into two series and tested in sequential order (B–F and G–J). Salamanders with either eyes or pineal intact oriented normally, but blinded animals with the pineal covered or removed did not. After D. Taylor and Adler (1978).

animals produced the same results as covering the top of the head with opaque plastic, thus implicating the pineal as the photoreceptive organ (fig. 6.10). These experiments showed that frogs and salamanders can orient using the pineal alone, but the pineal is not essential for orientation if the eyes are intact. Experiments with bullfrog tadpoles showed that tadpoles can orient correctly as long as one of their photoreceptive organs (eyes, pineal, frontal organ) is intact, but not if all three are impaired (Justis and Taylor 1976).

In most of the daylight orientation experiments discussed so far, the sun either was directly visible to test animals, or its position could be determined from brightness patterns. Some amphibians can determine the position of the sun by detecting polarized light. Polarized light is produced by atmospheric scattering of sunlight, which causes light waves to vibrate primarily in a plane perpendicular to the direction of propagation. At any particular time of day, the direction of vibration (i.e., the bearing of the "e-vector" of polarized light) is directly related to the position of the sun. If an animal can detect the bearing of the e-vector, it can use the information for compass orientation (Auburn and Taylor 1979).

The ability of amphibians to perceive polarized light was first demonstrated by Taylor and Adler (1973) in experiments with *Ambystoma tigrinum.* They placed salamanders in a training tank illuminated by polarized light, with the plane of polarization perpendicular to the long axis of the tank and parallel to the artificial shoreline (fig. 6.11). The animals were then tested in an aquatic arena lacking a shoreline. As expected, the animals oriented perpendicular to the

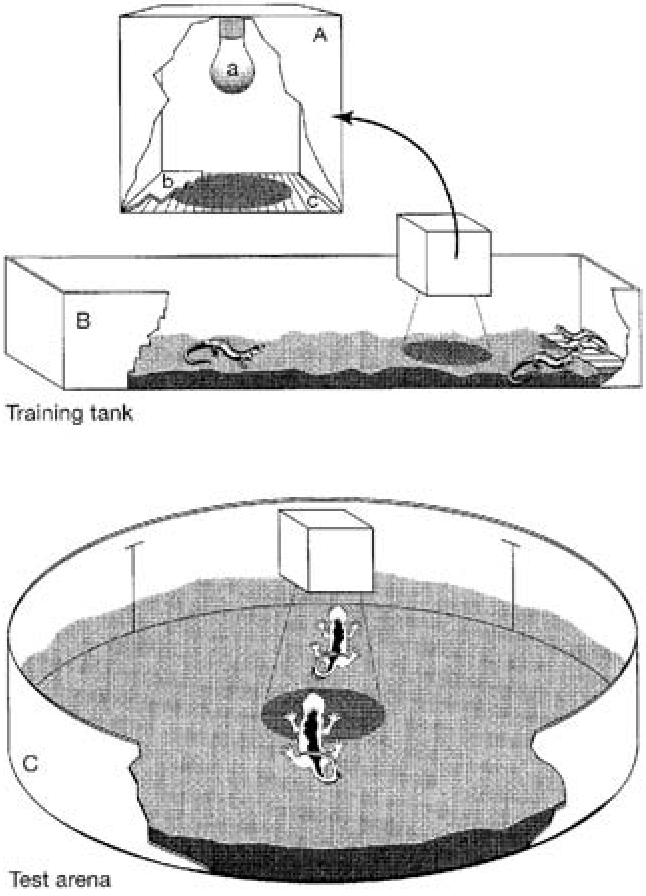

Fig. 6.11. Diagram of apparatus used to train and test salamanders under polarized light. Trained under polarized light (aquatic test) 21 days

Trained under polarized light (terrestrial test)

Fig. 6.12. Orientation of tiger salamanders (*Ambystoma tigrinum*) under polarized light. (A) Salamanders not trained to a particular direction and tested under nonpolarized light showed random orientation. (B) Salamanders exposed to polarized light but not trained to a shoreline also showed random orientation. Animals trained to move perpendicular to a shoreline under polarized light for 14 days (C) or 21 days (D) were placed in a test arena under polarized light with the e-vector rotated 90° relative to the training direction. These animals oriented in a direction perpendicular to the e-vector, as expected if they could perceive the plane of polarization. Animals in groups C and D were tested multiple times. Those tested under similar conditions only once (E) showed similar orientation. After D. Taylor and Adler (1973).

plane of polarization, a direction that also would have been perpendicular to the learned shoreline (fig. 6.12). Subsequent experiments with bullfrog tadpoles and both efts and adults of red-spotted newts (*Notophthalmus viridescens*) showed a similar ability to orient by polarized light (D. Taylor and Auburn 1978; Auburn and Taylor 1979). Experiments involving impairment of photoreceptors similar to those described above indicated that extraocular photoreceptors are involved in perception of polarized light, but eyes are not (fig. 6.13; Adler and Taylor, 1973; D. Taylor and Auburn 1978).

The ability to use polarized light for orientation is advantageous when animals are deprived of a direct view of the sun. Polarized light is readily perceived under water, and hence is an important cue for orientation by aquatic amphibian larvae. For terrestrial amphibians, the ability to perceive polarized light is particularly useful in forested areas, where the sun often is obscured, but patches of clear sky are visible. Finally, polarization of sunlight is greatest directly overhead at twilight, when many amphibians are moving (Adler 1976). Experiments with bullfrog tadpoles and adult newts showed that the animals could orient under a clear sky at sunrise and sunset, but not under a completely overcast sky, when skylight polarization is absent. Animals trained in an outdoor arena under a clear sky and tested indoors under artificial polarized light oriented in a direction relative to the plane of polarization that was appropriate for the time of day (D. Taylor and Auburn 1978; Auburn and Taylor 1979). These results clearly show that at least some amphibians can use the plane of polarization in natural sunlight for directional orientation.

In addition to perception of directional cues from polarized light, the pineal complex is important for orientation in amphibians because it is involved in synchronizing the animals' internal clocks, a process that is essential for sun-compass orientation. Experiments with several species have shown that blinded animals can be phase-shifted by altering the timing of their photoperiods, or entrained to a new activity pattern by changing the duration of the light and dark portions of the cycle (Adler 1969, 1970, 1971, 1976; Demian and Taylor 1977). If the frontal organ of frogs (Adler 1971) or the pineal body of salamanders (Demian and Taylor 1977) is removed, entrainment to a new photoperiod does not occur.

Magnetic Orientation and Navigation

For animals that can detect it, the earth's magnetic field is a potential source of information for compass orientation (Wiltschko and Wiltschko 1995; Phillips 1996). Detection of magnetic fields is the least understood sensory system of animals, but recent research has provided evidence of a magnetic sense in birds (reviewed in Able 1980; Phillips 1987, 1996), mammals (Mather and Baker 1981), alligators (Rodda 1984; Rodda and Phillips 1992), and sea turtles (Lohmann, Hester, and Lohmann 1999). The first demonstration of a magnetic sense in amphibians was the work of Phillips (1977) with cave salamanders (*Eurycea lucifuga*). He trained the salamanders to move in a dark corridor of a training box. Some animals were trained to move parallel to the earth's magnetic field. A second group was trained with the corridor parallel to the earth's field, but with the magnetic field shifted by 90° with a magnetic coil. The animals were subsequently tested in a cross-shaped device both with and without an altered magnetic field. Although the test groups did not all exhibit nonrandom orientation, those that did were oriented in the expected direction relative to the magnetic field during training. These responses were independent of other possible directional cues. Hence Phillips concluded that cave salamanders are capable of detecting the earth's magnetic field and using it for directional orientation. This would be particularly useful during those times of year when the salamanders retreat into the completely dark parts of their caves.

Subsequent work showed that red-spotted newts (*Notophthalmus viridescens*) also are capable of detecting slight changes in the earth's magnetic field (Phillips and Adler 1978) and exhibit compass orientation derived from magnetic cues

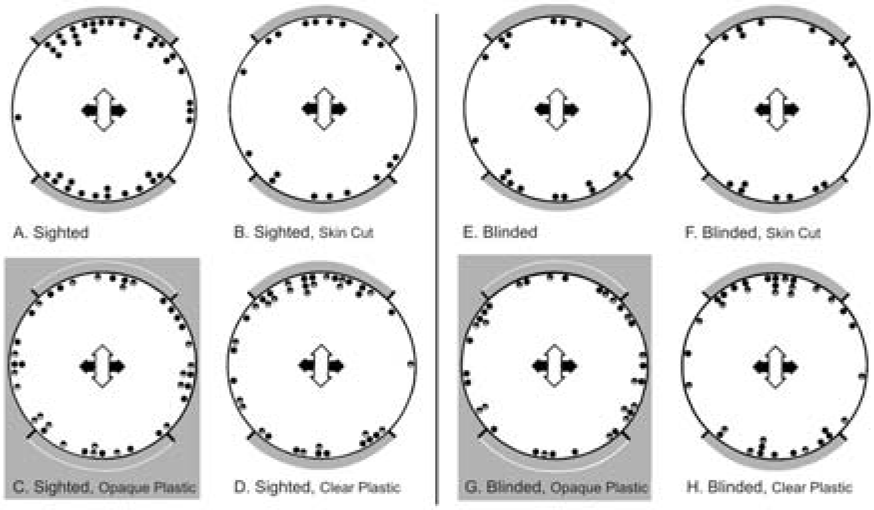

Fig. 6.13. Directional orientation of sighted and blinded tiger salamanders (*Ambystoma tigrinum*) under polarized light. Shaded areas at edges of circles indicate quadrants in which animals were expected to score if the plane of polarization is perceived. Black and white arrows as in Fig. 6.12. All blinded or sighted animals could perceive polarized light unless the head was covered by opaque plastic. After Adler (1976).

(Phillips 1986a, b). Newts can orient along a trained magnetic axis (Y-axis orientation), and they are capable of learning the direction of the Y-axis in relation to a magnetic field within 12 to16 hours (Deutschlander, Phillips, and Borland 2000). They also can orient in a true homeward direction after being displaced up to 45 km, even when tested indoors after being deprived of external cues during displacement (Phillips, Adler, and Borland 1995; Fischer et al. 2001). This indicates that newts can perform true navigation using some sort of map sense. Homeward orientation is affected by season. Newts exhibited homeward orientation during the spring migration season, but oriented along the magnetic axis of the training tank at other times (Phillips 1986a, b, 1987). There appear to be two distinct sensory systems involved in magnetic orientation. One is used for simple compass orientation, such as orientation to a trained direction in a tank. When the vertical component of the magnetic field was inverted, this form of compass orientation was reversed. This demonstrated sensitivity to axial components of the magnetic field. The treatment did not affect homeward orientation, suggesting that homing involves a response to the polarity of the magnetic field (Phillips 1986b).

The question that still must be resolved is the precise nature of the sensory system used for magnetic detection and orientation in these newts. Additional experiments have demonstrated a link between the visual system and the magnetic detection system (Deutschlander, Phillips, and Borland 1999). Specifically, changes in the wavelengths of light present during testing can alter the orientation responses of newts. When newts were tested under near-infrared light, with visible light not present, they oriented at random with respect to the magnetic field in a tank (Phillips and Borland 1992b). Orientation to a trained shoreline direction was maintained under full-spectrum visible light and short wavelengths, but was rotated by 90° under long wavelengths. This was shown to be the result of a direct effect of light on the magnetic compass that is sensitive to the inclination of the magnetic field (Phillips and Borland 1992a, c). In contrast, homing orientation is thought to depend on the ability to detect the polarity of the magnetic field. When homing newts were tested under long wavelengths, homeward orientation disappeared, rather than being shifted as in shoreline orientation. This indicated that newts possess two different systems for magnetic reception, one sensitive to light, the other not (Phillips et al. 2002).

Newts exhibiting homeward orientation probably receive inputs from both magnetic receptors (Phillips and Borland 1994). Exactly where these receptors are located, and how information from them is integrated in the brain, have yet to be determined. Ferromagnetic particles that could serve as magnetic detectors have been found in newts, although the precise location and function of these particles has not been determined (Brassart et al. 1999). There also is evidence of a link between polarized light detection by the pineal organ and a light-dependent magnetic compass sense (Phillips et al. 2001).

At present, the degree to which the results for red-spotted newts apply to other amphibians is unknown, but it seems unlikely that this species would have evolved a unique mechanism of orientation. Sinsch (1987c, 1988b) placed small magnets on the heads of toads in an attempt to disrupt the animals' magnetic compass. In *Bufo bufo,* the magnets altered the orientation response, but did not completely eliminate homeward orientation, presumably because other sensory systems were intact (Sinsch 1987c). In *Bufo spinulosus,* magnets shifted the direction of orientation, but they did not have this affect on toads rendered anosmic by blocking the nostrils with Vaseline. This lead Sinsch (1988a, 1992a) to speculate that the olfactory system was somehow linked to magnetic reception, but experimental evidence for this is not definitive. It is possible that with two senses disrupted, the toads simply switched entirely to visual orientation. In a test of celestial orientation in *Triturus marmoratus,* Diego-Rasilla and Luengo (2002) also used magnets to disrupt the ambient magnetic field, but this treatment did not affect orientation under a moonlit sky. In contrast, alteration of the magnetic field did disrupt orientation of *T. alpestris* under similar conditions (Diego-Rasilla 2003), and this species exhibited homeward orientation in response to magnetic cues alone (Diego-Rasilla , Luengo, and Phillips 2005). The reason for the apparent difference in these two congeneric species is unknown. There also is evidence for Y-axis orientation being influenced by the magnetic field in bullfrog (*Rana catesbeiana*) tadpoles (Freake, Borland, and Phillips 2002), and the response to magnetic cues is light dependent, as it is in newts (Freake and Phillips 2005).

Summary and Conclusions

A variety of techniques have been used to study the natural movements of amphibians. Most workers have used data on recaptures of marked individuals to estimate the magnitude of daily movements and the sizes of home ranges. Unfortunately, recaptures of individuals generally are infrequent and overall recapture rates are low, so the true extent of movements between recapture points cannot be determined. This is particularly true for species that spend most of their time under logs, in rock crevices, or in underground burrows. Use of mark-recapture data to calculate home ranges can exaggerate the area over which daily foraging activities take place. Data derived from continuous observation of individuals generally yield much lower estimates of daily movement distances. It is difficult to make quantitative comparisons of home range size among species, because a variety of methods have been used to calculate home range size, and these methods are not comparable statistically. In general, it appears that most amphibians are quite sedentary, except for seasonal migrations to breeding sites, although active foragers appear to move farther and occupy larger home ranges than sit-and-wait predators. Individuals often exhibit strong fidelity to a home area, and those that breed in water usually return to the same site each year. There is limited evidence that dispersing juveniles return as adults to natal ponds to breed, but data on juvenile dispersal for most species is meager at best.

Choice of a method for analyzing movement patterns and estimating home range sizes should depend in part on the questions being asked. All too often data on amphibian movements have been collected with no clear ecological question in mind, or have been incidental to more general natural history studies. If the goal is to determine the total area familiar to an individual as a prelude to studies of homing and orientation, then it is appropriate to combine recaptures made over a prolonged period at infrequent intervals. On the other hand, if the goal is to understand the normal foraging movements of the animal or estimate the area over which it searches for mates, then fine-grained data collected over shorter periods of time are appropriate. Unless the purposes of such studies are clearly defined in advance and methods of data acquisition and analysis standardized, it will be impossible to make detailed comparisons between species (see also B. Rose 1982).

There are a number of interesting questions relating to the adaptive significance of amphibian movement patterns that have yet to be addressed for most species. For example, the limited evidence available suggests that actively foraging species have larger home ranges than sit-and-wait predators, but we know very little about how such foraging species make decisions about when and how far to move while searching for food. When a dendrobatid frog is foraging for ants on the forest floor (see chapter 15), does it move at a relatively fixed rate, regardless of the number of food items encountered, or does it forage opportunistically, pausing at particularly rich food patches? At what point does it abandon a food patch to search for another? A variety of “optimal foraging” models have been proposed to explain the movement patterns of animals searching for food (reviewed in Pyke 1983). The relevance of these models to amphibians is not clear. Studies of plethodontid salamanders have shown that these animals are able to assess the density and profitability of prey in a simplified laboratory environment and adjust their behavior to take the most profitable prey (Jaeger and Barnard 1981; Jaeger, Joseph, and Barnard 1981, Jaeger, Barnard, and Joseph 1982; Jaeger and Rubin 1982). The movements of individuals between patches of prey in a natural environment and the relationship of these movements to prey profitability have not been investigated.

Another area that has received little attention from amphibian biologists is the question of dispersal strategies (for reviews of theoretical and empirical aspects of dispersal, see Wiens 1976; Greenwood 1983; Horn 1983; Shields 1982, 1983; Stenseth 1983). The lack of reliable information on juvenile dispersal for most species makes it impossible to draw broad conclusions about amphibian dispersal strategies at this point, but it is possible to pose general questions.

For example, how is dispersal related to environmental stability and predictability? At one extreme, that of a suitable breeding area surrounded by inhospitable habitat, the answer is obvious: dispersal is impossible, and in some amphibians this seems to have led to the evolution of neotenic populations that do not even undergo metamorphosis (see chapter 13). In other situations, the answer is not as clear. Certainly one would expect greater dispersal by toads emerging from unpredictable desert rain pools than those hatched in a garden pond in England. On the other hand, a species that uses temporary, but spatially predictable, desert pools for reproduction might show a greater degree of natal philopatry than those using pools surrounded by any other suitable breeding sites (Sinsch 1992d). Interspecific differences in dispersal strategies will have a major impact on the genetic structure and dynamics of populations.

Still another area of potential interest that has scarcely been explored for amphibians is the question of sex differences in dispersal. Among animals in general, one sex often shows a greater tendency to disperse than does the other. These differences are related to several factors, including the probability of breeding with close relatives, the benefits of remaining in groups of close kin, and the probability of finding an unoccupied breeding site or becoming established as an independent breeder in a social group (Greenwood 1980, 1983; Swingland 1983). Sex-biased dispersal has been reported for *Bufo calamita,* but the selective pressures favoring longer movements by females are unclear (Sinsch 1992b). In some species of frogs, such as the bullfrog (*Rana catesbeiana*), males are territorial during the breeding season (see chapter 9), and a young male's chances of obtaining a choice territory depend on the density of older males and the quality of available sites (R. D. Howard 1981a, 1984). It is conceivable that under some circumstances, young males would be better off dispersing to new ponds where competition might be reduced, rather than waiting several years to breed in a natal pond, provided that females visited those ponds as well.

There is limited evidence that either males or females of some species of terrestrial salamanders are territorial (Mathis et al. 1995; see also chapter 9), and competition for choice territory sites might force some individuals to disperse to new areas. This would be particularly true for species utilizing specialized retreat sites, such as rock crevices, that often are in short supply. How do individual males and females of these species trade off the risks of dispersal over unfamiliar ground against the potential benefits of finding uninhabited territories? Only additional fieldwork will provide answers to this and other questions about adaptive patterns of movement in amphibians.

Studies of homing and orientation in amphibians were much in vogue in the late 1960s and early 1970s, inspired in part by the pioneering work of Victor Twitty and his delightful account of the excitement and frustration of fieldwork (see "The Pepperwood Creek Affair" in Twitty 1966). Recently work in this area has diminished, and only a few laboratories remain active in the field. Possibly this is due in part to the technical problems involved in identifying the sensory mechanisms of orientation. Twitty spent years attempting to identify the sensory basis of homing in newts and never obtained a satisfactory result. Partly this was because he focused on senses that are most familiar to humans, mainly vision and olfaction, but was not aware of the potential importance of extraocular photoreceptors, polarized light, or magnetic orientation. Even when all of the potential sensory systems are considered, it often is impossible to determine the relative importance of each system for the orientation of animals in the field. For example, red-spotted newts (*Notophthalmus viridescens*) can orient by means of olfactory cues (Hershey and Forester 1980), celestial cues perceived by the eyes (Hershey and Forester1980), polarized light perceived by the pineal body (D. Taylor and Auburn 1978), magnetic cues (Phillips 1986a, b, 1987), and possibly local landmarks (Hurlbert 1969). How an animal integrates all of this information to find its way around its natural environment remains a mystery.

Perhaps the greatest technical challenges remaining for students of amphibian orientation are to determine how amphibians navigate using a "map sense," and to identify the organs or structures involved in magnetic detection. It seems likely that magnetic cues would be required for such a map sense, but a very high degree of sensitivity would be needed to detect slight changes in the local magnetic field (Phillips 1996). The short distances that most amphibians move would preclude using celestial cues for accurate navigation, although they still could be used to obtain basic compass directions. Recent work has shown that newts are sensitive to both the axis of a magnetic field and its polarity, suggesting that these animals have two distinct types of magnetic receptors that might interact to provide information on an animal's geographical position. In addition, there is evidence for other vertebrates that magnetic detection is involved in calibration of other compass information derived from celestial cues or polarized light, but the way in which these systems are integrated physiologically is not understood.

Chapter 7 Anuran Vocal Communication

The cry of frogs is one of the most wearying, croaking sounds possible, and we have only to place ourselves near some dirty pool in the spring, to convince ourselves of their deep, guttural voices; but bad as this is, it is music compared to the long shrieks, shrill whistlings, snorings, and bellowings of those in other parts of the world.
—Mrs. R. Lee, *Anecdotes of the Habits and Instincts of Birds, Reptiles and Fishes* (1855)

The toad's lullaby note comes from the far margin, sweeter than all others. . . . This song has been compared to the slow opening movement of Beethoven's "Moonlight Sonata."
—Mary C. Dickerson, *The Frog Book* (1906)

The sound, which the scientific books describe as "croaking," floats far and wide, and produces a beautiful, mysterious effect on a still evening when the last heavy-footed labourer has trudged home to his tea, leaving the world to darkness and to me.
—W. H. Hudson, *The Book of a Naturalist* (1919)

WHATEVER THEIR musical qualities, vocalizations are conspicuous features of the behavior of most frogs and toads. Although the functions of frog calls were not well understood until relatively recently, most early naturalists realized that calls are given almost exclusively by males, are associated with reproduction, and probably serve to attract mates. Julian Huxley (1927, 223) suggested that a frog's calls are analogous to the songs of a male bird, being in part "an advertisement of his maleness" and in part "an advertisement of the breeding grounds, a boasting of choice real estate." Nevertheless, even a relatively reliable observer such as Mary Dickerson (1906, 35) thought that frogs "feel physical joy and express it in song."

Much of the early literature on anuran vocalizations consisted of brief accounts of calling behavior and onomatopoeic descriptions of calls. For example, Wright (1914) listed seven different characterizations of the bullfrog's call: blood 'n' nouns, br-wrum, be-drowned, more-rum, jug-o-rum, knee-deep, and bottle-o-rum. With few exceptions, conclusions about the functions of calls were based on anecdotal evidence. Only with the advent of portable tape-recording equipment was it possible to analyze calls quantitatively or perform controlled playback experiments to investigate call functions (Rand 2001). Two early pioneers of anuran communication were Arthur A. Allen, an ornithologist at Cornell University, and Peter Paul Kellogg, who produced the first album of frog-call recordings in 1948 (Allen and Kellogg 1948). Even more important were the contributions of Frank Blair and his students at the University of Texas and Charles M. Bogert at the American Museum of Natural History in New York. Blair did extensive research on the role of vocalizations in species isolation, and the work of his students continues to this day. Bogert did less original research on frog calls, but he made major synthetic contributions in the form of the second album of frog-call recordings (Bogert 1958) and a comprehensive review of acoustic communication in amphibians and reptiles (Bogert 1960). This review was the first attempt to place information on anuran calls in an evolutionary and ecological framework. Since then the literature has expanded enormously, and many additional reviews have appeared (Blair 1963, 1968; Schneider 1966;

Lescure 1968; Paillette 1971; Schiøtz 1973; Straughan 1973; Salthe and Mecham 1974; Keister 1977; Littlejohn 1977; Wells 1977b, c, 1988; Gerhardt 1988, 1994a; Narins and Zelick 1988; Rand 1988; M. Ryan 1988a, 2001; Gerhardt and Schwartz 1995; Gerhardt and Huber 2002; Wells and Schwartz 2007).

This chapter focuses on the structure and function of anuran calls. I begin with a discussion of the production of vocal signals. This is followed by a review of the vocal repertoires of anurans, the way in which the physical environment affects the transmission of acoustic signals, and the influence of predators on calling behavior. Next, there is a discussion of the structure and dynamics of anuran choruses, the vocal interactions among frogs in a chorus, the interactions among species in multispecies choruses, and the responses of females to calls of conspecifics and heterospecifics. Finally, I briefly discuss the anatomy and neurobiology of call recognition. The role of vocalizations in mate choice and sexual selection is discussed in more detail in chapter 8.

Mechanisms of Sound Production

The basic mechanism of sound production in most anurans is a relatively simple system. During the respiratory cycle, air is pumped into the lungs by positive pressure from muscles of the buccal cavity (De Jongh and Gans 1969; Gans 1973). When the frog calls, air is forced from the lungs by contraction of muscles in the trunk region and moves through the larynx into the buccal cavity (fig. 7.1). As the air passes through the larynx, vibration of the vocal cords and associated cartilages produce sound. Actions of the laryngeal muscles shape the sounds into a variety of forms, from frequency-modulated peeps to noisy squawks and musical trills (fig. 7.2). The family Pipidae is an exception to this pattern. Males lack vocal cords and use a very different mechanism (see following) to produce calls that consist of a series of short clicks. In most species, sound is produced only as the air is expired from the lungs (Schneider 1988), but sound is produced during inspiration in *Bombina* (Lörcher 1969) and during both inspiration and expiration in *Discoglossus* (E. Weber 1974). Usually the sound is transmitted to an inflated vocal sac that couples the buccal cavity to the outside environment and serves as a sound radiator (Gans 1973; Duellman and Trueb 1986; Schneider 1986, 1988). The sound-producing system thus involves three major functional units: (1) the trunk muscles that power the system, (2) the laryngeal apparatus that produces the sound, and (3) the buccal cavity and vocal sac that transmit the sound. Although the mechanism of sound production is similar in most anurans, the details of call structure vary and are related to differences in the functioning of these three major components.

Fig. 7.1. Calling cycle of the Panamanian túngara frog *Physalaemus pustulosus* with (A) body inflated, and (B) vocal sac inflated. This small tropical frog has become a model organism for the study of anuran communication and behavior. Recent taxonomic rearrangments place this species in the genus *Engystomops* (Ron, Santos, and Cannatella 2006), but I use the name *Physalaemus* throughout this book. Photos by Kentwood D. Wells.

Trunk Muscles

The power for sound production is provided mainly by contraction of two pairs of broad muscular sheets that enclose much of the thoracic and abdominal cavities (fig. 7.3). The outer layer is composed of the external oblique muscle. The inner layer has been called the internal oblique muscle by many authors (W. Martin 1972; Martin and Gans 1972; Gans 1973; Taigen, Wells, and Marsh 1985; R. Marsh and Taigen 1987), while others have referred to it as the transverse muscle (Duellman and Trueb 1986). The confusion arises because most urodeles have three layers of flank muscles, with the transverse being the deepest. There is considerable variation in the number of muscle layers that are present in

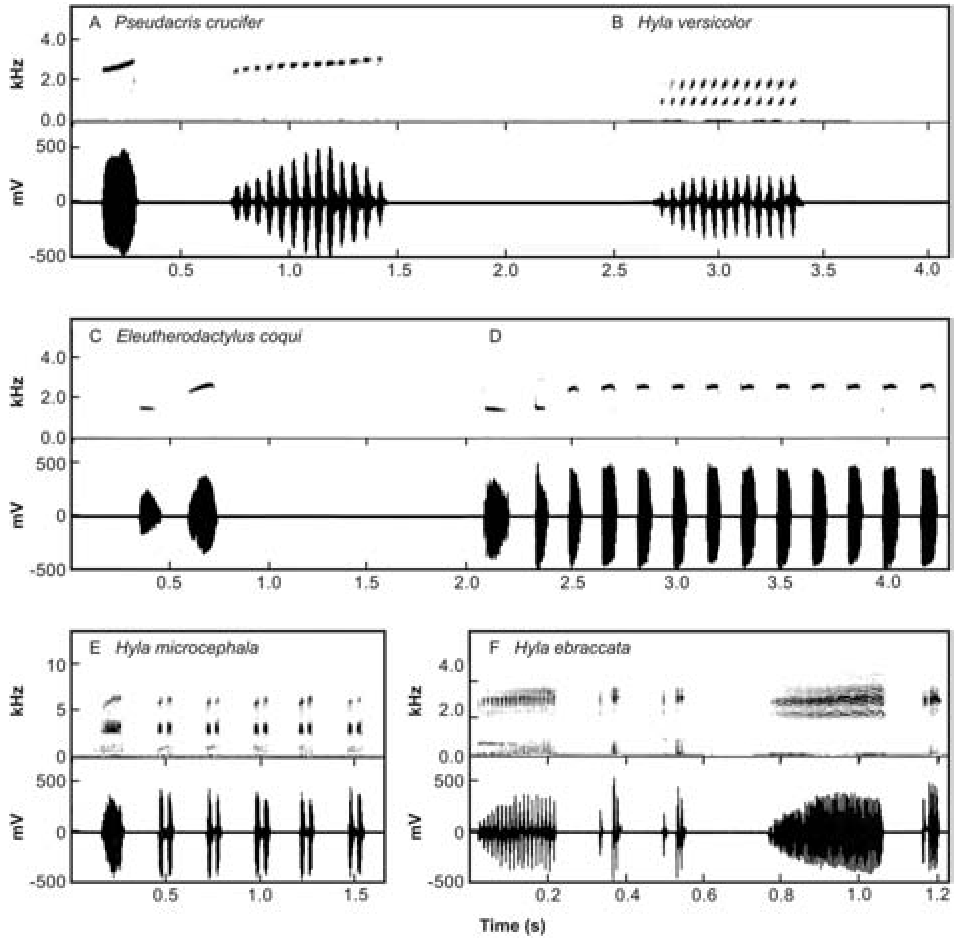

Fig. 7.2. Representative anuran calls. The sonagrams at the top of each part show changes in frequency (kHz) over time. The oscillograms at the bottom of each part show changes in amplitude (mV), over time. (A) Tonelike peep of *Pseudacris crucifer* (left) and amplitude-modulated aggressive call (right). (B) Amplitude-modulated advertisement call of *Hyla versicolor.* (C) Tonelike "co" note and frequency-modulated "qui" note of *Eleutherodactylus coqui* advertisement call. (D) Multinote aggressive call of *E. coqui.* (E) Multinote advertisement call of *Hyla microcephala,* composed of an introductory note followed by several biphasic secondary click notes. (F) Three-note advertisement call of *Hyla ebraccata* (left) and three-note aggressive call (right), with much higher pulse rate in the introductory note. From recordings by the author.

urodeles, even within the same family, with some having all four layers and others having only two or three (R. S. Simons and Brainerd 1999; Brainerd and Simons 2000). Anurans have lost the middle layer, leaving only two. One layer is composed of the external oblique muscles, but the homologies of the second layer are uncertain. These muscles have been called both the internal oblique and the transverse muscles by various authors (Ecker 1889; Duellman and Trueb 1986). These layers of muscles are attached to the rectus abdominus muscle that runs longitudinally along the belly and also is involved in call production. These muscles are highly sexually dimorphic, being much larger in males than in females. The muscles of male frogs also exhibit many morphological and biochemical adaptations for call production, including highly aerobic muscle fibers, high concentrations of mitochondria, high activities of aerobic enzymes, heavy vascularization, and ample supplies of energy substrates (see chapter 5 for a more detailed discussion).

The action of the trunk muscles during calling is poorly understood for most anurans. In species that produce a series of simple single-note calls, each call probably is produced by a single contraction of the trunk muscles. For example, each short peep produced by a male *Pseudacris crucifer* (fig. 7.2 A) is preceded by a conspicuous contraction of the body wall. The same is true of the much longer whine call of *Physalaemus pustulosus* (fig. 7.25); males of this species exhibit a contraction of the body wall and a dramatic expansion of the vocal sac as each call is produced (Drewry, Heyer, and Rand 1982; Dudley and Rand 1991). In species that produce a long series of distinct notes, such as *Hyla microcephala* (fig. 7.2 E), each note represents a single contraction of the trunk muscles (Wells and Taigen 1989). In species with

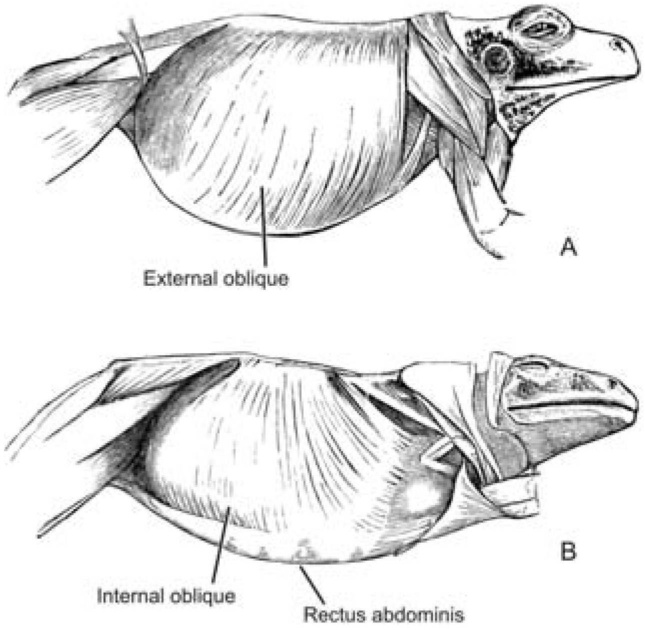

Fig. 7.3. Trunk muscles of a male frog, *Rana esculenta,* showing muscles involved in call production. (A) First layer of muscles, viewed from the right side. (B) Second layer of muscles, viewed from the right side and below. The external oblique, internal oblique, and rectus abdominis muscles are the principal call-producing muscles. After Ecker (1889).

long, amplitude-modulated calls consisting of closely spaced pulses, trunk-muscle activity is more complex. W. Martin (1972) speculated that some bufonids with very long calls (sometimes 30 seconds or more) have pulsatile contractions of the trunk muscles. With only a single contraction, the length of a call would be limited by the volume of air in the lungs, but a series of short contractions would allow for alternating periods of expiration and inspiration (Gans 1973). Pulsatile contractions of the trunk muscles have been observed during production of release calls in bufonids (W. Martin and Gans 1972; R. Schmidt 1972b).

In other families, low rates of amplitude modulation are produced by periodic contractions of the trunk muscles alone, or coordinated activity of the trunk and laryngeal muscles (W. Martin 1972). For example, the aggressive calls of several species of European hylids consist of an irregular series of short pulses (Schneider 1967, 1968, 1977; Schneider and Nevo 1972). E. Weber (1976) found that *Hyla savignyi* males could produce these pulses even when the laryngeal muscles were removed, indicating that the trunk muscles are involved. In the two species of North American gray tree frogs (*Hyla versicolor* and *H. chrysoscelis*), each pulse in the call (fig. 7.2 B) corresponds to a separate cycle of contraction and relaxation of the trunk muscles, as demonstrated by electromyographic recordings of muscle activity (Girgenrath and Marsh 1997). *Hyla chrysoscelis,* a diploid species, has a pulse-repetition rate about twice that of *H. versicolor,* a tetraploid species, at the same temperature, and this is reflected in differences in the frequency of trunk-muscle contraction (R. Marsh 1999). The muscle contraction frequencies that maximize the power output of the muscles at 20–25° C (44 Hz in *H. chrysoscelis* and 21 Hz in *H. versicolor*), are very similar to the contraction frequencies observed in calling males (Girgenrath and Marsh 1999).

Laryngeal Apparatus

The anuran laryngeal apparatus lies between the lungs and the buccal cavity and therefore is involved in both respiration and sound production. Both the laryngeal skeleton and the laryngeal muscles are much larger in male frogs than in females (Wahl 1969; Schneider 1970, 1977, 1986, 1988; Eichelberg and Schneider 1973, 1974; R. Marsh and Taigen 1987; McClelland and Wilczynski 1989; McClelland, Wilczynski, and Ryan 1990; McClelland, Wilczynski, and Rand 1997; Boyd et al. 1999). The development of laryngeal muscles has been studied in detail only in *Xenopus laevis,* which has a mechanism of sound production that is atypical for frogs in general. In this species, sexual dimorphism in laryngeal muscles develops after metamorphosis under the control of male hormones (Kelley 1986, 1996; Sassoon and Kelley 1986; Sassoon, Gray, and Kelley 1987). Not only are the laryngeal muscles of *Xenopus* females smaller than those of males, but they also have different fiber types and are incapable of contracting very rapidly. Hence, females cannot give calls like those of males even when the appropriate parts of the brain are stimulated (Tobias and Kelley 1987), although they do give simple calls that will be discussed in more detail later (Tobias, Viswanathan, and Kelley 1998).

The laryngeal muscles of male frogs resemble the trunk muscles in their fiber composition, high mitochondrial and capillary density, and biochemical features (see chapter 5). Laryngeal anatomy varies among species of anurans (for comprehensive morphological studies, see Ridewood 1897, 1900; Blume 1931, 1932, 1933; Trewavas 1933; Sedra and Michael 1957; Paulsen 1965; Lörcher 1969; Wahl 1969; Heinzmann 1970; Schneider 1970, 1986, 1988; W. Martin 1972; E. Weber 1974; E. Schmid 1977, 1978; McClelland and Wilczynski 1989; M. Ryan and Drewes 1990; Steinwarz 1990; McClelland, Wilczynski, and Ryan 1990, 1998; McClelland, Wilczynski, and Rand 1997).

In most anurans, the sound-producing apparatus consists of two arytenoid cartilages that articulate to form a closed, dome-shaped structure that houses the vocal cords (fig. 7.4). The vocal cords can be activated only when the arytenoid cartilages are moved apart to allow passage of air through the larynx. These moveable cartilages are supported by the cricoid cartilage, which attaches the larynx to the hyoid apparatus and serves as a point of attachment for various

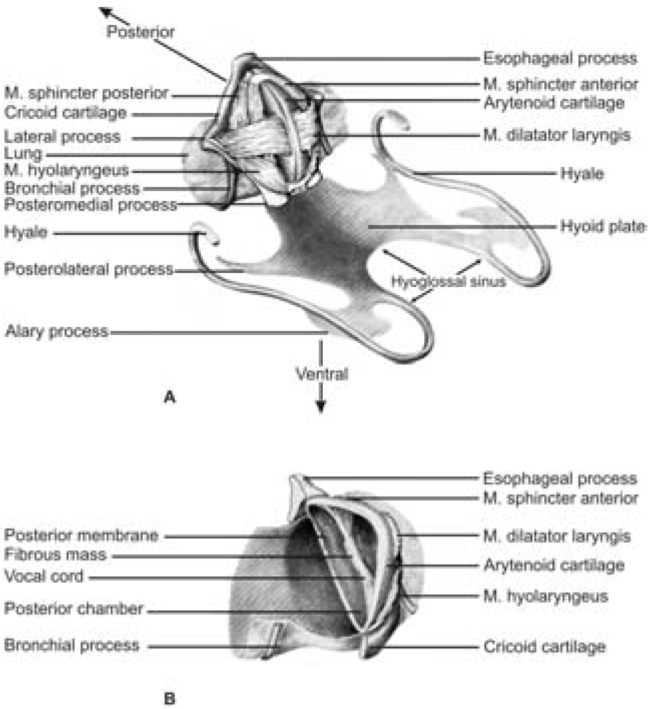

Fig. 7.4. The laryngeal apparatus of a typical anuran. (A) Diagram of the laryngeal apparatus of an anuran, showing the hyoid apparatus and the cartilages and muscles of the larynx. The dilator muscles open the cartilages, allowing an airstream to pass over the vocal cords, which are not visible in this figure. The sphincter and hyolaryngeus muscles close the larynx. (B) Cross section of the larynx of an anuran, showing one of the paired vocal cords suspended between the cartilages. After Duellman and Trueb (1986).

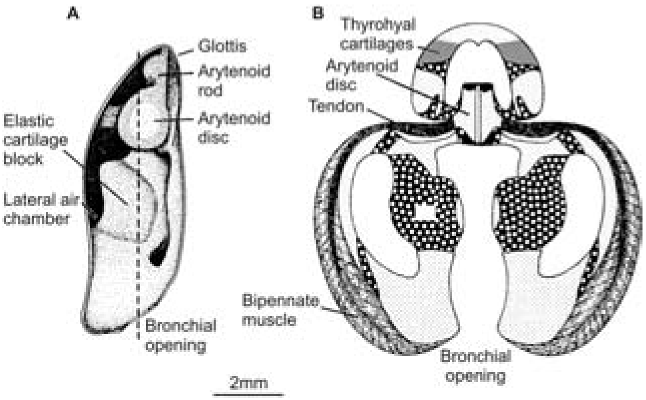

Fig. 7.5. Larynx of a male pipid frog, *Xenopus borealis.* (A) Midsagittal view of the interior of the larynx. Dorsal is to the right; anterior to the top. Dashed line indicates the plane of the horizontal section in part B. (B) Horizontal section through the larynx. After Yager (1992b).

laryngeal muscles. In most derived frogs, such as hylids, ranids, leptodactylids, and bufonids, the arytenoid cartilages are large and the cricoid cartilage forms a narrow ring, whereas in *Bombina* and *Discoglossus,* the cricoid cartilage is flattened and considerably larger than the arytenoids (Lörcher 1969; E. Weber 1974; Schneider 1988).

In pipids, the laryngeal skeleton is highly modified (fig. 7.5), with an enormous cricoid cartilage that forms a boxlike structure that partially encloses the greatly reduced arytenoids (Ridewood 1887, 1900). The arytenoid cartilages are held together by fluid surface tension. These frogs lack vocal cords; calls consist of sharp clicking sounds produced when the arytenoid cartilages are suddenly pulled apart, and the sounds are amplified by the boxlike cricoid cartilage (Rabb 1960; Yager 1992a, b, 1996). Hence, sound production in pipids requires contraction of the laryngeal muscles, but does not involve contraction of the trunk muscles or the production of vibrations in an air stream.

In anurans other than pipids, sound is produced only when three conditions are met: (1) the arytenoid cartilages are opened to allow air to pass from the larynx through the glottis to the buccal cavity; (2) the vocal cords are brought into the proper position in the airstream to cause them to vibrate; and (3) pulmonary air pressure is sufficient to set the vocal cords and associated structures in motion. The various laryngeal muscles (fig. 7.4) are involved in the control of all three aspects of sound production, as well as the control of normal respiration. The laryngeal dilator muscles originate on lateral processes of the hyoid and insert on the medial edges of the arytenoid cartilages; they serve to open the arytenoids during normal respiratory movements and vocalization. Two pairs of constrictor muscles (also called the anterior sphincter and hyolaryngeal muscles) originate on the hyoid and wrap around the anterior edge of the arytenoids to insert on the opposite member of each pair. When these muscles contract together, they slide over the arytenoids toward the midline and serve to close the larynx. The posterior sphincter muscles insert on the dorsal ends of the arytenoids and in some species serve to bring the vocal cords together into the air stream (R. Schmidt 1972a; Duellman and Trueb 1986; Schneider 1988).

The action of the various laryngeal muscles during vocalizations varies among species, but has been investigated in detail only for ranids, bufonids, and hylids. In most species, removal of the laryngeal dilators makes vocalization and even normal respiration impossible. These muscles are required to open the larynx during inspiration because the elasticity of the larynx causes it to remain closed unless actively opened by muscle contraction. Frogs lacking these muscles cannot fill the lungs with air and therefore cannot generate the pulmonary pressure required for vocalization (E. Weber 1975a, 1976, 1977, 1978a; Schneider 1988). In some species, these muscles also open the larynx during vocalization. For example, in both hylids and ranids, bursts of sound are preceded by active opening of the larynx by the laryngeal dilators (R. Schmidt 1965, 1973b; Schneider 1977, 1988). In bufonids, on the other hand, the larynx apparently is opened passively by pulmonary air pressure; the call is terminated when the laryngeal dilators contract and move the arytenoid cartilages out of the air stream (W. Martin 1972; Martin and Gans 1972). In some frogs, individual pulses of sound are terminated by rapid closure of the larynx when the constrictor muscles contract (R. Schmidt 1965, 1972a, 1973b). This enables the frog to produce pulses that are highly stereotyped in shape and duration, features that often are important for species recognition (Gerhardt 1988). Removal of these muscles disrupts the spacing and duration of the pulses (E. Weber 1975a, 1976, 1977, 1978a).

In addition to the active amplitude modulation of calls produced by contractions of the laryngeal muscles, some anurans exhibit passive amplitude modulation resulting from oscillations of various elements of the sound-producing apparatus. In many bufonids, the edges of the arytenoids vibrate as pulmonary pressure forces air through the glottis, producing a series of short pulses with very fast rise times. In some species, including *Bufo bufo, B. calamita, B. gariepensis,* and members of the *B. regularis* group in Africa, these pulses are the only type of amplitude modulation in the call. In primitive bufonids, pulses produced by vibration of the arytenoids are imbedded in longer pulses produced by active contraction of the laryngeal muscles. Calls that have only passive amplitude modulation presumably are derived from this pattern through loss of active modulation. Some derived species of toads have gone the other direction and have lost passive amplitude modulation, but retain active modulation (e.g., *Bufo americanus,* W. Martin 1971, 1972). Passive amplitude modulation also can be produced by oscillations of the vocal cords rather than the arytenoids. For example, the release calls of *Rana pipiens* consist of a series of major pulses produced by contraction of the laryngeal muscles; these are subdivided into minor pulses produced by air pressure suddenly pushing apart the paired vocal cords (R. Schmidt 1973b).

The mass and tension of the vocal cords are the major determinants of the dominant frequency of a frog's call. As the mass of the vocal cords increases, the frequency at which they vibrate decreases, thereby decreasing the frequency of the call. Since vocal-cord mass often is positively correlated with overall body size, larger frogs typically produce lower-pitched calls, both within and between species (Zweifel 1968a; W. Martin 1972; Schneider 1977, 1988; M. Ryan 1988a; Penna and Veloso 1990; M. Ryan and Wilczynski 1991; Keddy-Hector, Wilczynski, and Ryan 1992; Wilczynski, Keddy-Hector, and Ryan 1992). The morphology of vocal cords varies among families (Paulsen 1965; E. Schmid 1978), as does the relationship between dominant frequency and body size. In many species, there are fibrous masses imbedded in the membranous vocal cords or attached to them; these increase the mass of the vocal cords and lower the frequency of the call (W. Martin 1972). If the mass of the vocal cords evolves somewhat independently of body size, then the relationship between body size and call frequency will be be relatively weak, as it is in the genus *Physalaemus* (M. Ryan 1985b), or it can differ among populations of the same species (M. Ryan and Wilczynski 1991).

Frequency modulation of a call is most likely achieved by active changes in the tension of the vocal cords, brought about by changes in the shape of the larynx or direct muscular action on the vocal cords. Many frogs of the family Leptodactylidae have frequency-modulated calls (fig. 7.2 C), as do members of several other families. In these groups, the vocal cords insert on flexible tissue at the tips of the arytenoid cartilages, and the posterior sphincter (= constrictor) muscles insert in the same area. Contraction of these muscles increases the tension on the vocal cords, causing an increase in the frequency of the call. In bufonids and most of their relatives, this mechanism for changing the tension of the vocal cords has been lost, and most species show little frequency modulation of the call. W. Martin (1972) suggested that the bufonid lineage shows an evolutionary trend in which the laryngeal muscles have a reduced role in determining the frequency structure of the call, while the role of vocal-cord mass becomes more important. Nevertheless, the tension of the vocal cords still can be changed by changes in the shape of the larynx and play some role in determining the dominant frequency of the call.

Buccal Cavity and Vocal Sacs

Most anurans have vocal sacs that are inflated during vocalization (fig. 7.6). These are connected to the buccal cavity through openings in the floor of the mouth that range in size from narrow slits to substantial holes. Vibrations produced by the larynx are transmitted through the buccal cavity to the air-filled vocal sac; the vocal sac in turn radiates the sound to the external environment. In general, the efficiency with which frogs convert metabolic energy into radiated sound energy is quite low, due mainly to a mismatch between the size of the vocal sac and the wavelength of the sound being radiated (M. Ryan 1985a; Prestwich, Brugger, and Topping 1989; Prestwich 1994; McLister 2001). Most frogs have vocal sacs that are much smaller than the wavelength of the call and cannot radiate sound very efficiently, although the efficiency is greater than it would be if the larynx served as the only sound radiator. This problem is most acute for species with very low-pitched calls, because low-pitched sounds have long wavelengths. Small species with high-pitched calls and large vocal sacs relative to the size of the head (and larynx) can be expected to be more efficient sound radiators and have unusually loud calls for their body size (e.g., *Hyla microcephala;* see table 7.1).

It had been suggested that vocal sacs might alter the

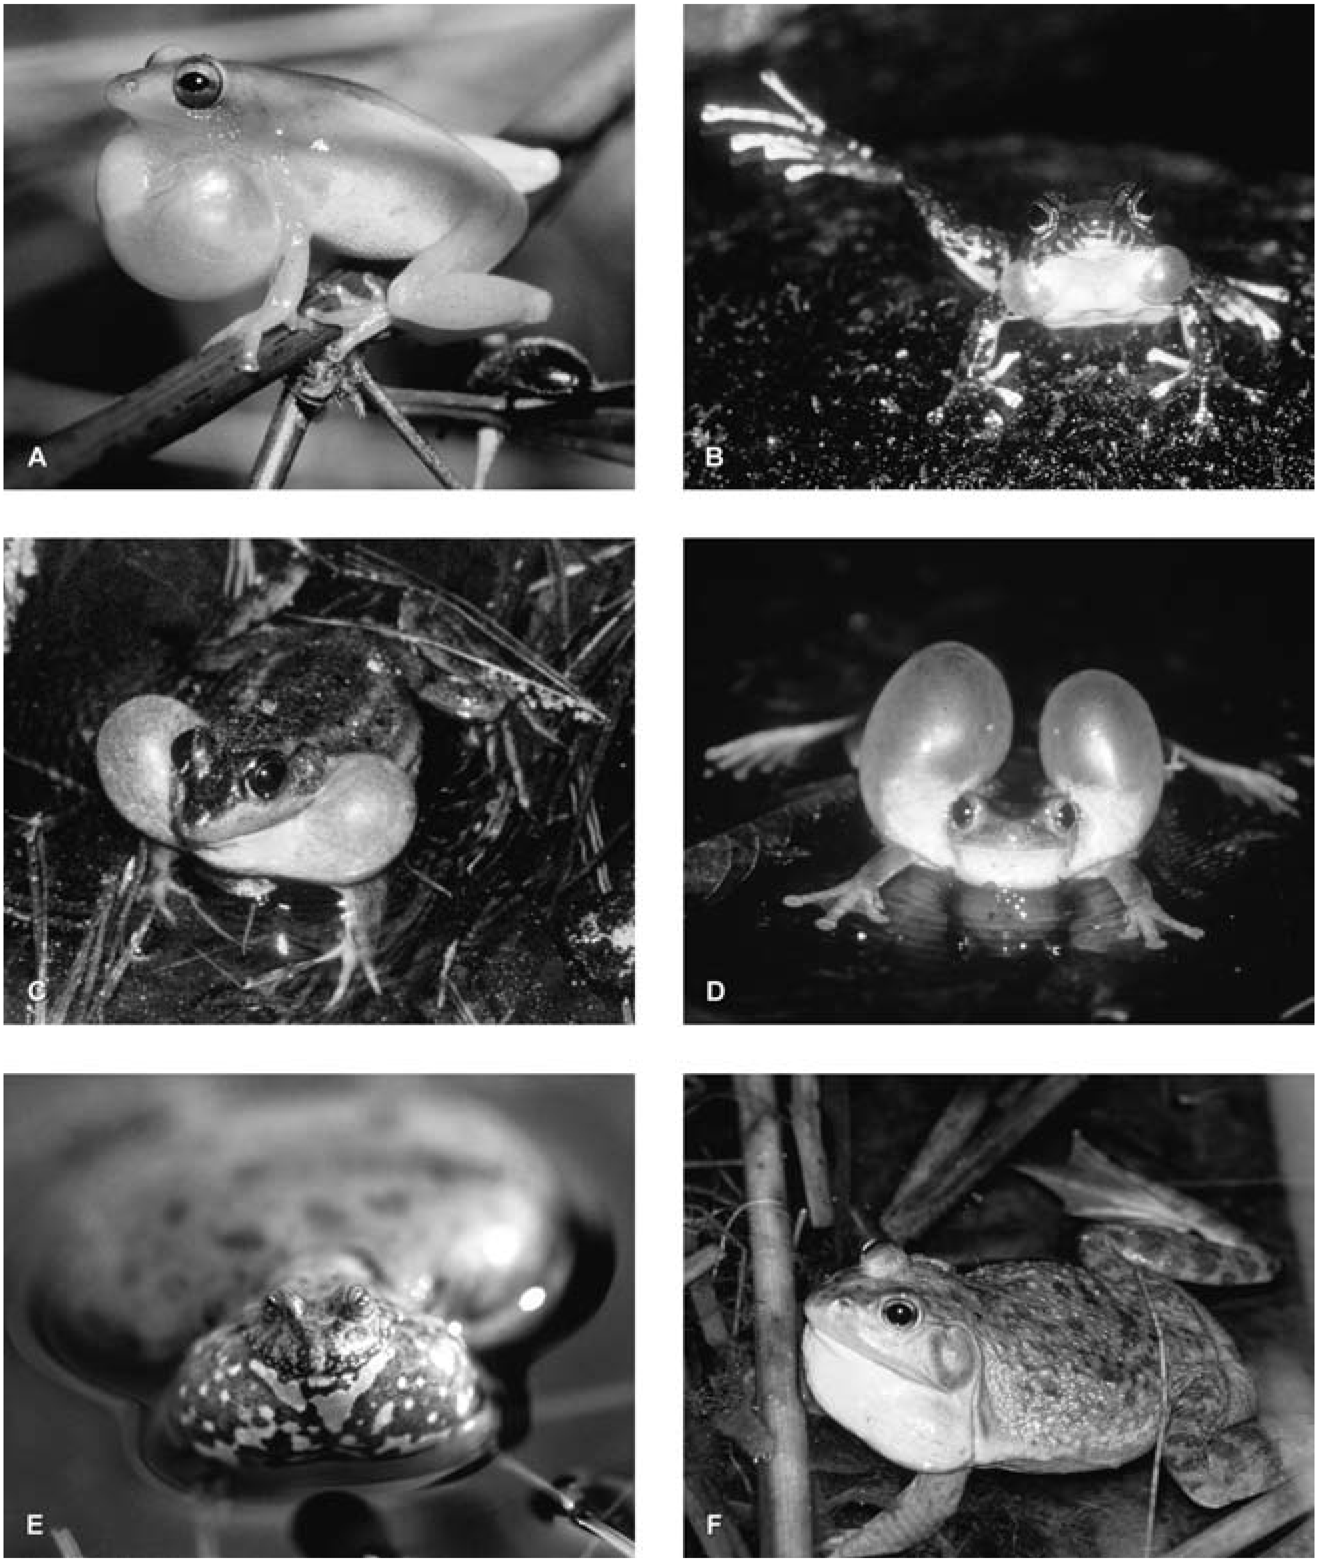

Fig. 7.6. Vocal sac morphology is highly variable among anurans. Many frogs that call from elevated perches have relatively large single medial vocal sacs like that of *Hyperolius concolor* (A). The small paired vocal sacs of *Hylodes asper* (B) produce relatively low-intensity calls, which are supplemented by the visual leg-waving display. Paired vocal sacs that project above the water, like those of *Rana virgatipes* (C) and *Phrynohyas coriacea* (D), radiate most of the acoustic energy of the call to the air. *Bombina bombina* (E) has a relatively primitive vocal sac formed by a loose pocket of the lining of the mouth. The internal vocal sac of *Rana catesbeiana* (F) radiates sound energy to both the air and the water and is typical of many frogs that call from the water's surface. frequency composition of calls by acting as cavity resonators. Experiments with frogs (*Physalaemus pustulosus*) calling in helium showed that dominant frequency was not altered, as would be expected with a cavity resonator (Rand and Dudley 1993). Nevertheless, frequency modulation of calls in this species is affected by the nature of the vocal sac. As the frog calls, the rate of vocal sac inflation gradually decreases as the expansion of the sac reaches its elastic limits. This decrease in inflation rate corresponds with a downward sweep in call frequency and a decrease in call amplitude (Dudley and Rand 1991). Consequently, frequency modulation can be a result of changes in the rate of air flowing over the vocal cords, and not just changes in vocal-cord tension. The size of the head and the capacity of the buccal cavity also can affect the frequency of the call. In *Hyla microcephala,* a frog with a small head and buccal cavity, high frequencies around 6 kHz are emphasized in calls, whereas in *H. ebraccata,* a species with a larger buccal volume, the dominant frequency is around 3 kHz (McClelland, Wilczynski, and Rand 1997).

The morphology of vocal sacs varies considerably among species of anurans (fig. 7.6). Most accounts of vocal sac anatomy have focused on taxonomic implications rather than the functional significance of structural variation (C. Liu 1935b; Liem 1970; M. Tyler 1971, 1972, 1974, 1985a; M. Hayes and Krempels 1986). We currently know very little about how the structure of a vocal sac influences the way in which sound is transmitted. These sacs are not simply formed by the skin of the throat, but are located between the superficial mandibular muscles and the deeper muscles of the throat (M. Tyler 1971, 1972). This gives the sac a high degree of elasticity and, in some cases, muscle contraction pumps air back into the lungs after a call is produced. The vocal sac of *Physalaemus pustulosus* increases in volume by a factor of 20 to 40 during calling (fig. 7.1; Dudley and Rand, 1991). The vocal sac is highly elastic, due to a layer of elastic fibers located between the skin and the outer surface of the vocal sac muscles. This provides for substantial elastic recoil that facilitates deflation of the sac and refilling of the lungs (Jaramillo, Rand, Ibáñez, and Dudley 1997). This in turn probably reduces the energetic cost of vocalization.

The most common type of vocal sac is a single subgular sac that inflates like a balloon when the frog calls (fig. 7.6 A). Some species have paired subgular sacs (fig. 7.6 B) that are partially separated by connective tissue running between the superficial and deep muscle layers (Duellman 1970). Others have paired lateral sacs that are completely separate chambers on either side of the throat (fig. 7.6 C, D). These are formed by extensions of the interhyoideus muscle (M. Tyler 1971). In at least one species, *Rhinophrynus dorsalis,* the muscles forming the walls of the lateral vocal sacs are quite thick (M. Tyler 1974), suggesting an active role in a vocalization cycle. It seems likely that the biochemical and morphological characteristics of vocal sac muscles are similar to those of the trunk muscles, but this has not been investigated in any species.

The three basic types of vocal sacs (median subgular, paired subgular, and paired lateral) often are further differentiated as internal or external, following the terminology of Noble (1931) and C. Liu (1935b). However, these terms are somewhat misleading, since all sacs actually are internal, with the major difference being the thickness of the vocal sac wall. Small frogs that call in air often have very thin vocal sacs (fig. 7.6 A), whereas those that call in water, particularly very large species, often have thick-walled vocal sacs that appear swollen when inflated (fig. 7.6 E, F). Some ranid frogs have balloonlike extensions of the vocal sacs, called gular sacs, which project beyond the vocal sacs themselves when inflated. These gular sacs are invaginations of the gular skin surrounding the interhyoideus muscle and are everted during sound production. These sacs are found in African ranids of the genus *Ptychadena* and several Old World species of *Rana,* including *R. esculenta, R. ridibunda,* and *R. nigromaculata,* but are not found in any New World ranids (Inger 1956). These gular sacs probably serve to radiate sound to the air when a frog is calling in the water, as do the lateral vocal sacs of species such as *Rana virgatipes* (fig. 7.6 C) and *Phyrnohyas coriacea* (fig. 7.6 D)

Although vocal sacs probably are the main sound-radiating organs in most frogs, they are not the only ones. Purgue (1997) discovered that a significant proportion of the sound energy produced by a calling male bullfrog (*Rana catesbeiana*) is radiated not from the vocal sacs, which sit in the water in this species, but from the very large tympanic membranes. Male bullfrogs, and a number of other species of *Rana,* have tympana up to 50% larger than those of females (fig. 7.7). This difference in size could be related to

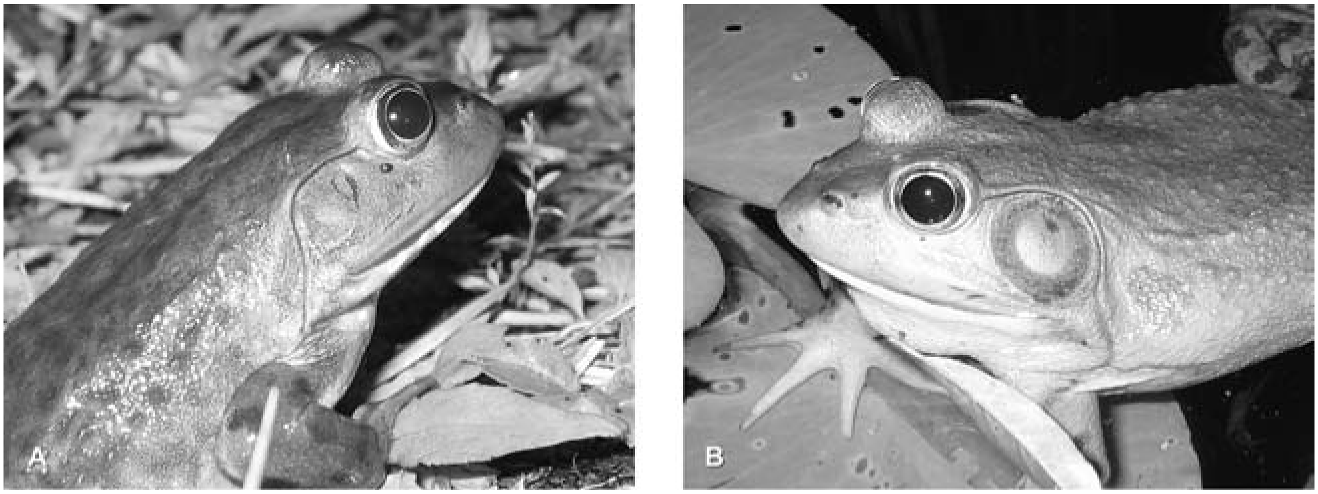

Fig. 7.7. Comparison of tympanum size and structure in a female (A) and a male (B) bullfrog (*Rana catesbeiana*). The tympanum of the male is much larger in proportion to the size of the head and has a thickened central area. Photos by Susan Z. Herrick.

greater hearing sensitivity in males (Hetherington 1994), but it also appears to relate to the use of the ears as sound radiators. Furthermore, the tympana of male bullfrogs and other ranids with enlarged tympana have an unusual structure, with a thickened central patch that accounts for most of the mass of the eardrum. This patch apparently reduces displacement of the center of the membrane and serves to decouple the auditory and sound-broadcasting functions of the eardrum. In an unusual African frog, *Petropedetes parkeri,* the thickening of the tympanum is carried even further. Males have a conspicuous spongy papilla projecting from the tympanum, but the structure is offset from the center of the membrane. There is some evidence that the ears of these frogs are used for both sound reception and sound transmission, as in North American bullfrogs (Narins et al. 2001).

Various species of frogs lack vocal sacs, but the selective pressures favoring this condition are not always clear. Presumably the pipids never evolved vocal sacs because they do not use a vibrating air stream for sound production. Primitive aquatic species such as *Ascaphus* and some discoglossids also lack vocal sacs (C. Liu 1935b; M. Tyler 1980). *Bombina bombina* lacks a vocal sac, but can expand the floor of the buccal cavity to perform the same function as a vocal sac (fig. 7.6 E). This also is true of the Australian myobatrachids *Heleioporus* and *Neobatrachus* (M. Tyler 1972). Some more-derived frogs have lost vocal sacs secondarily. Loss of vocal sacs and partial or complete loss of long-distance vocal communication sometimes is associated with breeding near cascades or torrential streams. Examples include Australo-Papuan hylids such as *Litoria lesueuri, L. booroolongensis,* and *L. nannotis;* Neotropical hylids such as *Hyla altipodens,* the *H. mixomaculata* group, some members of the *H. bistincta* group, and various species of *Plectrohyla;* the Australian myobatrachid *Taudactylus diurnis;* and some species in several genera of leptodactylid frogs (*Alsodes, Insuetophrynus, Telmatobufo, Telmatobius;* Zweifel 1958; Duellman 1970; M. Tyler 1971, 1972; Menzies 1976; Trueb 1979; Penna, Veloso, and Contreras 1983; Penna and Veloso 1987, 1990; Duellman and Campbell 1992; Barker, Grigg, and Tyler 1995). The usual explanation for this is that the background noise of waterfalls makes vocal communication difficult. However, this argument is weakened by the fact that many anurans that breed in or near torrents have well-developed vocal signals (for example, centrolenid frogs). Some of the species previously listed lack vocal sacs, but still produce vocalizations that presumably are used in close-range communication (e.g., *Litoria nannotis;* S. Richards 1992) or serve as release signals (Penna and Veloso 1987). In some genera, some species have vocal sacs and long-distance vocal signals, but close relatives breeding in similar habitats do not (Duellman 1970; Penna and Veloso 1990).

Various bufonids also lack functional vocal sacs, and some apparently do not have long-distance vocal signals. However, loss of vocalizations generally is not associated with breeding near noisy streams and waterfalls. Rather, it seems to be associated with explosive breeding in permanent water or sites that do not change in location from year to year (Wells 1977b). Males do not need calls to attract females to breeding sites because they are in traditional locations; once at the site, males generally locate females by active searching. Examples include *Bufo alvarius, B. boreas, B. exsul, B. nelsoni, B. holdridgei, B. periglenes, B. rosei,* and most populations of *B. bufo* (W. Blair and Pettus 1954; Heusser 1961, 1969a; Schuierer 1962; J. Savage 1966; Hotz 1970; Black and Brunson 1971; W. Martin 1972; Tandy and Keith 1972; Novak and Robinson 1975; Kagarise Sherman 1980). A number of voiceless toads are active during the day and are sexually dichromatic, with males more brightly colored than females (e.g., in *B. periglenes* males are bright orange, whereas females are dark, with a mottled pattern). The bright color of the males could serve as a visual signal to females that partially replaces vocal signaling (J. Savage 1966; Tandy and Keith 1972; Kagarise Sherman 1980).

In ranids, loss of vocal sacs and reduction of vocal communication has evolved independently in several different lineages, apparently in response to different selective pressures. In western North America, several ranid frogs lack vocal sacs (*R. aurora, R. cascadae, R. muscosa, R. pretiosa*), whereas others retain them (*R. draytonii, R. boylii*). Those lacking vocal sacs do vocalize, but generally do so under water and have relatively weak calls, whereas those with vocal sacs usually call in air (Zweifel 1955; F. Turner 1958; Licht 1969a, b; Morris and Tanner 1969; Altig and Dumas 1971; Hayes and Krempels 1986). Some large African ranids, including *Conraua goliath* and *Aubria subsigillata,* lack vocal sacs and apparently do not call, but their breeding habits are very different. The former breeds in or near river rapids, whereas the latter breeds in temporary ponds (Perret 1966; Lamotte and Perret 1968; Sabater-Pi 1985). Several so-called voiceless ranid frogs also are found in Borneo (*Limnonectes leporinus, L. ibanorum, L. kuhlii, L. laticeps, L. luctuosa, L. microdisca, L. paramacrodon;* Inger 1966). These frogs breed in a variety of habitats from small streams to pools and swampy areas, but their modes of communication are poorly understood (Emerson 1992; Emerson and Inger 1992). The behavior of these frogs varies geographically, probably reflecting hidden taxonomic diversity in the group (Emerson et al. 2000). For example, males of *L. leporinus* (formerly *L. blythii*) in Borneo apparently do not call, but Matsui (1995) reported that males of a *L. blythii*-like species in Malaysia did produce short, single-note calls, as do males of a species from Vietnam, which may be *L. blythii* (Orlov 1997). Males of *L. kuhlii* from Taiwan also produce calls (Tsuji and Lue 1998), but this almost certainly is not the same species as in Borneo; *L. kuhlii* sensu stricto occurs only on Java and differs from those on both Borneo and Taiwan (Iskandar 1998).

The Vocal Repertoires of Frogs and Toads

Bogert (1960) classified anuran calls into six categories based on the context in which they occur: (1) mating calls, (2) territorial calls, (3) male release calls, (4) female release calls, (5) distress calls, and (6) warning calls. He added a tentative category of rain calls, vocalizations given sporadically by males away from the breeding site during rains or in high humidity. The function of rain calls is unknown and will not be discussed further. Bogert's classification was useful in drawing attention to the diversity of call types and summarizing the available information on their functions. It was later modified by Littlejohn (1977) and Wells (1977a, b, 1988), and the terminology used in this book is derived from those papers.

Advertisement Calls

Bogert used the term *mating call* to describe the principal signals given by males during the breeding season. These calls are now generally termed advertisement calls (Wells 1977b) because they often serve more than one function or convey more than one type of message (Gerhardt 1992b). Playback experiments have shown that female frogs will approach conspecific calls presented alone or in choice tests with heterospecific calls (see the following and table 7.2). In species in which males call over long periods of time and females are in the same habitat, advertisement calls also could stimulate hormone production in females and maintain reproductive condition in females, although this has rarely been demonstrated experimentally (Lea, Dyson, and Halliday 2001). Advertisement calls also advertise a male's position to other males and help to maintain spacing between calling individuals (Whitney and Krebs 1975b; Wells 1977a, b, 1978b). The distance between males is a function of perceived call intensity (Fellers 1979a; Brzoska, Schneider, and Nevo 1982; J. Robertson 1984; Brenowitz, Wilczynski, and Zakon 1984; Wilczynski and Brenowitz 1988; Brenowitz 1989; Gerhardt, Diekamp, Ptacek 1989; Murphy and Floyd 2005; Owen and Gordon 2005).

Males of some species can use the pitch of other males' advertisement calls to assess the body size of potential opponents in agonistic encounters over females or calling sites (Davies and Halliday 1978; Arak 1983b; Ramer, Jenssen, and Hurst 1983; J. Robertson 1984; Given 1987; Wagner 1989a). Males are more likely to approach or attack speakers playing high-pitched calls of small males, but retreat from the low-pitched calls of large males (fig. 7.8). Males of some species alter the pitch of their calls in response to those of neighboring males (e.g., *Rana catesbeiana;* Bee and Bowling 2002), but it is not always clear that this provides more accurate information about male body size to opponents (Bee, Perrill, and Owen 2000; Bee 2002; see further discussion of aggressive interactions in the following).

There also is evidence for bullfrogs (*Rana catesbeiana*) that features of the advertisement call can be used by males to identify their neighbors individually (M. Davis 1987; Bee and Gerhardt 2001a, b, c, 2002). This allows males to accommodate to the vocalizations of familiar neighbors that do not represent a significant threat to their own territories. Both bullfrogs and green frogs (*R. clamitans*) exhibit short-term habituation to familiar calls (Owen and Perrill 1998; Bee and Gerhardt 2001a; Bee 2003a). This could provide a mechanism for individual recognition of calls (see also Bee and Schachtman 2000; Owen and Perrill 2000). It also appears that there is sufficient individual variation in call properties of both species to enable males to discriminate among neighbors (Bee et al. 2001; Bee 2004). Individual recognition probably is common in territorial frogs that maintain relatively stable spatial relationships within a pond (e.g., *Rana dalmatina;* Lesbarrères and Lodé 2002), but convincing experimental evidence is lacking for most species. Playback experiments with a highly territorial frog from Panama, *Dendrobates pumilio,* failed to demonstrate discrimination between calls of neighbors and those of unfamiliar males (Bee 2003b).

Although the advertisement calls of most anurans consist of a single note, a series of identical repeated notes, or a long trill, some have complex advertisement calls with more than one kind of note (Littlejohn 1977; Wells 1977a, 1988). Most frogs have only a few kinds of notes in their calls, but some rhacophorid treefrogs have extraordinarily complex calls, with a dozen or more distinct kinds of notes. The functions of the different note types in species with exceptionally complex calls are not fully understood, but at least some call components appear to be used in aggressive interactions among males (Narins, Lewis, and McClelland 2000; Christensen-Dalsgaard, Ludwing, and Narins 2002; Feng, Narins, and Xu 2002).

In some species, different types of notes apparently convey separate messages to males and females. For example, in *Eleutherodactylus coqui* (fig. 1.17 F in chapter 1), the beginning co note (fig. 7.2 C) elicits calling and aggressive responses from males, but they show little response to the qui note (Narins and Capranica 1978). In contrast, females are attracted to the qui note, played with or without the co note, but show little response to the co note alone (Narins and

Notes: Both the number of choices of conspecific (CS) and heterospecific (HS) calls and the number of females choosing each type of call are shown. *P* values are for two-tailed binomial tests comparing the number of females choosing each type of call.

Capranica 1976). In the Australian myobatrachid *Geocrinia victoriana,* the long, pulsatile introductory note conveys an aggressive message to males, while the shorter secondary notes are attractive to females (Littlejohn and Harrison 1985). A somewhat similar system is found in the African hyperoliid *Afrixalus brachycnemis,* which has a rapidly pulsed zip note that serves as an aggressive signal and a longer trill component that is attractive to females (Backwell 1988). In *Afrixalus fornasinii,* males give long trains of very short pulses (trills) that often grade into a series of repeated pulsed notes that are given mainly in response to other males (Schneichel and Schneider 1988). These distinct call components probably convey separate attractive messages to females and aggressive messages to males, but playback experiments needed to determine the functions of the different parts of the call have not been performed. Some other species, such as European frogs in the genus *Pelodytes,* have multinote calls, but the function of the different call notes is unclear (Márquez, Pargana, and Crespo 2001). There also are frogs that add components to their calls during chorusing interactions; these are discussed in a later section.

Male Courtship Calls

Male frogs often alter their vocal behavior when females are nearby, producing calls that render the male more conspicuous in a chorus (Wells 1977a, 1988). Males of some species respond to females by lengthening their advertisement calls. For example, male spring peepers (*Pseudacris crucifer*) give longer peeps when females are nearby (M. Rosen and Lemon 1974). Male gray treefrogs (*Hyla versicolor*) respond to approaching females by giving trills that can be several times the length of normal advertisement calls (Fellers 1979a; Wells and Taigen 1986; Klump and Gerhardt 1987). Similar behavior is seen in a dendrobatid frog, *Mannophryne trinitatis* (Wells 1980c). Males normally give two-note advertisement calls, but combine these into a continuous trill when females are approaching (fig. 7.9). The result is a 50% increase in the number of notes delivered per minute.

In many species, males simply respond to approaching females by increasing calling rates (P. Anderson 1954; M. J. Coe 1974; Wells 1977a; Fellers 1979a; Wells and Greer 1981; Schwartz and Wells 1984a, b, 1985; Wells and Schwartz

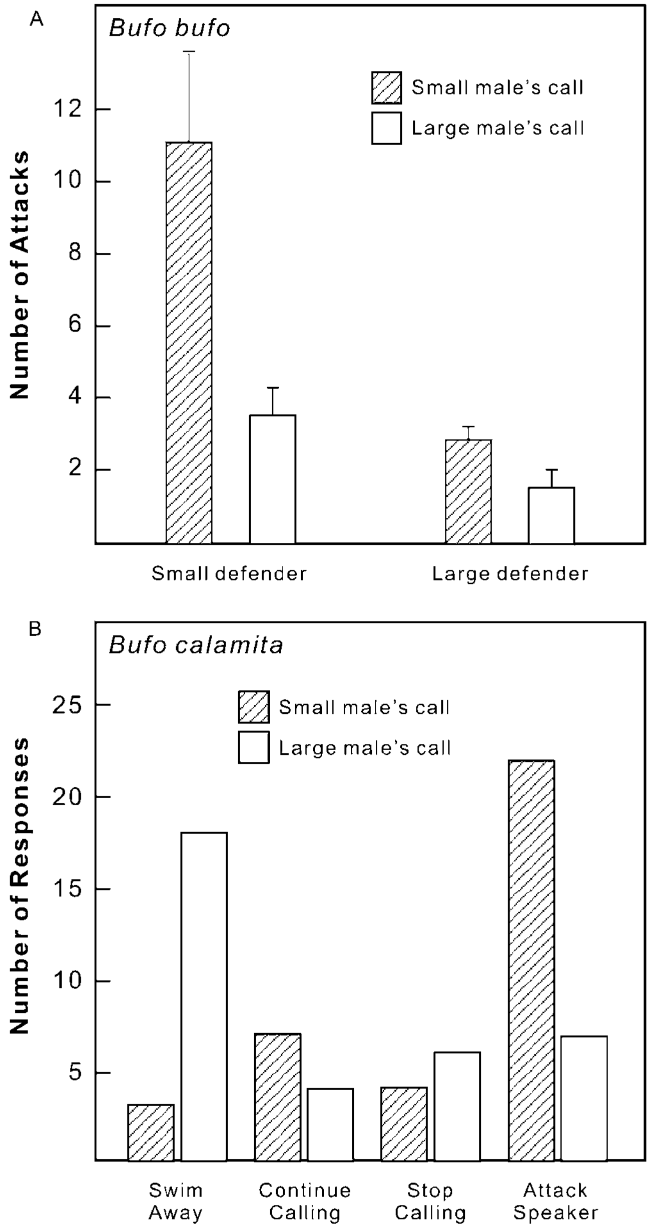

Fig. 7.8. Use of call pitch by toads to assess body sizes of opponents in aggressive encounters. (A) In *Bufo bufo,* medium-sized males allowed to attack either large or small males in amplexus with females. Defending males were prevented from calling by rubber bands in their mouths. Tape-recorded calls of large or small males were played during the experiment. Males were more likely to attack when they herd the calls of a small male, but they seldom attacked large defending males. After N. Davies and Halliday (1978). (B) Responses of males of *Bufo calamita* to a speaker playing calls of a large or small male in a chorus. Males were most likely to retreat from calls of large males, but often approached and attacked a speaker playing the calls of a small male. After Arak (1983c).

1984a; Akef and Schneider 1985; Martins and Haddad 1988; Ibáñez 1991) or by giving calls that are modified versions of the advertisement call (Owen and Tucker 2006). In others, males give courtship calls that are quite distinct from the advertisement call. Distinctive courtship calls appear to be particularly common in species in which the male leads the female to a concealed oviposition site during a prolonged bout of courtship (Jameson 1954, 1955a, b; Dixon 1957; Pengilley 1971a; Lüddecke 1976; Wells 1977a, 1980c; H. and E. Zimmermann 1981, 1985; K. Jungfer 1985; Townsend and Stewart 1986; Hoskin 2004), although they sometimes occur in species in which the male calls from a fixed location to attract the female (Greer and Wells 1980; Kluge 1981; J. Robertson 1986b). In midwife toads (*Alytes obstetricans*), males give courtship calls while moving toward females (Heinzmann 1970), and females sometimes respond with calls of their own (see the following). Courtship calls sometimes are given at lower intensity than advertisement calls, perhaps to avoid alerting other males to the presence of a female. Ovaska and Caldbeck (1997b) showed that males of *Eleutherodactylus antillensis* respond to playbacks of courtship calls by approaching the speaker playing the call, a response that was not seen during playbacks of advertisement or aggressive calls.

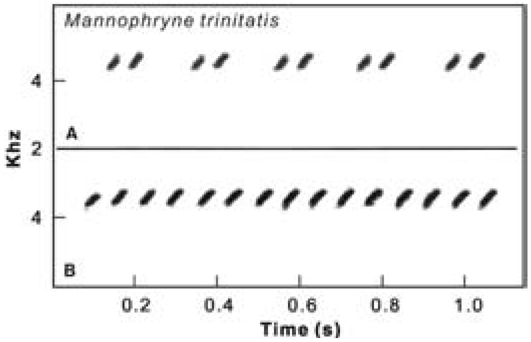

Fig. 7.9. Sound spectrograms of (A) the advertisement call and (B) a courtship trill of *Mannophryne trinitatis.* From recordings by the author.

Some species have more than one type of courtship call. In *Hyalinobatrachium fleischmanni,* a male gives long, frequency-modulated calls when a moving frog is first detected nearby. This appears to serve as an aggressive call when directed at males, but probably also provides direction cues to females. Once a female begins to approach the male, he switches to a series of short chirps (Greer and Wells 1980). In *Mannophryne trinitatis,* a male gives a long trill when courting a female at a distance (fig. 7.9), but switches to quiet chirps as he leads the female to a hidden oviposition site (Wells 1980c). Males of the Australian microhylid *Cophixalus ornatus* give long courtship calls that are distinct from advertisement calls while leading females to nest sites, but give a shorter call when in the nest with a female (Hoskin 2004). Both types of calls are delivered at a high rate, but low intensity. Short-range courtship calls also have been reported in *Dendrobates speciosus* (K. Jungfer 1985) and several species of *Eleutherodactylus* (Ovaska and Hunte 1992; Michael 1996; Bourne 1997; Ovaska and Caldbeck

1997a, 1999). Courtship calls probably are widespread in anurans, but have not been reported for many species because of the lack of detailed observations of courtship behavior.

Female Courtship Calls

Some female frogs give calls in response to the calls of males, and these often are called reciprocation calls (Littlejohn 1977; Roy, Borah, and Sarma 1995; Schlaepfer and Figeroa-Sandí 1998; Emerson and Boyd 1999). Such calls are unusual, but perhaps are more common than generally recognized because they tend to be given at very low intensity and therefore are hard to hear. The best-studied species are midwife toads in the genus *Alytes*. Female midwife toads call in response to male calls, and these calls elicit soft courtship calls from males (Heinzmann 1970; Márquez and Verrell 1991; S. Bush 1997; Bosch and Márquez 2001b). The calls given by females probably enhance the ability of males and females to find each other, but do not appear to function in competition among females (Bosch 2001, 2002a). In some instances, female midwife toads even call spontaneously to advertise themselves to males. Male midwife toads often call from hidden locations in rock crevices or burrows, but sometimes move toward females and engage in vocal duets with them (S. Bush, Dyson, and Halliday 1996; Bush 1997).

Females of a number of other anuran species call in response to male vocalizations, and in some cases, this elicits a change in vocal behavior by the male. Dixon (1957) described a call given by females of *Eleutherodactylus angustidigitorum* that elicited a switch by males from advertisement calls to courtship trills. Very similar behavior was observed in *E. podiciferus* from Costa Rica, but in this case, the normal advertisement call is a trill. Males switched to squeak calls after hearing similar squeaks given by approaching females (Schlaepfer and Figeroa-Sandí 1998). Females of *Leptodactylus fragilis* from Panama are reported to give very soft calls during courtship interactions with males, but the calls have not been recorded (Bernal and Ron 2004). Females sometimes call in response to male calls in *Hyla microcephala* (J. Schwartz, personal communication) and two species of *Pelobates* (Andreone and Piazza 1990; Lizana, Márquez, and Martin-Sanchez 1994), but the reactions of males to these calls have not been studied. Duetting between males and females occurs in the strictly aquatic pipid frog *Xenopus laevis* (Tobias, Viswanathan, and Kelley 1998). As in midwife toads, female *Xenopus* sometimes give calls spontaneously, and this elicits calling from nearby males.

Courtship calling by females has been reported in several species of ranid frogs. Given (1987) recorded low-intensity calls given by female *Rana virgatipes* as they approached territorial males; these elicited an increase in calling from the males (Given 1993a). Similar calls are given by female bullfrogs (*R. catesbeiana;* Judge, Swanson, and Brooks 2000), and females of *Rana ridibunda* also are reported to call when approaching territorial males (Frazer 1983). In a so-called voiceless frog from Borneo, *Limnonectes blythii,* and its relatives, males do not give advertisement calls to attract females to their nests, but females sometimes give soft calls when approaching males (Emerson 1992; Orlov 1997). Reciprocal calling by females has been reported in several other Asian ranids that are not closely related to one another, including *Limnonectes limnocharis, Euphlyctis cyanophlyctis,* and *Rana erythraea* (Roy, Borah, and, Sarma 1995), as well as a ranid treefrog from Fiji, *Platymantis vitiensis* (Boistel and Sueur 1997).

A number of functions of female courtship calling have been proposed, including facilitation of mate location by eliciting more calling from nearby males, identification of territorial and satellite males, and identification of females as receptive potential mates rather than territorial competitors (Emerson and Boyd 1999). To date, only a handful of experimental studies of male responses to female calls have been done (e.g., Given 1993a; S. Bush, Dyson, and Halliday 1996; S. Bush 1997; Tobias, Viswanathan, and Kelley 1998; Bosch 2001, 2002a). All of these hypotheses remain as plausible explanations for females calling in some species. A major difficulty in testing hypotheses about the function of female calling is that the distribution of such behavior even among closely related species is not well understood, because the presence of female calling can be documented with much greater certainty than can its absence.

Aggressive Calls

Many male frogs defend their calling sites against conspecifics (see chapter 8) and often have distinctive aggressive vocalizations. Several terms have been applied to these calls. Bogert (1960) referred to all aggressive calls as territorial calls, whereas Salthe and Mecham (1974) used the term territorial call for calls given in long-range interactions and aggression or aversion call for those given in close-range encounters. McDiarmid and Adler (1974) and Wells (1977b) used the term encounter call for the latter. Littlejohn (1977) retained Bogert's territorial call for calls given in long-range encounters, but adopted encounter call for close-range signals.

I believe the more general term aggressive call is preferable to territorial call to describe vocalizations given in any kind of aggressive encounter. These calls can then be subdivided into long-range and short-range signals, although the two functions often are combined in a single call. Unfortunately the term territorial call has been applied to vocalizations given by many species that clearly are not territorial (see chapter 8). For example, males of some species in the *Rana esculenta* complex are aggressive toward one another, but do not defend long-term mating territories (Blankenhorn 1974, 1977; Tunner 1976; Klöckner 1982). Instead, they maintain a small space between themselves and neighboring males and attempt to clasp any noncalling individuals moving nearby. Hence use of the term territorial call to describe their aggressive vocalizations (e.g., Wahl 1969; Blankenhorn 1974; Brzoska 1980, 1982) seems inappropriate. The term territorial call also has been used for calls given by males of *Rana temporaria* when other males approach them (Brzoska, Walkowiak, and Schneider 1977; Walkowiak and Brzoska 1982). Males of this explosive breeder locate mates by active searching and show no sign of territorial behavior (R. Savage 1961; Arak 1983a; Elmberg 1986).

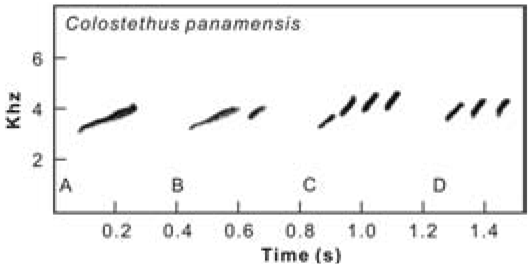

Fig. 7.10. Sound spectrograms of the calls of *Colostethus panamensis.* (A) Single-note aggressive call. (B) Two-note aggressive call. (C) Transition from the aggressive call to an advertisement call. (D) Three-note advertisement call. From recordings by the author.

The Structure of Aggressive Calls

In most anurans, aggressive and advertisement calls have similar dominant frequencies, but differ in temporal structure (fig. 7.2), but there is no unique temporal structure common to all aggressive calls. There are, however, physical constraints on call production that limit how different advertisement and aggressive calls can be. For example, frogs that produce calls with a wide frequency range typically produce relatively short pulses of sound and probably are incapable of producing notes of long duration, whereas frogs that produce narrowly-tuned calls typically have longer notes (Gerhardt and Huber 2002). Consequently, aggressive calls often are modifications of advertisement calls. For example, many North American ranid frogs have wide-spectrum calls, and aggressive calls are subtle variations on the advertisement calls (Wells 1978b; Given 1987; Bee and Perrill 1996; Owen and Perrill 1998; Bee, Perrill, and Owen 1999; Owen 2003; Bevier et al. 2004; K. Larson 2004). In *Pseudacris crucifer,* the advertisement call is a tone-like peep (fig. 7.2 A), whereas the aggressive call is a long trill consisting of a series of relatively long pulses (fig. 7.2 B). In other species of *Pseudacris,* the advertisement call consists of trains of very short pulses, and aggressive calls are longer trains of short pulses, sometimes delivered at faster rates (Owen 2003).

In *Colostethus panamensis,* the call structures are reversed, with the advertisement call being a short trill and the aggressive call a long tone-like peep (Wells 1980a). These calls sometimes grade into one another as a male makes the transition from aggressive to advertisement calling (fig. 7.10). Males of another species in the same genus, *C. subpunctatus,* sometimes respond to calls of other males by grouping call notes into bouts of two or three notes. This does not appear to enhance the attractiveness of males to females, but does function as an aggressive signal (Lüddecke 2002a). The Neotropical hylid frog *Scinax rizibilis* has an advertisement call consisting of a series of repeated notes, but aggressive calls consist of irregular trains of short pulses. This species also has a close-range aggressive call (encounter call) consisting of short bursts of pulses (Bastos and Haddad 2002). In *Eleutherodactylus urichi,* the advertisement call is a short, tone-like peep, the aggressive call an even shorter click (Wells 1981b). On the other hand, the advertisement calls of the African frog *Leptopelis viridis* are short clicks, whereas the aggressive calls are about twice as long and have a slightly lower dominant frequency (Grafe, Steffan, and Stoll 2000).

Aggressive calls with a structure similar to that of advertisement calls, but with a much higher pulse repetition rate, are characteristic of several South and Central American hylids, including *Hyla ebraccata* (fig. 7.2 F), *H. microcephala, H. minuta,* and *H. phlebodes* (Cardoso 1981b; Wells and Greer 1981; Schwartz and Wells 1984a, b, 1985; Wells and Schwartz 1984b). Several hyperoliid frogs from Africa have aggressive calls with a similar structure (Telford 1982). The hylids all have pulsed or trilled advertisement calls, whereas many of the hyperoliids produce insect-like clicks. Some anurans have aggressive calls that are essentially more rapidly repeated versions of the advertisement call (e.g., *Hyla rosenbergi,* Kluge 1981; *Rana virgatipes,* Given 1987; *Leptodactylus albilabris,* Lopez et al. 1988) or have more notes than do advertisement calls (Perrill and Shepherd 1989; Wagner 1989c). On the other hand, some species have several distinct aggressive calls with very different temporal patterns (Capranica 1968; Wells 1978b; Kluge 1981; Given 1987; Martins and Haddad 1988). Because aggressive calls do not function in species recognition, one might expect such calls to be less stereotyped than are advertisement calls. Indeed, in several anuran species, temporal features such as pulse repetition rate and number of pulses are much more variable in aggressive calls than in advertisement calls (Schwartz and Wells 1984a; Littlejohn 2001; Owen 2003).

Some frogs lower the dominant frequency of their advertisement calls when responding to the calls of other males. This type of behavior has been reported in *Leptodactylus albilabris* from Puerto Rico (Lopez et al. 1988) and in several North American frogs, including cricket frogs (*Acris crepitans;* Wagner 1989a, 1992), green frogs (*Rana clamitans;* Bee and Perrill, 1996; Bee, Perrill, and Owen 1999, 2000), carpenter frogs (*R. virgatipes;* Given 1999), and bullfrogs (*R. catesbeiana;* Bee and Bowling, 2002). Lowering the dominant frequency of calls has been interpreted as an aggressive response, perhaps a means of conveying information about the size of the caller, although in bullfrogs, such changes do not appear to be correlated with fighting ability (Bee 2002). This behavior is discussed in more detail in a later section (see "Changes in Call Intensity and Frequency Structure").

Graded Aggressive Calls

When a species has both long-range and short-range aggressive calls, these generally have been interpreted as discrete call types (hence the terms encounter call and territorial call). Some frogs, however, have graded signaling systems in which long and short-range aggressive calls represent two ends of a continuum. This has been studied in most detail in *Hyla ebraccata* from Panama (Wells and Schwartz 1984b; Wells and Bard 1987; Wells 1989). This species has compound advertisement calls consisting of an introductory note and a series of shorter secondary notes, which have the same dominant frequency and pulse repetition rate. Aggressive calls have introductory notes with much higher pulse rates than do advertisement calls and are more variable in duration (fig. 7.2 F, G). As males approach one another, the introductory notes of their aggressive calls become progressively longer (fig. 7.11 B) and the secondary click notes are dropped (fig. 7.11 A). The secondary notes make the calls more attractive to females, which are not strongly attracted to aggressive calls with only the high-pulse-rate introductory note (Wells and Bard 1987). Hence, males gradually adjust the relative aggressiveness and attractiveness of their calls, depending on the proximity of their opponents. In playbacks of aggressive calls, males increased the duration of aggressive call introductory notes as playback intensity or stimulus duration increased (Wells and Schwartz 1984b; Wells 1989); the number and length of secondary click notes were simultaneously decreased. Similar results were obtained with *H. microcephala* (Schwartz and Wells 1985) and *H. phlebodes* (Schwartz and Wells 1984b), two other Panamanian species that have aggressive calls of variable duration with pulse rates that are higher than those of advertisement calls. Playback experiments with females of *H. microcephala* showed that as in *H. ebraccata,* females prefer the lower pulse rates of advertisement calls to the higher pulse rates of aggressive calls (Schwartz 1987b).

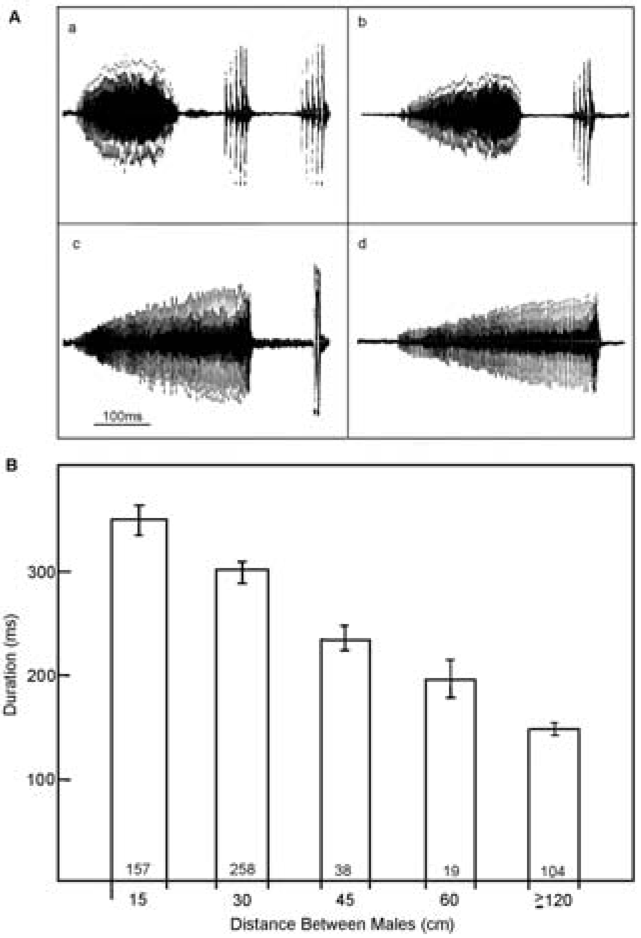

Fig. 7.11. Graded aggressive calls of the Panamanian treefrog *Hyla ebraccata.* (A) Oscillograms of four aggressive calls recorded from the same male, showing a gradual increase in the duration of the introductory note and reduction in the duration and number of secondary click notes. Call (a) was given at the longest distance between males; call (d) was given at the shortest distance. (B) Duration of introductory notes of aggressive calls as a function of the distance between interacting males. Numbers at the bottom of each column are sample sizes. After Wells and Schwartz (1984b).

Most North American hylid frogs have less complex vocal repertoires than those of the tropical hylids discussed above, with relatively simple, discrete aggressive calls. A few species have graded aggressive calls, however. Male spring peepers (*Pseudacris crucifer*) have trilled aggressive calls that are easily distinguished from the advertisement peep call (fig. 7.2 A, B). Males increase the duration of the trilled aggressive call in response to both increases in call intensity and the duration of an aggressive call stimulus (Schwartz 1989). Several other species in the genus *Pseudacris* also have trilled aggressive calls, and some of these show evidence of graded variation similar to that seen in spring peepers (Owen 2003). Cricket frogs (*Acris crepitans*) have a somewhat simpler system. Males produce calls with progressively more pulses as they approach one another, but they do not have structurally distinct aggressive calls (Perrill and Shepherd 1989; Wagner 1989b, c, 1992; Burmeister, Wilczynski, and Ryan 1999; Burmeister et al. 2002).

In the Old World, graded aggressive calls have been described in myobatrachid, hyperoliid, ranid, and rhacophorid frogs. In the Australian frog *Geocrinia victoriana,* males increase the duration of the introductory notes of their multinote advertisement calls in aggressive encounters. At close range, the calls have very long introductory notes, but lack secondary notes (Littlejohn and Harrison 1985; Scroggie and Littlejohn 2005). There is limited evidence for graded calls in *Geocrinia laevis,* but the behavior of this species has not been studied in as much detail as that of *G. victoriana* (Harrison and Littlejohn 1985). Australian frogs in the genus *Pseudophryne* give long aggressive calls in close-range encounters, but give shorter calls in more distant interactions. The temporal structure of short and long calls is very similar, with calls that overlap or nearly overlap in duration (Pengilley 1971a). This strongly suggests that the calls are part of a graded system.

In *Hyperolius marmoratus broadley*i, an African treefrog with a mating system and chorus structure similar to those of the Panamanian hylids, males lengthen their aggressive calls by increasing the number of pulses as opponents approach one another (Grafe 1995). In *Afrixalus brachycnemis,* the duration of aggressive notes does not change, but males gradually increase the proportion of aggressive notes in their calls as chorus size increases (Backwell 1988). Several other species of *Afrixalus* have aggressive calls that are similar in structure to those of the Neotropical hylids, and some of these very likely have graded aggressive calls as well (Schiøtz 1967, 1999).

Some frogs exhibit an extraordinary range of variation in call structure, with graded variation in both advertisement and aggressive calls. Males of *Rana nicobariensis* from Malaysia produce multinote advertisement calls that usually have 1–6 click notes, but when males are calling very close to each other, advertisement calls can have as many as 25 notes (Jehle and Arak 1998). These long calls have shorter notes and higher note repetition rates than do short calls. Males in dense choruses give distinctly different squawk-like aggressive calls, and these sometimes are followed by a series of click-like notes similar to those in the advertisement calls. These compound calls apparently represent transition calls that convey an aggressive message to other males while retaining notes attractive to females, similar to the calls of *Hyla ebraccata.* Males interacting at very close range give yet another type of aggressive call, a short click.

Complex graded vocal repertoires seem to be particularly characteristic of some Old World treefrogs. Several species have vocal repertoires composed of a number of distinct call types, but in most cases, the functions of these calls are not well understood (Kuramoto 1986; Kasuya, Kumaki, and Siato 1992; Andreone 1993; Matsui and Wu 1994; Narins et al. 1998). Males of *Philautus leucorhinus,* a rhacophorid treefrog from Sri Lanka, give longer aggressive calls in close range encounters than in more distant interactions, and the nearly overlapping duration of these call types suggests they are part of a graded aggressive call system (Arak 1983c). Males of another rhacophorid, *Polypedates leucomystax* from Thailand, have a repertoire of at least 12 distinct call types. Many of these calls consist of trains of pulses or clicks that appear to function as aggressive signals, but there is little evidence that the different call types grade into one another (Christensen-Dalsgaard, Ludwing, and Narins 2002). A mantellid treefrog from Madagascar, *Boophis madagascariensis,* has an even more variable vocal repertoire. Narins, Lewis, and McClelland (2000) described 28 different types of calls in this species, although most of these appear to be variants of a single call type that differ in the number of notes and pulses produced (fig. 7.12). The most variable call types, which were termed "iambic" notes, often were given in response to playbacks of similar notes at high intensities and have many of the characteristics of the graded aggressive calls seen in other species.

Males of the Puerto Rican frog *Eleutherodactylus coqui* produce multinote aggressive calls (fig. 7.2 D), but in this case, variation in number of call notes appears to be more related to the types of resources being defended than to the calls given by other males or proximity of competitors. Males of this species seldom defend their calling sites with overt aggression, but when they do give aggressive calls in this context, the calls usually have relatively few notes (O'Brien 2002). Males produce more aggressive calls as the intensity of advertisement call playbacks is increased (Stewart and Bishop 1994) and in response to playbacks of aggressive calls. They do not, however, exhibit a clear tendency to give longer calls to playbacks of longer aggressive calls (O'Brien 2002). On the other hand, males give very long calls when defending retreat sites, and the longest calls of all are given in defense of nest sites containing eggs (Stewart and Rand 1991). Two closely related species, *E. antillensis* and *E. cochranae,* have very similar multinote aggressive calls (Michael 1997b; Ovaska and Caldbeck 1997b). In all three species, the repeated notes resemble the second note of the advertisement call. Michael (1997b) suggested this is at odds with the interpretation of Narins and Capranica (1978) that the second "qui" note of the advertisement call *of E. coqui* is used to attract females, whereas the "co" note functions in male-male interactions. The contradiction is more apparent than real, however, because the co note is a long-range signal that probably mediates spacing between

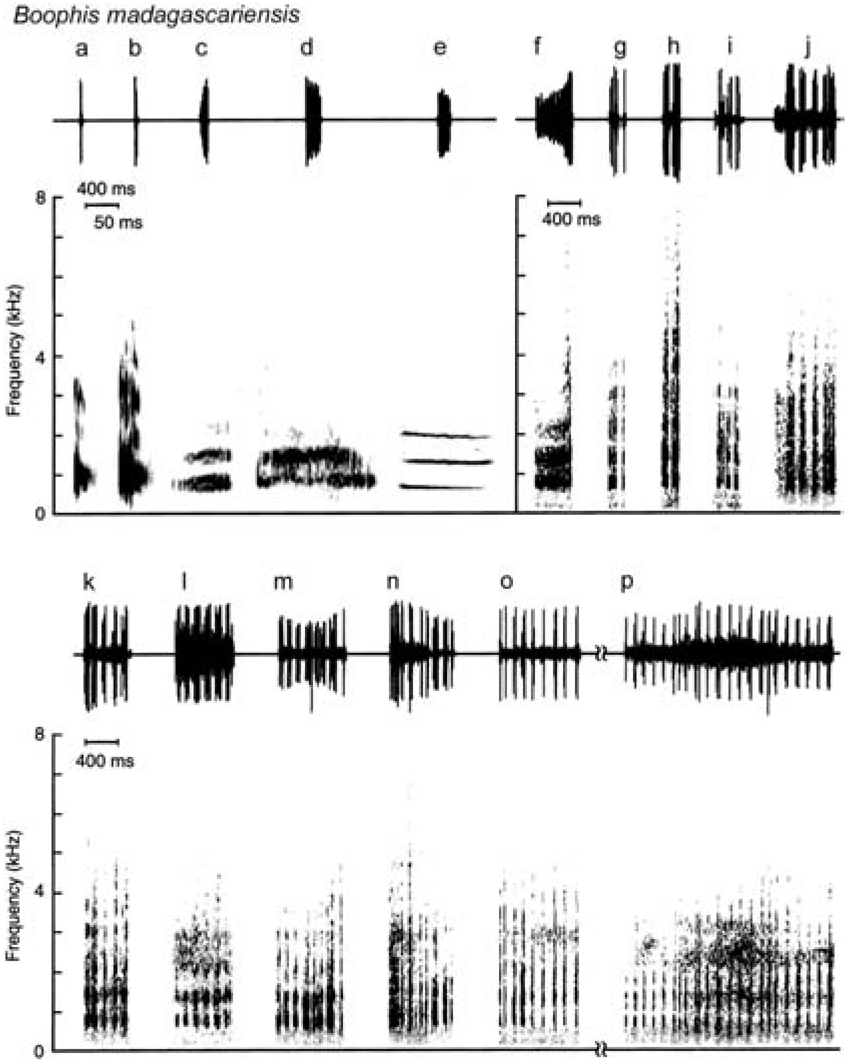

Fig. 7.12. Complex vocal repertoire of *Boophis madagascariensis.* Oscillograms are shown on top of each part, sound spectrograms on the bottom. For the first set of calls (a–e), the time scale on the sound spectrograms has been magnified to show details of call structure. Time scales are the same for oscillograms and sound spectrograms for all other calls. (a) toc note. (b) short click note. (c) short rip note. (d) loud click note. (e) tonelike note. (f) long rip note. (g) creak note. (h–p) iambic notes with increasing number of pulses. Males give iambic notes more frequently in response to playbacks of conspecific calls, and these may represent a graded aggressive call system. After Narins et al. (2000).

males in a chorus, whereas the multinote aggressive call is used mainly at close range.

Behavioral Responses to Aggressive Calls

Playbacks of aggressive calls can inhibit calling, cause males to retreat from speakers or make aggressive advances toward them, or result in increased levels of aggressive calling (W. Snyder and Jameson 1965; Emlen 1968; Wiewandt 1969; Allan 1973; M. Rosen and Lemon 1974; Passmore 1978; Wells 1978b, 1988, 1989; Gambs and Littlejohn 1979; Whitney 1980; Wells and Greer 1981; Brzoska 1982; Brzoska, Schneider, and Nevo 1982; Perrill, Gerhardt, and Daniel 1982; Ramer, Jenssen, and Hurst 1983; Schwartz and Wells 1984b, 1985; Wells and Schwartz 1984a, b; Telford 1985; Given 1987; Backwell 1988; Lopez et al. 1988; Brenowitz 1989; Schwartz 1989; Wagner 1989b; G. Rose and Brenowitz 1991, 1997, 2002; Dyson and Passmore 1992b; Brenowitz and Rose 1994; Grafe 1995). Males usually give more aggressive responses to playbacks of aggressive calls than to playbacks of advertisement calls, and they respond to aggressive calls at lower intensities. These behavioral responses can be relatively plastic, with males habituating to the local density and proximity of other males in the chorus (Brenowitz and Rose 1994; G. Rose and Brenowitz 1997;

V. Marshall, Humfeld, and Bee 2003; see "Spatial Organization of Choruses").

The precise message conveyed by aggressive signals is not entirely clear. Long-range aggressive calls usually are interpreted as warnings that an intruder is trespassing too closely on an occupied calling site (Littlejohn 1977; Wells 1977b). Close-range signals often are considered indicators of imminent attack if the intruder fails to withdraw. Graded aggressive signals can be used by an animal to gradually escalate an encounter and provide increasingly accurate information about the probability that it will attack an opponent (D. Nelson 1984; Grafen 1990a; Capp and Searcy 1991; Hauser and Nelson 1991). In a graded system such as that of *Hyla ebraccata* or *Hyperolius marmoratus broadleyi,* the use of graded signals probably allows the male to signal increased levels of aggressiveness without making the call completely unattractive to females (Wells and Schwartz 1984b; Wells 1989; Grafe 1995).

The same seems to be true of the graded signals of cricket frogs, in which males respond to opponents by modifying the basic advertisement call used to attract females (Wagner 1989b, 1992; Burmeister, Wilczynski, and Ryan 1999). Burmeister et al. (2002) found that lowering of dominant frequency by males in response to playbacks of calls was a good predictor of their likelihood of attacking the speaker. The function of changes in temporal features of calls was less clear. Males that did not respond behaviorally to a simulated intruder gave relatively short calls with fewer pulses and few groups of pulses per call than did those that abandoned their calling sites or attacked the speaker, but there was no difference in call characteristics of those that abandoned a calling site or attacked. None of the changes in dominant frequency or temporal features was clearly related to body size. Hence, while graded changes in frequency and temporal features could signal a male's intention to respond or not respond to an opponent, it is not clear that such variation is related either to actual fighting ability. Adult male cricket frogs are small and exhibit relatively little variation in size, so size-related variation in fighting ability probably is small as well.

Some authors have argued that animals should not give reliable information about their motivational states or the likelihood of attacking an opponent (Dawkins and Krebs 1978; Clutton-Brock and Albon 1980). Instead, aggressive signals might be used mainly to signal the size and strength of an animal to its opponent, thereby allowing animals to avoid costly escalated contests when they have little chance of winning a fight (G. Parker 1974; Maynard Smith and Parker 1976; Dawkins and Krebs 1978; Riechert 1978; Clutton-Brock and Albon 1980; Enquist et al. 1990). This does not seem to be the case in cricket frogs (Burmeister et al. 2002), but might be true for other frogs. It also is possible that physiological condition is a better indicator of fighting ability than is body size alone, especially in frogs with high calling rates and high levels of energy expenditure.

Wells and Schwartz (1984b) speculated that the ability of *H. ebraccata* males to sustain production of long aggressive calls, which are expensive to produce, might be a reliable indicator of size or physical vigor. Aggressive calls of most frogs are exchanged between males in an alternating fashion, a pattern seen in the aggressive signaling of other animals as well (Greenfield 1994a). This would enable males to assess the call structure of their opponents and perhaps evaluate their fighting ability. In a preliminary test of this idea with *Hyla microcephala,* Schwartz (1994) used a computerized playback system to broadcast aggressive calls to males in a chorus in response to spontaneous aggressive calls given by the males. The responses were programmed to be either longer, shorter, or the same length as the initial call of the test male. When Schwartz presented males with calls that were of similar duration to their own calls, they tended to increase call duration in response to the playbacks. They did not increase call duration as much when they were presented with calls that were longer or shorter than their own calls. This suggests that males might escalate their aggressive responses to elicit information about whether the opponent is capable of producing even longer calls (see Greenfield and Minckley 1993, for a similar system in grasshoppers).

Release Calls

Male anurans usually give release calls when clasped by other males, either when the male being clasped is alone or in amplexus with a female. Unreceptive females, or those that have completed oviposition, often give similar calls. Usually these calls consist of a series of rapidly repeated broad-spectrum notes. They indicate to a clasping male that he has grabbed an inappropriate mate. Male release calls have been described in bombinatorids, discoglossids, pipids, pelobatids, leptodactylids, bufonids, hylids, and ranids (Eibl-Eibesfeldt 1950; Bogert 1960; R. Savage 1961; Rabb and Rabb 1963a; Capranica 1968; R. Schmidt 1972b, 1976; Heusser 1969a; Lörcher 1969; Wahl 1969; Heinzmann 1970; J. Pierce and Ralin 1972; Salthe and Mecham 1974; E. Weber 1974; Brzoska, Walkowiak, and Schneider 1977; Schneider 1977; Wells 1978b; Cei 1980; Picker 1980; Penna and Veloso 1981, 1987; Schneider and Brzoska 1981; Odendaal, Bull, and Telford 1983; Akef and Schneider 1985; R. Schmidt, Kemnitz, and Hudson 1990; Castellano et al. 2002). Females probably give release calls in many of these species as well. In some species, males and females give release vibrations when clasped by other frogs, but do not produce audible sound (Bogert 1960; Penna and Veloso 1982). It has been suggested that the advertisement calls of anurans originally evolved from simple release signals (R. Schmidt 1966, 1968b; Rand 1988; R. Schmidt, Kemnitz, and Hudson 1990). There has not been any phylogenetic analysis that would support this hypothesis, and such a test might be impossible because of the prevalence of advertisement calling in extant anurans.

Distress Calls, Alarm Calls, and Defensive Calls

Bogert (1960) used the term distress call to describe vocalizations given by frogs being attacked by predators. Usually these are relatively loud screams, often delivered with the mouth open. Many such calls have been described since Bogert's paper appeared (Wahl 1969; Heinzmann 1970; J. Hoff and Moss 1974; E. Weber 1974, 1975b, 1978b; Sazima 1975; Lescure 1977; Tunner and Hödl 1978; Kluge 1981; Hödl and Gollmann 1986; Penna and Veloso 1987; Leary and Razafindratsita 1998), but their function remains obscure. Possibly they serve to warn neighbors of danger or startle the predator, thereby allowing the victim to escape. There is little direct evidence to support either hypothesis, other than reports than humans often are startled by such cries (e.g., Hödl and Gollmann 1986). Leary and Razafindratsita (1998) reported an unusual response to distress calls given by a treefrog, *Trachycephalus* (= *Phrynohyas*) *venulosus,* which was seized by a snake. In less than a minute, 17 other frogs emerged from retreat sites in a tree and oriented toward the sound, but did not do anything else.

Some large frogs actually threaten or attack predators while giving hisses or screams (Barrio 1963; Villa 1969; Vaz-Ferreira and Gehrau 1975; Veloso 1977; Hödl and Gollmann 1986). Although some authors have referred to these as aggressive calls, the term defensive call is more appropriate to distinguish them from calls used in intraspecific aggressive encounters. The effectiveness of the calls in deterring predators is unknown.

Call Structure and the Physical Environment

The physical environment can distort a signal before it reaches a receiver, making it difficult to predict what an animal will hear when it receives a signal broadcast by another individual some distance away. The most important environmental effects are: (1) attenuation of signals due to spherical spreading, atmospheric absorption, scattering, and boundary interference; (2) degradation of signal structure due to reverberations or irregular amplitude fluctuations brought about by atmospheric turbulence; and (3) masking of signals by background noise (Michelsen 1978; Wiley and Richards 1982; Gerhardt 1983, 1994a; Gerhardt and Klump 1988a; Narins and Zelick 1988; M. Ryan 1988a; Forrest 1994).

Attenuation of signals refers to the reduction in signal intensity over distance. All sounds radiating from a point source suffer attenuation due to spherical spreading of sound waves. Sound pressure level decreases by 6 decibels (dB) for each doubling of distance from the sound source, and this attenuation is independent of the frequency of the sound. Additional reductions in sound intensity due to atmospheric absorption, scattering, or boundary interference constitute excess attenuation. Excess attenuation is greater for high frequencies than for low frequencies in all habitats, so in general, low-frequency sounds are more suitable for long-distance communication, especially when both the signaler and receiver are near the ground (Michelsen 1978; Wiley and Richards 1982; Gerhardt 1983; 1994a).

In addition to suffering excess attenuation in certain habitats, the temporal features of calls are degraded by reverberation of sound through reflecting surfaces such as vegetation or irregular amplitude fluctuations caused by atmospheric turbulence. These processes tend to distort features of calls that are important for species recognition or message transmission. Reverberations are most severe in densely vegetated habitats and obscure high rates of amplitude modulation in calls. Consequently, either tone-like signals or signals with gradual frequency modulation would be best suited for long-distance communication in such habitats (D. Richards and Wiley 1980; Wiley and Richards 1982). Irregular amplitude fluctuations are particularly significant in open environments, especially during the daytime when temperature gradients increase atmospheric turbulence. The environment tends to impose amplitude fluctuations on calls that are not amplitude-modulated, such as pure tones, although this is not likely to affect frogs that call at night, when temperature gradients are minimal.

Several early studies of bird songs (Chappuis 1971; Morton 1975) indicated that birds in tropical forests have lower-pitched songs than those in open savannas, and it was suggested that low frequencies are better suited for propagation through forest habitats. However, D. Richards and Wiley (1980) did not find consistent differences in the frequency structure of bird songs from forested and open habitats in the temperate zone, and there seems to be little evidence that excess attenuation of high frequencies is greater in forested habitats (Wiley and Richards 1978, 1982). Instead, the use of low-frequency sounds by some tropical forest birds seems to be related to their tendency to sing from the ground rather than elevated perches. Differences in the temporal features of bird songs are related to habitat preferences as well. Many forest birds have tone-like songs, while many open country birds have songs with rapid frequency modulation (analogous to rapid amplitude modulation in frog calls; Chappuis 1971; Morton 1975; D. Richards and Wiley 1980). These analyses also are complicated by phylogenetic differences in the birds that live in open and forested habitats, which in turn are correlated with differences in song structure (M. Ryan and Brenowitz 1985).

Several investigators have attempted to apply the ideas derived from studies of birds to studies of call structure in frogs. Some studies have examined the relationship between call structure and habitat in a range of anuran species, while others have used experimental playbacks of recorded calls to determine the effect of habitat structure on call attenuation and degradation.

Observational Studies of Call Structure in Relation to Habitat

Several authors have proposed that habitat structure is related to the frequency of frog calls (Littlejohn 1977; Telford 1982), but there have been few systematic attempts to examine this question. Any attempt to identify best frequencies for certain habitats is complicated by differences in acoustic properties of habitats that appear superficially similar. Two open habitats can have very different characteristics, depending on the type and density of vegetation, the presence or absence of standing water, temperature gradients, humidity, and atmospheric turbulence (Wiley and Richards 1982). Even more important are differences in calling site preferences of different species. If a male frog calls near the ground, and if females receiving his signals also are on the ground, then high frequency components of calls will suffer much greater attenuation than low frequency components (e.g., Odendaal, Bull, and Telford 1986; Kime, Turner, and Ryan 2000), particularly if the frog is surrounded by vegetation (Zimmerman 1983). However, if either the caller or receiver is elevated, then differential loss of high frequencies will be reduced (Gerhardt 1981b, 1983, 1994a; Forrest 1994; Gerhardt and Huber 2002; Parris 2002).

Frequency Structure

Zimmerman (1983) compared frogs living in Amazonian forests with those in floating meadow habitats and found that forest species have significantly lower-pitched calls. Unfortunately, the analysis is complicated by the effect of body size and phylogeny. The forest species generally are larger than those in open areas, and call frequency decreases with increasing body size. Since the relationship of body size to dominant frequency was the same in the two habitats, there is no evidence that habitat per se influences dominant frequency. This is consistent with Wiley and Richards' (1982) conclusion that the best frequency for long-distance transmission does not differ between habitats. Furthermore, the calls of many species probably are not adapted for long-range propagation, but for ease of localization at short distances. Phylogenetic differences probably are important as well. Frogs that are common in forests, such as *Eleutherodactylus,* are uncommon in open areas and tend to have a very different call structure than open-habitat frogs such as hylids. Studies of leptodactylid frogs in marsh and bog habitats in southern Chile also failed to find a clear relationship between habitat and call dominant frequency (Penna and Solis 1998), as did a study of several families of frogs in open and forested habitats in Panama (Kime, Turner, and Ryan 2000). Bosch and De la Riva (2004) found a relatively weak tendency for Bolivian frogs in closed microhabitats to have frequency-modulated calls, but the effect of taxonomy (family and genus) was much stronger. They did not, however, perform a detailed phylogenetic analysis using modern comparative methods.

Temporal Structure

Many open-habitat frogs have calls with rapid amplitude modulation (e.g., Schwartz and Wells 1984a, b, 1985; Wells and Schwartz 1984a), but there have been few systematic surveys of call types in different habitats. Zimmerman (1983) found that forest species tend to have more narrowly tuned calls with lower pulse repetition rates than open habitat frogs. In Panama, hylid frogs that call in open, grassy areas tend to have noisy, broad-spectrum calls, but this also is true of hylids that call along forested streams, such as species of *Smilisca.* Leptodactylids that call from forested habitats, such as *Eleutherodactylus,* have narrowly tuned calls, but so do species of *Leptodactylus* and *Pleurodema* that call from open habitats (Kime, Turner, and Ryan 2000). Clearly these comparisons are confounded by differences in the phylogenetic distribution of species that live in forested and open habitats. Furthermore, many open habitat frogs, such as those breeding in marshes, actually call in the midst of dense vegetation, so the acoustic environment does not differ dramatically from that of a densely vegetated forest. Until more precise characterizations of anuran calling sites are available, it will be difficult to discern relationships between habitat types and call structure.

Call Intensity

The distance over which a call can be detected will be determined in part by its initial intensity; calls of high sound pressure level will be transmitted over greater distances than low-level calls of the same frequency. Schiøtz (1973) and Dubois (1977a) reported their impressions that the calls of open-habitat species are much louder than are those of forest species, but they did not present actual measurements of sound pressure level. Most of the available data (table 7.1) are for species calling in open habitats such as ponds or flooded fields (Gerhardt 1975; Passmore 1981; Schwartz and Wells 1984a). The only data on forest species are for *Eleutherodactylus coqui* in Puerto Rico (Narins and Hurley 1982) and *Hyalinobatrachium fleischmanni* in Panama

(Wells and Schwartz 1982). The data reveal few general patterns. There is no evidence that interspecific differences in call intensity are consistently related to body size, calling site elevation, or habitat. For example, several species of leptodactylid frogs from southern Chile that call in bogs, where sound transmission is relatively poor, have calls of unusually low intensity (Penna and Solis 1998). Perception of calls in this environment can be enhanced by acoustic properties of the frogs' burrows, however (Penna and Solis 1996, 1999; see following). Call intensity is related to factors other than habitat structure per se. For example, frogs that call in open habitats tend to call in much denser choruses than do those in forested habitats, and competition among males should favor the evolution of very loud calls.

Experimental Studies of Call Degradation

Only a few experimental studies have examined the effects of vegetation and other environmental factors on the degradation of calls produced by frogs. Wells and Schwartz (1982) showed that excess attenuation of calls of *Hyalinobatrachium fleischmanni* was greater for males calling in the midst of dense vegetation than for those calling from more open, elevated sites. M. Ryan and Wilczynski (1991) found that two subspecies of the cricket frog *Acris crepitans* have calls that differ in temporal and frequency structure. One lives in a forested habitat, the other in more open areas. When the calls of both subspecies were broadcast through each habitat, both suffered more degradation in frequency structure in a forested habitat than in an open habitat, but the subspecies native to forests suffered less degradation in that habitat (M. Ryan, Cocroft, and Wilczynski 1990). Perception of calls by females in the forested habitat was enhanced by more precise tuning of the ear, thereby improving the signal-to-noise ratio of the call (Witte et al. 2005). These studies did not examine degradation of temporal structure in detail. However, in a study of two species of toads, *Bufo woodhousii* and *B. valliceps,* M. Ryan and Sullivan (1989) found that their amplitude-modulated trills were degraded as transmission distance increased in both open and heavily vegetated habitats. The calls of *B. valliceps* suffered greater degradation, possibly because their calls have longer pulses.

Penna and Solis (1998) compared the sound propagation properties of five species of leptodactylid frogs in southern Chile. In two of these species, *Hylorina sylvatica* and *Pleurodema thaul,* males call from open water in marshes. The other three species, *Eupsophus emiliopugini, Batrachyla antartandica,* and *B. leptopus,* males call from hidden locations in bogs and sometimes from burrows. Calls of all of these species exhibited less excess attenuation in the more open marsh habitat than in the bog habitat, regardless of which habitat they actually use. Species with call dominant frequencies below 2 kHz were better adapted for long-distance propagation of calls, but the two species of *Batrachyla* had the highest dominant frequencies, and they called from the habitat most likely to result in attenuation of calls. Castellano, Giacoma, and Ryan (2003) compared attenuation degradation of calls of diploid and triploid species in the *Bufo viridis* complex in different habitats. Although the propagation of calls differed in different habitats, there was no evidence of adaptation to local habitat conditions.

Kime, Turner, and Ryan (2000) obtained similar results in a broad survey of call transmission in open and forested habitats in Panama. They tested the calls of 22 species of bufonids, hylids, centrolenids, leptodactylids, and dendrobatids, using an index of call degradation that combined excess attenuation and degradation of the temporal structure of the call. Degradation was greater in the forested habitat than in the open habitat, and calls with high dominant frequencies suffered the greatest degradation. The height at which calls were broadcast had a major effect on call degradation, being much greater near the ground than when calls were broadcast from elevated sites. Call structure clearly was strongly affected by phylogeny, although this was not analyzed in detail in the study. Most of the hylids had relatively noisy, broad-spectrum calls, whereas many of the leptodactylids, centrolenids, and dendrobatids had more narrowly tuned, tone-like calls or frequency-modulated calls, regardless of the habitat in which they called. Overall, both observational and experimental studies provide little support for the idea that the structure of frog calls is adapted for particular habitats.

Background Noise

A serious problem faced by many animals is the presence of background noise that masks their calls or makes detection of conspecifics difficult (Gerhardt and Klump 1988a; Narins and Zelick 1988). Such noise can be derived from the physical environment or the signals of other animals. The influence of animal sounds is discussed in later sections, so here I will concentrate on the physical environment. Although high wind and rustling vegetation generate considerable background noise, this probably is not a serious problem for frogs. Many stop calling in heavy wind, especially in dry weather, probably to reduce the risk of desiccation (personal observations). Rain beating down on vegetation also could create considerable background noise, but its effect on frog calling has not been studied, mainly because investigators cannot make recordings during rainstorms and tend to retreat indoors. Although high levels of background noise often inhibits calling by frogs (e.g., Schwartz and Wells 1983b), low background noise may induce frogs to call at higher rates or produce louder calls, thereby improving the signal-to-noise ratio of their calls (Penna, Pottstock, and Velasquez 2005).

One source of environmental noise that could influence the evolution of both call structure and calling behavior is running water. Dubois (1977a, b) found that frogs calling near waterfalls in Nepal generally produce a series of click-like calls delivered in rapid succession, with long pauses between calling bouts. The discontinuous production of very repetitive calls enhances contrast with the continuous background noise of the water. South American frogs of the genus *Hylodes* generally live near torrents and produce calls consisting of a repeated series of frequency-modulated peeps, also separated by long periods of silence (Haddad, Pombal, and Batistic 1996; Vielliard and Cardoso 1996; Haddad and Giaretta 1999). Other stream-breeding frogs that tend to call in discontinuous bouts include some species of centrolenid frogs and *Smilisca sila,* a Central American hylid that often calls near waterfalls and has click-like calls (Ibáñez 1991). Possibly a similar explanation applies to these frogs, although the tendency of *Smilisca sila* to call in synchronized bouts also has been explained as an adaptation to reduce predation by bats (Tuttle and Ryan 1982).

Another way to maximize contrast with the wide-spectrum noise of running water would be to have calls with energy concentrated into a narrow frequency band. Some frogs and birds that call near torrents have narrowly tuned calls (Greer and Wells 1980; Wells 1980a; Passmore 1981; Dubois 1977a, b; Dubois and Martens 1984; Haddad and Giaretta 1999; Feng, Narins, and Xu 2002), but whether this behavior represents a specific adaptation to that environment is not known. In some small stream-dwelling frogs, the dominant frequency of calls is well above that of the sound produced by waterfalls, so acoustic interference is minimal (Haddad and Giaretta 1999). Some frogs that breed in streams near noisy waterfalls deal with background noise in another way; they have evolved visual signals such as foot-flagging displays that either supplement or replace acoustic signals (Haddad and Giaretta 1999; Hödl and Amezquita 2001). Presumably these visual displays make the frog conspicuous to other males or to females at a distance, while vocalizations function mainly in short-distance communication.

Transmission of Signals from Holes and Burrows

While many anurans call from elevated perches or in the water, others typically call from underground burrows or the surface of the ground. Such behavior is particularly common in leptodactylids (Heyer 1969), myobatrachids (A. K. Lee 1967; Pengilley 1971a; Roberts 1981, 1984), and some burrowing microhylids from New Guinea and Australia (Zweifel 1985). Some species call while completely hidden in a burrow or crevice. Examples include *Leptodactylus albilabris* (E. Lewis and Narins 1985; Lopez et al. 1988; Narins 1990), *L. syphax* (Cardoso and Heyer 1995), *Eupsophus emiliopugini* (Penna and Solis 1996), *Alytes muletensis* (Bush 1997), and various species of *Heleioporus* and *Pseudophryne* (A. K. Lee 1967; Pengilley 1971a; Bailey and Roberts 1981). Males of the Australian turtle frog (*Myobatrachus gouldii*) often call with only the posterior half of the body buried in sand, while *Arenophryne rotunda* males call either underground or on the surface (Roberts 1981, 1984). Males of the leptodactylid frog *Lithodytes lineatus* often call inside nests of leaf-cutter ants (*Atta*), from burrows, or from sheltered sites in leaf litter (Lamar and Wild 1995). Calling from burrows and rock crevices can be disadvantageous for transmission of sound through air because of problems of excess ground attenuation, but the burrow would help to protect the frogs from predators that might home in on their calls.

Frogs that call in burrows have the potential to communicate through two distinct channels, the airborne channel and through ground vibrations. The latter would provide a transmission channel relatively free of background noise (E. Lewis and Lombard 1988; Narins 2001b). There is no evidence that females of any species of frog approach males in their burrows by tunneling through the ground, so the airborne channel probably is essential for attracting mates. Bailey and Roberts (1981) used plaster models of burrows to investigate burrow acoustics in several species of *Heleioporus.* They found that the resonant frequencies of the burrows corresponded to the dominant frequencies of the calls of the different species. They also found that transmission of the calls was maximized when males call near the entrance to the burrow, which serves as a resonator. These frogs lack vocal sacs, and the burrow might compensate for this by increasing the sound pressure level of the call.

A somewhat analagous situation has been reported in a microhylid frog from Borneo, *Metaphrynella sundana,* which calls from water-filled treeholes. Males of this species have vocal sacs, but they appear to adjust the fundamental frequency of their calls to match the resonance frequency of the chamber, thereby enhancing the transmission of the call (Lardner and Lakim 2002). Because both the resonance properties of different treeholes and the dominant frequencies of male calls vary considerably, the result is a wide range of variation in the perceived calls of males in the population (Lardner and Lakim 2004).

A burrow or chamber also can affect the reception of calls produced by other males calling nearby. Penna and Solis (1996, 1999) investigated the burrows of *Eupsophus emiliopugini* affected the ability of the burrow inhabitat to perceive calls of neighboring males. They found that the burrows increased the sound pressure level of the calls of nearby males inside a male's burrow. Males alternate calls with one another and respond to other males calling close to

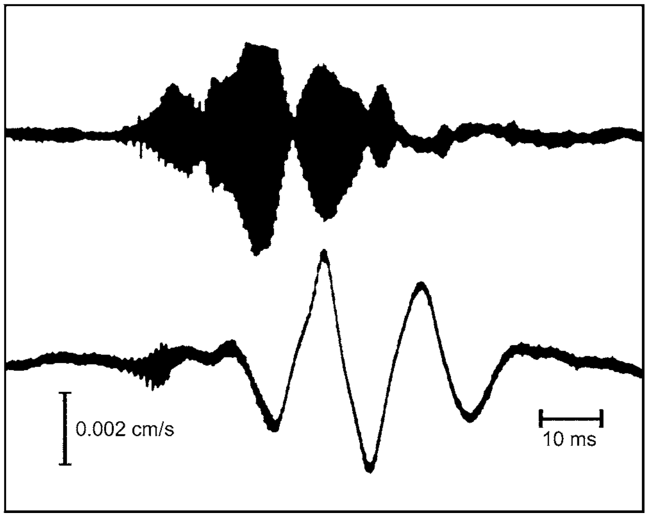

Fig. 7.13. Seismic communication in *Leptodactylus albilabris.* The oscillogram on top shows the airborne signal recorded with a microphone. The one on the bottom shows the ground-borne signal recorded with a geophone 1 meter from the calling male. Horizontal time bar = 10 ms. After Narins (1990).

their burrows with aggressive calls. The acoustic properties of the burrow are therefore likely to affect spacing among males in the chorus.

The use of substrate-born signals has been studied in detail only in the Puerto Rican frog *Leptodactylus albilabris.* E. Lewis and Narins (1985) showed that calling males produce a distinct thump that can be detected with a geophone (fig. 7.13). Apparently the vocal sac hitting the walls of the burrow produces this sound. This frog is extremely sensitive to substrate-born vibrations that apparently are detected by the sacculus of the ear (Narins and Lewis 1984; E. Lewis and Narins 1985; E. Lewis et al. 2001). Males alter their vocal behavior in response to both airborne and substrate-born signals (Lopez et al. 1988; Narins 1990). Substrate-born signals appear to be important in maintaining spacing between calling males. Because sound travels more slowly through the ground than through air, there would be a difference in the time a signal arrives at the receiver through the two channels. The frogs could use this information to estimate the distance between themselves and their neighbors.

Cardoso and Heyer (1995) described another form of seismic communication in *Leptodactylus syphax*. Males calling in burrows responded to playbacks of advertisement calls by giving aggressive calls, emerging from the burrow, and pounding their front feet on the ground. This produced an audible clicking sound and very likely produces a seismic signal to which the frogs are sensitive. Females of the Asian rhacophorid frog *Polypedates leucomystax* respond to calling males by tapping their toes on a reed or blade of grass, and males respond by moving toward the females (Narins 1995a).

Transmission of Signals Underwater

Many frogs call while floating on the surface of the water or while partially submerged. The calls produced by these species probably are audible underwater as well as in air. Dudley and Rand (1992) recorded the underwater sounds of *Physalaemus pustulosus* in Panama and found that the calls were very similar to those recorded in air at close range, but at long distances, high frequencies were more attenuated in water than in air. The calls of bullfrogs (*Rana catesbeiana*) also propagated effectively in both air and water, but it is not known whether either males or females make use of underwater acoustic cues (Boatright-Horowitz, Cheney, and Simmons 1999). In shallow water, frequencies below 1,400–2,000 Hz were greatly attenuated, especially in ponds with soft bottoms. Frogs calling while floating on the surface produce calls that can be detected at least 4 m away underwater. If they were fully submerged, propagation of calls would be reduced to about 1 m.

Some species of anurans typically call while completely submerged. These include not only the aquatic pipids (Osterdahl and Olsson 1963; Rabb and Rabb 1963a; Weygoldt 1976a; Vigny 1979; Picker 1980; Yager 1992a, b, 1996), but also frogs in several other families, including the leptodactylid genus *Telmatobius* (Cei and Roig 1965), the ranid frogs *Rana aurora* (L. Licht 1969a; M. Hayes and Miyamoto 1984), *R. palustris* (personal observations), *R. dalmatina* (Christensen-Dalsgaard and Elepfandt 1995), and *R. subaquavocalis* (Platz 1993), and possibly the highly aquatic bombinatorid genus *Barbourula* (G. Myers 1943). Species that call in shallow water often produce a signal that is audible both underwater and in air, but *Rana subaquavocalis,* a species from Arizona, calls in deep pools, and its calls are not audible above the water.

Probably all anurans are capable of hearing sounds underwater, both those that normally call above the surface (Lombard, Fay, and Werner 1981; Hetherington and Lombard 1982) and those that call exclusively underwater (Christensen-Dalsgaard, Breithaupt, and Elepfandt 1990; Christensen-Dalsgaard and Elepfandt 1995; Elepfandt 1996; Yager 1996). Water is an excellent medium for transmitting sound, which travels about five times faster in water than in air. Also, a sound produced at a given energy level produces a sound pressure level that is much higher in water than in air (Elepfandt 1996). In deep water, sound can be transmitted over long distances with very little distortion. In shallow water, which is more typical of the habitats inhabited by amphibians, the transmission of signals is affected by reflection of sound from both the bottom substrate and the surface of the water, resulting in a complex set of pathways between the signaler and receiver (Rogers and Cox 1988). This complicates the job of females attempting to localize a signaler.

Shallow water environments also tend to filter out very low frequencies, with the cutoff frequency varying depending on the physical characteristics of the substrate (Forrest, Miller, and Zagar 1993). Most frogs are small and tend to produce calls with dominant frequencies above those likely to be filtered out by shallow water environments. Ponds and other bodies of water generally seem relatively quiet to human observers, but some ponds can be surprisingly noisy. For example, Elepfandt (1996) reported that acoustic signals produced by aquatic insects in some African ponds are potential sources of interference with the calls of pipid frogs. Despite the complexities of sound transmission and detection in shallow water, the calling behavior of aquatic species such as *Xenopus laevis* is not markedly different from the behavior of anurans that call out of water (Yager 1992a, 1996). Female pipids readily approach males calling underwater (Picker 1980; M. D. Picker 1983; Yager 1996; Kelley and Tobias 1999; Kelley, Tobias, and Horng 2001) and even exchange vocal signals with them (Tobias, Viswanathan, and Kelley 1998). They appear to have little difficulty locating calling males (Elepfandt 1996).

Predation and Calling Behavior

Although predation is frequently invoked as a potential cost of acoustic signaling (e.g., Schiøtz 1973), there are only a few studies demonstrating that predators home in on acoustic signals of their prey. Jaeger (1976) provided circumstantial evidence that *Bufo marinus* uses sound to locate calling males of *Physalaemus pustulosus.* Other large anurans, such as *Leptodactylus pentadactylus,* commonly prey on smaller frogs (M. Ryan, Tuttle, and Taft 1981), but whether they use the calls to locate prey is not known. A Neotropical opossum, *Philander opossum,* can use frog calls to locate prey (Tuttle, Taft, and Ryan 1981), and a Neotropical bat, *Trachops cirrhosus,* regularly locates prey by auditory cues and will approach speakers playing anuran calls (Tuttle and Ryan 1981). Other bats are known to eat frogs, and mammals such as raccoons and European polecats often take large numbers of frogs from breeding choruses (see chapter 14). It is not known, however, whether any of these predators home in on the calls of frogs.

The presence of bats and other predators could affect many aspects of a frogs' calling behavior, including selection of calling sites, calling rates, the structure of advertisement calls, and the formation of choruses. Bats are readily attracted to the calls of *Hyalinobatrachium fleischmanni* (Tuttle and Ryan 1981), and this species' habit of calling upside down from the undersides of leaves probably is a defense against such predation (Greer and Wells 1980; Wells and Schwartz 1982). Many other tropical forest frogs call from well-concealed sites under dead leaves or in the axils of bromeliads, probably as a defense against predation (Zimmerman and Bogart 1984, 1988). Some frogs exhibit lunar phobia, reducing their calling activity on bright moonlit nights, perhaps to avoid predation (personal observations).

In contrast, the neotropical hylid *Smilisca sila* is more likely to call in the open on moonlit nights than on dark nights. Apparently they can detect bats more easily on bright nights and take evasive action or reduce calling rates in response to the presence of the bats (Tuttle and Ryan 1982; Nunes 1988b). This species typically calls in the vicinity of waterfalls. Bats are less likely to approach speakers playing calls near waterfall sounds than speakers farther from such sounds, suggesting that the waterfall noise partially masks the frog's calls and makes it hard for bats to locate them. *Smilisca sila* produces complex multinote calls, and males respond very rapidly to the calls of their neighbors, producing a burst of synchronized calling by groups of males, which are followed by long periods of silence. Males overlap their calls with those of their neighbors, but tend to alternate individual notes within calls, a means of avoiding acoustic interference (see the following). Males also tend to increase the number of notes in their calls as the number of notes in a neighbor's calls increase (Ibáñez 1991). The overlapping of calls in synchronized bursts make the calls difficult for bats to locate (Tuttle and Ryan 1982). M. Ryan (1986b) maintained that males of this species respond to the calls of neighbors so quickly that the normal neural pathways used in such vocal interactions would be too slow to account for the behavior. In a more thorough study of response latencies, however, Ibáñez (1991) found that while the responses of this frog are fast, they are within the range of response times observed in a number of other hylids. Very similar synchronized chorusing behavior has been observed in a stream-breeding centrolenid frog, *Cochranella granulosa,* and this probably represents an anti-predator adaptation as well (Ibáñez 1991).

Tuttle and Ryan (1981) showed that bats are more attracted to speakers playing frog calls at high rates than at low rates. Many tropical forest frogs call at relatively low rates, often with long pauses between calling bouts (Duellman 1967b; Dubois 1977a; Lynch and Myers 1983; Zimmerman and Bogart 1984, 1988). This could make it difficult for predators to locate the calls, although low calling rates also could be related to low levels of vocal competition among males. Some acoustic insects exhibit similar adaptations against bat predation (Bellwood and Morris 1987; Bellwood 1990; G. Morris et al. 1994). *Smilisca sila* males reduce their calling rates when bats pass by (Tuttle and Ryan 1982). In another Panamanian frog, *Physalaemus pustulosus,* males often stop calling completely when bats or models of bats are detected overhead (Tuttle, Taft, and Ryan 1982). When two males are calling, they tend to remain silent for longer periods than when only a single male is calling, but the duration of silent periods in response to bat models gradually decreases as chorus size increases from two to five males (Jennions and Backwell 1992). This indicates that males probably assess not only the presence of the predator, but also the relative risk of being eaten, which decreases with chorus size (M. Ryan, Tuttle, and Taft 1981). As in *Smilisca sila,* males of *Physalaemus pustulosus* produce complex multinote calls consisting of an introductory whine note followed by one or more secondary chuck notes (M. Ryan 1985b). Males calling alone often give single-note calls, but they give more complex calls in dense choruses. Complex calls are more attractive to females than are single-note calls (Rand and Ryan, 1981), but they also are more easily located by bats (M. Ryan, Tuttle, and Rand 1982), so there is a cost associated with producing calls that are especially attractive to females.

The Structure and Dynamics of Anuran Choruses

The mating systems of chorusing frogs and the criteria used by females to select mates are discussed in chapter 8. Here I will focus on the spatial structure and behavioral dynamics of an anuran chorus, especially acoustic interactions among calling males. Reviews of these topics are provided by Schwartz (2001), Gerhardt and Huber (2002), and Wells and Schwartz (2006). There are a number of reasons why males might aggregate at suitable breeding sites. In many cases, such sites are limited, forcing males to call in close proximity to one another. Aggregations also can reduce individual exposure to predation. This would occur if the number of calling males overwhelms the ability of predators to feed on them (M. Ryan, Tuttle, and Taft 1981), but only if the aggregation does not attract substantially more predators to the area. Calling in groups also can decrease rates of predation if acoustic interactions among males, such as the synchronized calling of *Smilisca sila* and *Cochranella granulosa,* confuses predators and makes the frogs more difficult to locate (Tuttle and Ryan 1982; Ibáñez 1991).

Aggregation by calling males can increase the proportion of time that the group as a whole produces signals (the duty cycle of the chorus) or increase the total sound level emanating from the chorus. Changes in the amount of signaling time or chorus intensity do not, however, increase in direct proportion to the number of males in the chorus. It is unlikely that these acoustic properties will lead to an increase in the number of females available for each male (Bradbury 1981; Greenfield 1994a, b). Males also might aggregate because females prefer groups that enable them to compare several potential mates (R. Alexander 1975; Bradbury 1981; Bradbury and Gibson 1983; Greenfield and Shaw 1983; Thornhill and Alcock 1983; Höglund and Alatalo 1995). Several studies of insects and frogs have shown that more females are attracted to multiple sound sources than to single sound sources (G. Morris, Kerr, and Fullard 1978; Cade 1981; Aiken 1982; Walker 1983; Schwartz 1994). Females also are more likely to be found in large choruses than in small choruses (Doolan and Mac Nally 1981; M. Ryan, Tuttle, and Taft 1981; Tejedo 1993a; C. Murphy 2003). Most of these studies have not demonstrated an increase in the per capita availability of females to males in larger choruses, however.

Aggregations of calling male frogs can be formed either because of independent responses of many individuals to the same environmental cues or because the calling of males elicits calling by other males competing to attract mates. There is a large literature showing that numbers of calling males often are correlated with environmental variables such as temperature, rainfall, humdity, wind speed, and ambient light intensity (Blankenhorn 1972; Obert 1975; Wells 1978b; Woolbright 1985a; Banks and Beebee 1986a; Henzi et al. 1995; Navas 1996b; Brooke, Alford, and Schwarzkopf 2000; Friedl and Klump 2002; C. Murphy 2003). Often the abundance of females at a breeding site parallels variation in numbers of males, suggesting either that females are differentially attracted to large aggregations, or that males and females respond to similar environmental cues. For one species, *Hyla gratiosa,* there is evidence that females are attracted to chorus sounds from a distance (Gerhardt and Klump 1988b), but variation in the number of females in a chorus is better predicted by environmental variables (C. Murphy 2003).

There is limited evidence that the presence of calling males attracts other males to calling sites (Oldham 1966, 1967), and calling by males clearly stimulates males in a chorus to increase calling rates or call for longer periods each night (Wells 1988; Schwartz 1991; Brooke, Alford, and Schwarzkopf 2000; Friedl and Klump 2002). Once such choruses are formed, males are faced with the problem of competing for the attention of females in a noisy and acoustically complex environment, and they employ a variety of behavioral tactics to enhance their ability to communicate effectively.

Spatial Organization of Choruses

To a naive observer, a very large chorus of frogs, like the deafening choruses of spring peepers (*Pseudacris crucifer*), seems like a disorganized cacophony produced by randomly spaced individuals. In fact, most anuran choruses exhibit some degree of spatial structuring. Individual males typically maintain some minimum distance between themselves and their neighbors. They use the perceived sound-pressure level of other males' calls to assess inter-male distance (Fellers 1979a; Brzoska, Schneider, and Nevo 1982; Narins and Hurley 1982; J. Robertson 1984; Brenowitz, Wilczynski, and Zakon

1984; Telford 1985; Wilczynski and Brenowitz 1988; Brenowitz 1989; Gerhardt, Diekamp, and Ptacek 1989; Schwartz 1989; Wagner 1989c; Stewart and Bishop 1994). The distance at which males tolerate other calling males is relatively plastic, and tends to decrease as the number of males in a chorus increases. This is because males accommodate to the close proximity of their neighbors in dense choruses and do not waste time and energy trying to repel them.

In *Pseudacris regilla* and *P. crucifer,* males with close neighbors had a higher threshold for giving aggressive calls than did males with more distant neighbors (G. Rose and Brenowitz 1991; V. Marshall, Humfeld, and Bee 2003), and the threshold was correlated with the sound-pressure level of the neighbors' calls (fig. 7.14 A). When near neighbors were removed, the threshold for aggressive calling decreased (that is, a lower intensity playback of advertisement calls was required to elicit aggressive calling). On the other hand, when loud advertisement calls were played to males, the threshold for responding with aggressive calls eventually increased. As in most frogs, males give aggressive responses to aggressive calls at lower playback intensities than those required to elicit aggressive calls in response to advertisement calls (fig. 7.14 B). These thresholds were not changed after repeated presentations of advertisement calls at a high level (Brenowitz and Rose 1994). The frogs did accommodate to loud playbacks of aggressive calls by increasing the threshold for aggressive responses, however (G. Rose and Brenowitz 1997; Brenowitz, Rose, and Adler 2001).

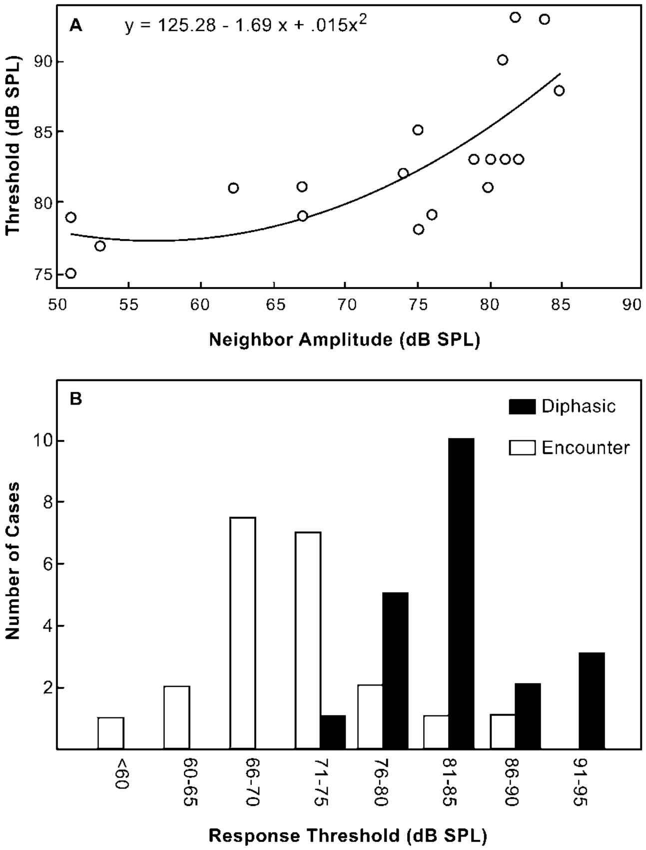

Fig. 7.14. Vocal responses of male Pacific treefrogs (*Pseudacris regilla*) in a chorus. (A) Change in aggressive threshold as a function of the amplitude of the nearest neighbor's call. The threshold indicates the playback intensity (SPL) required to elicit aggressive calls in response to playbacks of advertisement calls. Males required a louder stimulus to elicit aggressive responses when other males were nearby. (B) Aggressive thresholds of males in response to playbacks of the advertisement call (diphasic call) and the aggressive call (encounter call). Males gave aggressive responses at lower SPL's in response to aggressive calls that to advertisement calls. After G. Rose and Brenowitz (1991).

The advantage of this sort of plastic response to the call of near neighbors is that males can adjust their aggressive responses to changes in chorus density. As long as a neighboring male remains in one place and does not continue to approach a calling male, it probably represents only a minimal threat to that male's calling territory or his ability to attract mates. If males did not accommodate to the presence of close neighbors, they might spend much of their time giving aggressive calls and spend relatively little time advertising for mates. Experiments with several species have shown that females strongly prefer advertisement calls to conspecific aggressive calls (Oldham and Gerhardt 1975; Schwartz 1987b; Wells and Bard 1987; Grafe 1996b; Brenowitz and Rose 1999; Brenowitz, Rose, and Adler 2001), so there is a clear cost to producing aggressive calls. V. Marshall, Humfeld, and Bee (2003) found that female spring peepers (*Pseudacris crucifer*) preferred advertisement to aggressive calls, but this preference could be reversed by relatively modest increases in the intensity of the aggressive calls. They suggested that energetic constraints also might be important in limiting production of aggressive calls, since these are much longer than are advertisement calls, and production of aggressive calls resulted in a temporary increase in calling effort.

In most anuran choruses, males sort out spatial relationships early in the evening. Once the positions of calling males are relatively stable, males concentrate their efforts on advertising for mates (fig. 7.15). Often there is an intense period of aggressive calling in the first hour or so of chorus formation. This period usually is followed by several hours of advertisement calling in which aggressive calls are heard only occasionally (Jameson 1954; Pengilley 1971a; Allan 1973; Garton and Brandon 1975; Wells 1978b, 1988; J. Robertson 1986b; Wells and Bard 1987; Stewart and Rand 1992; Grafe 1995). One advantage of establishing spatial relationships relatively early in the evening is that the cost of producing aggressive calls that are less attractive to females is minimized because most disputes over calling space are settled before females arrive in the chorus (Wells 1988). Males in very dense choruses tolerate neighbors at relatively close proximity simply because the tradeoff between giving aggressive calls and producing calls that are more attractive

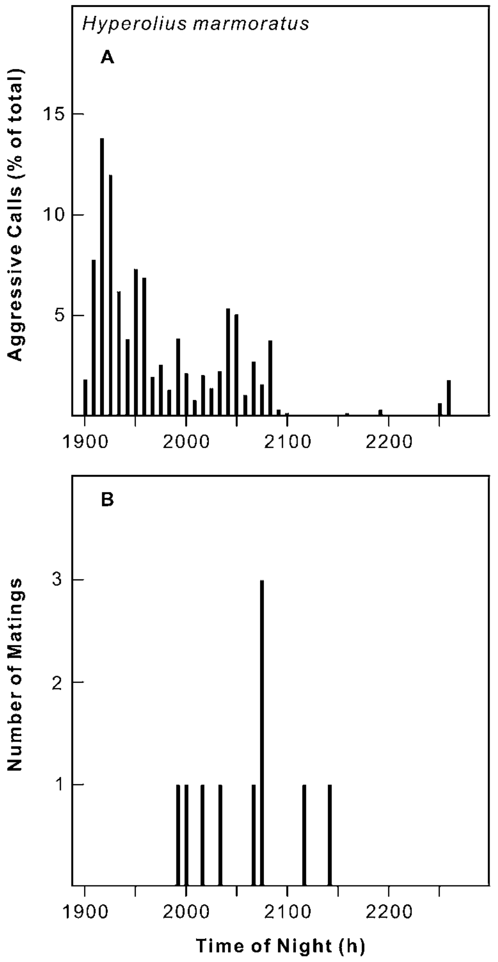

Fig. 7.15. Timing of aggressive calling and mating by males of an African frog, *Hyperolius marmoratus broadleyi.* (A) Temporal occurrence of aggressive calls as a percentage of total calls given in a chorus of 11 males on one night. (B) Temporal pattern of mating, based on males seen in amplexus for 18 consecutive nights. Males contest calling territories early in the evening, but exhibit relatively low levels of aggressive calling later in the evening when females are most likely to mate. After Grafe (1995).

to females becomes more costly as the evening progresses and more females are searching for mates. At very high densities, the costs of defending a calling site becomes so high that males simply abandon aggressive calling altogether and even become unresponsive to playbacks of aggressive calls at high intensities (Wells 1988; Brenowitz and Rose 1994; Grafe 1995; G. Rose and Brenowitz 1997).

There seem to be two main advantages to males that maintain exclusive calling spaces in a chorus. First, it reduces the chances that nearby males will interfere with a male's courtship of females. In very dense choruses, this tactic is only moderately successful, because of the tendency for males to adopt satellite tactics and attempt to intercept females that are attracted to calling males (see chapter 8). Spacing in a chorus also provides acoustic advantages by reducing the amount of interference from the calls of other males (Telford 1985). Often the background noise in a frog chorus is very loud and can mask the calls of individual males and make it difficult for females to locate them (Ehret and Gerhardt 1980; Gerhardt and Klump 1988a; Schwartz and Wells 1983b; Wollerman 1999; Gerhardt and Huber, 2002; Wollerman and Wiley 2002a). The most important sources of interference are likely to be a male's immediate neighbors, because their calls will be perceived by females are being the loudest relative to that male's own calls. In experiments with *Hyla cinerea,* Schwartz and Gerhardt (1989) presented females with a choice of an attractive call (advertisement call) and an unattractive call (aggressive call) in the presence of background noise. The frogs were able to detect the calls more readily when the speakers broadcasting the calls were separated from the noise by 45° or 90° than when the speakers were immediately adjacent to those broadcasting noise. The improvement in call detection was relatively small, however, so spatial separation alone probably is less effective than are adjustments in the timing of vocalizations to avoid overlap with those of near neighbors.

Vocal Interactions among Chorusing Frogs

In addition to the exchange of aggressive calls to facilitate spacing in a chorus, male anurans engage in a number of other kinds of vocal interactions that serve either to reduce acoustic interference from nearby males or to make their signals more attractive to females. These include changes in the timing of calls to reduce call overlap with neighbors and changes in the rate, duration, or complexity of calls. In dense, noisy choruses, these types of vocal interactions usually involve only a male and a few of his closest neighbors, with other males simply contributing to the overall background noise (Narins 1992, 1995a, b; Schwartz 2001). For example, in choruses of *Eleutherodactylus coqui* and *Physalaemus pustulosus,* males usually respond to only one or two near neighbors and ignore the calls of more distant males (Brush and Narins 1989; Greenfield and Rand 2000). In a study of *Hyla microcephala,* Schwartz (1993) used a computerized system to simultaneously monitor groups of four to six males calling in close proximity to one another. He found that a male usually responded only to the calls of his loudest neighbor, even when the perceived intensities of other males' calls were only a few decibels lower. These results indicate that males tend to interact mainly with those males that represent the most important source of acoustic interference and the most immediate competition for any females that are nearby. Nevertheless, the remaining males in a chorus contribute to general background noise that can interfere with a male's ability to attract mates.

Not all frogs exhibit this type of strict selective attention to nearest neighbors. For example, in a chorus of *Hyla ver-*

sicolor in an artificial pond, males avoided overlapping calls when only two males were calling, but call overlap increased in larger choruses (up to eight males). Furthermore, males were more likely to overlap at least part of their calls with those of their nearest neighbors than expected by chance (Schwartz 2001; Schwartz, Buchanan, and Gerhardt 2002). Hence, there is no evidence for selective avoidance of call overlap with nearest neighbors in this species. Males of *H. versicolor* respond to other males' calls by lengthening their own calls (see following), and this could partially compensate for parts of their calls overlapping those of other males (Schwartz, Buchanan, and Gerhardt 2001). In addition, spatial separation among males in a chorus improves the ability of females to locate individuals, even when calls overlap (Schwartz and Gerhardt 1995).

Boatwright-Horowitz, Horowitz, and Simmons (2000) reported that male bullfrogs (*Rana catesbeiana*) were more likely to respond to the calls of distant males than to those of close neighbors. They argued that calling by near neighbors tends to inhibit calling by a male, whereas calling by more distant frogs tends in stimulate calling. Nevertheless, male bullfrogs callling within a few meters of one another often alternate calls or call notes with one another (personal observations). Male bullfrogs tend to be widely separated in a chorus, calling rates are low, but individual calls are loud, so males can readily hear the calls of distant males. This probably is not true for very dense choruses, like those of *Pseudacris crucifer* or *Hyla microcephala,* where general background noise masks the calls of distant individuals (Schwartz and Gerhardt 1998; Schwartz 2001).

Unison Bout Calling

In very dense frog choruses, with many males competing to be heard by females, calling is not always continuous. Instead, there often are bursts of calling activity in which many males call at the same time, followed by periods of silence. This waxing and waning of chorus activity can continue for much of the evening (Rosen and Lemon 1974; Wickler and Seibt 1974; Garton and Brandon 1975; Whitney and Krebs 1975b; Arak 1983c; Schwartz and Wells 1983a, b, 1984b, 1985; Schwartz 2001). Similar behavior occurs in many acoustic insects (Alexander 1975; Otte 1977; Otte and Loftus-Hills 1979; Greenfield 1983, 1990, 1994 a, b; Greenfield and Shaw 1983) and has been termed unison bout singing. This type of calling pattern probably results from mutual acoustic stimulation by males in the chorus. It could be advantageous for males to call together because the resulting cacophony is confusing to predators. Males also are likely to call in response to the calls of other males simply because they must compete for the attention of females (Brooke, Alford, and Schwarzkopf 2000; Schwartz 2001). Unison bout calling has clear disadvantages as well, especially the high level of background noise and acoustic interference that results from synchronized calling. Individual males can minimize acoustic interference by adjusting the timing of their calls within bouts (see following).

One question that arises from unison bout calling is why frogs stop calling periodically instead of calling continuously throughout the evening. This has been investigated in a series of experiments with *Hyla microcephala* in Panama. In this species, additional males soon join a male that begins calling during a silent period. The males tend to gradually increase the number of repeated notes in their calls as they compete for the attention of females (Schwartz and Wells 1985; Schwartz 1986, 1987b, 1991; Wells and Taigen 1989). Each bout of calling usually lasts about 30 seconds and then subsides. Three hypotheses have been tested to explain this pattern of calling: (1) females prefer males that call in a cyclic pattern to those that call continuously; (2) males stop calling because acoustic interference becomes too great for them to continue; or (3) males stop calling periodically to reduce the high cost of call production (Schwartz 2001).

Schwartz (1991) presented females with a choice of two speakers playing advertisement calls at the same average rate, but one broadcast calls continuously, while the other broadcast calls grouped into bouts separated by silent periods. Females did not exhibit a significant preference for one pattern over the other, so the first hypothesis was refuted. Schwartz (1991) tested the second hypothesis by presenting males in the field with several types of stimuli that were stored on a computer and triggered by the test male's own calls. In one experiment, males were presented with a synthesized chorus at several intensity levels. These generally stimulated more calling by the males rather than inhibiting their calling or causing them to shift their calls to silent periods. When males were presented with simulated choruses of 1, 2, or 12 frogs, they increased the duration of their calling bouts in response to the 12-male chorus, just the reverse of the pattern predicted from the acoustic interference hypothesis. Schwartz (1991) concluded that the energy conservation hypothesis was the most likely explanation for why males stop calling. This was tested in another series of experiments in which rates of glycogen depletion in the trunk muscles of males (see chapter 5) were measured (Schwartz, Ressel, and Bevier 1995). These measurements showed that depletion of glycogen reserves was very rapid. If males attempted to call continuously at rates observed during calling bouts, they would not have sufficient reserves to sustain calling through an entire evening. Because females arrive relatively late in the evening, but over an extended period of time, those males that can sustain several hours of calling probably have the best chance of attracting a mate. Preliminary data using a simulated chorus supported this hypothesis. In this experiment, one speaker broadcast calls in cycles and persisted for five hours, while the others broadcast continuously and stopped earlier. Females were more likely to enter a trap at the cyclical speaker than those at the other speakers (Schwartz 2001). Thus, it appears that periodic pauses in calling represent a way of conserving energy and extending a male's calling period.

Changes in the Timing of Calls

Male frogs, especially those that call in dense choruses or in unison bouts, often shift the timing of their calls to reduce call overlap with neighboring males (Foster 1967; Paillette 1967; Schneider 1967, 1968; Lemon 1971; Loftus-Hills 1971, 1974; Rosen and Lemon 1974; Wickler and Seibt 1974; Wells 1977b, 1988; Awbrey 1978; Narins and Capranica 1978; Lemon and Struger 1980; Narins 1982a, b, 1992, 1995a, b; Zelick and Narins 1982, 1983, 1985a; Wells and Schwartz 1984a; Akef and Schneider 1985; Sullivan 1985a; Sullivan and Leek 1986; Forester and Harrison 1987; Schwartz 1987a, 1993, 1994; Schneider, Joermann, and Hödl 1988; Walkowiak 1988b, 1992; Brush and Narins 1989; Ibáñez 1991, 1993; Klump and Gerhardt 1992; Given 1993b; Gerhardt 1994a; Greenfield 1994a, b; Grafe 1996b, 2003; Ovaska and Caldbeck 1997b; Penna 1997; Bosch and Márquez 2001a; Márquez and Bosch 2001; Schwartz 2001; Gerhardt and Huber 2002). Similar behavior occurs in many acoustic insects (Alexander 1975; Otte 1977; Greenfield and Shaw 1983; Greenfield 1990, 1994a, b, 2002; Gerhardt and Huber 2002) and singing birds (Todt 1970; Wasserman 1977; Gochfeld 1978; Hultsch and Todt 1982; Dabelsteen et al. 1996).

The precise pattern of vocal interaction varies among species. In some frogs, the calls of two males are precisely alternated (fig. 7.16 A). This not only minimizes call overlap, but also results in neighboring males giving approximately the same number of calls per minute. In other species, the calls of the second male begin immediately after the end of the first male's calls (fig. 7.16 B). Again, call overlap is minimized, and calling effort is very similar. In species that produce long sequences of repeated notes, two males sometimes overlap long calls, but alternate individual notes, resulting in little or no acoustic interference (fig. 7.16 C). Alternatively, some frogs produce a series of repeated notes, with the calls of the second male falling in the intervals between the calls of the first male (fig. 7.16 D). In either case, there is the potential for relatively precise matching of the number of call notes. Finally, in some anurans, males respond to the calls of other males by initiating their own calls so that the calls of two males overlap extensively, with no apparent attempt to avoid acoustic interference (fig. 7.16 E). In the example shown in fig. 7.16 E, the calls are trills consisting of repeated trains of short pulses, but similar call overlap can occur in species in shorter, single-note calls. Examples of each of these types of interactions are discussed in more detail in the following discussion.

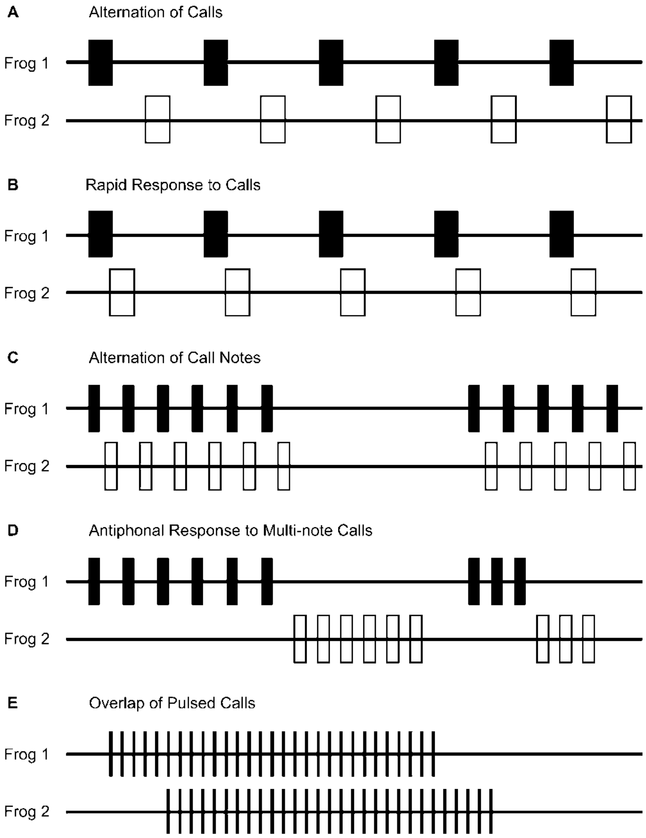

Fig. 7.16. Diagram of several possible types of vocal interaction between neighboring males in a frog chorus. (A) Calls consist of relatively long notes given at regular intervals, with the calls of the second male precisely alternated with those of the first. (B) Calls consist of relatively long notes given at regular intervals, with the calls of the second male starting immediately after the end of the first male's calls. (C) Calls consist of a variable number of closely spaced short notes, with individual notes of the second male's calls alternating with those of the first male. The result is minimal acoustic interference and relatively precise matching of the number of call notes. (D) Calls consist of a variable number of short notes. Calls of the second male are given immediately after the entire sequence of notes of the first male has ended, with fairly precise matching of the number of call notes. (E) Calls are trills made up of a rapid series of short pulses. Calls are overlapped with no attempt to avoid acoustic interference.

Most frogs probably have a neural pacemaker or oscillator that sets the spontaneous calling pattern of an individual male (Loftus-Hills 1974; Wickler and Seibt 1974; Lemon and Struger 1980; Zelick and Narins 1985a; Walkowiak 1988b, 1992; S. Moore et al. 1989; Klump and Gerhardt 1992; Greenfield 1994a, b). In most species, especially those with relatively high calling rates, males calling without interruption from other males usually call at a relatively constant rate, which varies with temperature. The call oscillatory period is the time between the onset of one call and the onset of the male's next call (fig. 7.17). This can be divided up into several sub-periods that describe the responsiveness

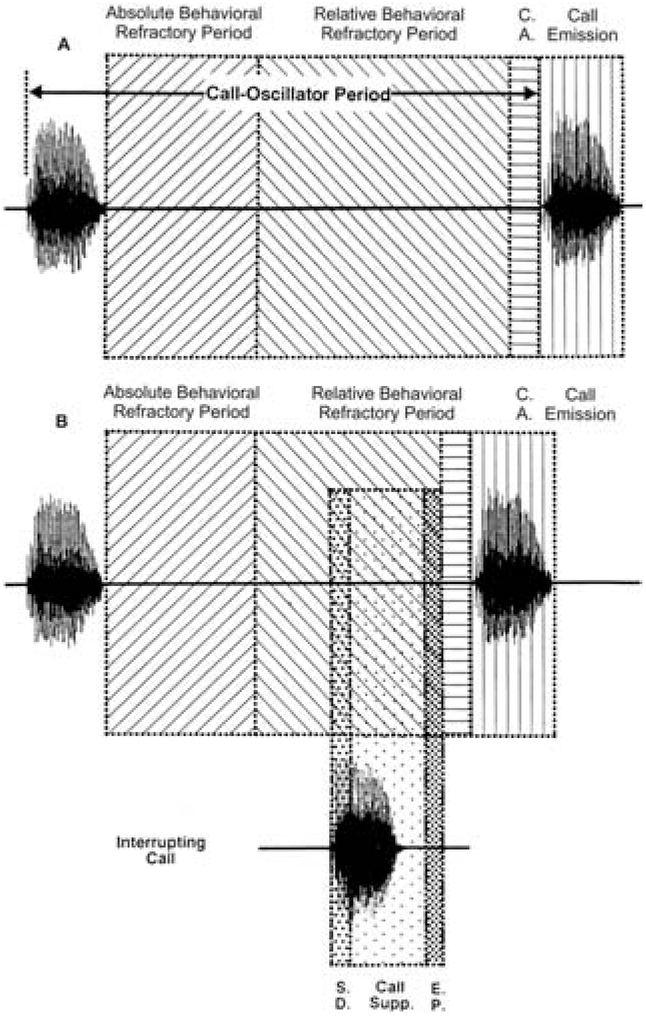

Fig. 7.17. Schematic representation of the phases of a calling cycle in frogs. (A) Internally triggered call generation. The period of the calling cycle is set by an internal oscillator, which sets the timing of the next call. (B) Externally triggered call generation. When the frog hears the call of a neighboring male, he resets his calling period so that calls do not overlap. Interrupting calls that occur during the absolute behavioral refractory period do not elicit vocal responses. Interrupting calls falling with the relative behavioral refractory period initially suppress calling and then stimulate calling after a delay. During the call activation phase (C.A.), calling cannot be suppressed, and calls other males are less likely to be perceived while a male is calling (emission phase, E.P.) S.D. indicates suppression delay that occurs when the frog is listening to the other male's call. After Klump and Gerhardt (1992).

of the male to external acoustic stimuli. Most frogs probably have an absolute behavioral refractory period immediately after the production of their own calls, during which they will not call even when they hear the call of another male. The length of this refractory period varies among species (Narins 1982a). After the absolute behavioral refractory period is a period in which males do not normally call spontaneously, but do respond to the calls of another male. In other words, hearing the call of another male causes an individual to call sooner than it otherwise would. Once a male's neural circuits have initiated call production (the call activation phase in fig. 7.17), it cannot be suppressed by hearing another call, and males probably have difficulty hearing calls produced during their own call emission. Consequently, frogs often do not respond to the calls or other males or to playbacks of calls that overlap all or part of their own calls.

Some frogs are capable of responding very rapidly to changes in background noise. For example, males of *Eleutherodactylus coqui* can accurately place their calls in gaps of only 750 milliseconds in continuous background noise, a time only slightly longer than that of their own calls. Furthermore, they can do so even if the timing of the gap is unpredictable, or if the sound level in the gap is only 4–6 dB below that of the overall background noise (Zelick and Narins 1982, 1983). This means that they must initiate production of their own calls within a few milliseconds of perceiving the reduction in background noise. In *Hyperolius marmoratus broadleyi,* males can insert their calls into gaps as short as 600 milliseconds, but not into 300 millisecond gaps (the calls themselves are about 83 milliseconds long). Responses are very fast, with most males initiating calls within 40–80 ms after a stimulus call ended (Grafe 1996b).

In *Hyla microcephala,* males not only alternate individual notes in longer overlapping multinote calls (as in fig. 7.16 C), but they also lengthen the gaps between the notes in their own calls to further reduce the chances of acoustic interference (Schwartz and Wells 1985). Males can respond to gaps in background noise as short as 20 milliseconds, which allows them to make this sort of note-by-note adjustment in the timing of their calls (Schwartz 1993). As a result, less than 10% of a male's calls usually suffer acoustic interference from his loudest neighbor, and even in groups of up to six males, 34–92% of a male's call notes are free of interference. In response to synthetic stimuli of variable duration, males lengthened the gap between their own call notes in response to stimuli up to 200 ms long (Schwartz 1993). They could not lengthen the gap sufficiently to avoid note overlap in response to 400 ms stimuli (fig. 7.18).

Acoustic interference between neighboring males could be detrimental to males either because it reduces a female's ability to locate a male, or because it obscures features that are critical for species identification or are attractive to females. Acoustic interference also could affect communication between males, because males do not hear the calls of other males that overlap their own calls, thereby making it difficult to judge the distance between them (Lemon 1971). Passmore and Telford (1981) found that females of *Hyperolius marmoratus* could locate speakers broadcasting simultaneous or alternating calls equally well. However, since

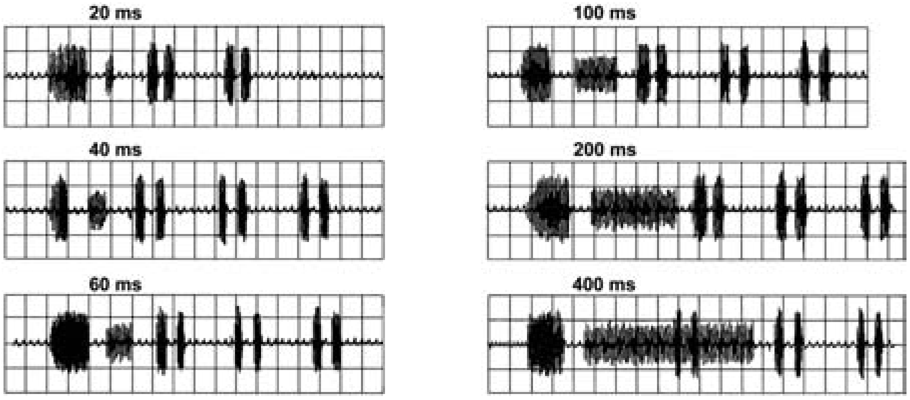

Fig. 7.18. Variation in call timing in *Hyla microcephala* in response to interruptions of the call by a synthetic stimulus of variable duration. The call of this species consists of a single introductory note followed by a variable number of diphasic secondary notes. The call notes with lower amplitude in each panel are the interrupting stimulus calls. Males responded to interrupting calls of 20–200 ms by increasing the gap between their call notes, thereby avoiding overlap of individual notes. They were not able to lengthen the gap sufficiently to avoid overlap in response to a 400 ms call. After Schwartz (2001).

calls were broadcast precisely in phase, species-specific temporal patterns were not obscured. Hence, their experiment did not address the second possible consequence of acoustic interference (Wells and Schwartz 1984a).

A definitive test of hypotheses advanced to explain the adaptive significance of call alternation was performed by Schwartz (1987a) using a four-speaker playback design. He found that in species with pulsed calls (*Hyla microcephala* and *H. versicolor*), females preferred alternated calls to those that overlapped so that the temporal structure of the call was obscured. No such discrimination occurred when the overlapped calls were completely in phase. Subsequent experiments with *H. microcephala* showed that the degrading effects of an interfering call were eliminated if the interfering call was only 6 dB lower than a male's own calls. These experiments support the hypothesis that call alternation is advantageous in allowing males to preserve species-specific temporal information in the call. In *Pseudacris crucifer,* a species with tone-like calls lacking temporal structure, females showed no preference for alternated vs. overlapped calls. Schwartz (1987a) also found that males gave more aggressive responses to advertisement calls broadcast in alternation with their own calls than to those that overlapped their calls. This supports the hypothesis of Lemon (1971) and Passmore and Telford (1981) that call alternation is advantageous in allowing interference-free communication with neighboring males. In short, call alternation can improve the effectiveness of communication with individuals of either sex, depending on the structural features of the call.

Experiments with other species generally are consistent with these interpretations. In *Physalaemus pustulosus,* which has a frequency-modulated call, females did not discriminate between overlapped and alternating calls (Schwartz and Rand 1991). In studies with *Hyperolius m. marmoratus,* a species with a tone-like advertisement call, Dyson and Passmore (1988) found that females did not discriminate between overlapping, simultaneous, and alternating calls. They did tend to prefer the leading call when stimulus calls overlapped, or one followed immediately after the other, even when the lead call was broadcast at a lower intensity. Females of *H. m. broadleyi,* which also have tone-like calls, also did not discriminate against overlapping calls, but showed a consistent preference for leading calls when the second call followed shortly afterward, perhaps because the beginning of the second call was masked by the first call. Results of experiments with *Alytes obstetricans* and *A. cisternasii* are not entirely consistent with Schwartz's (1987a) results, however. These frogs have very simple, tone-like calls and show only moderate precision of call alternation (Bosch and Márquez 2001a). Females did discriminate against overlapped calls in favor of nonoverlapped calls, but did not discriminate between leader and follower calls when they were overlapped (Bosch and Márquez 2000).

Synchronized Calling

In some species, a very rapid response to calls of other males produce a synchronizing effect that results in partial overlap of calls of neighboring males. This represents an extreme form of the unison bout calling described earlier and would seem to be disadvantageous to individual males in attracting mates. This type of chorusing is less common in anurans than in acoustic insects, where synchronized chorusing appears to have evolved as a byproduct of males attempting to out-signal one another (Greenfield 1990, 1994 a, b; Greenfield and Roizen 1993). Some examples of call overlap in anurans appear to be related to anti-predator behavior. For example, males of *Smilisca sila* typically call within 60–80 milliseconds of the onset of other males' calls. Their advertisement call notes are about 136 milliseconds long, so this results in the beginning of the second male's calls overlapping the end of the first male's calls (Tuttle and Ryan 1982; M. Ryan 1986b; Ibáñez 1991). In natural choruses, the calls of individual males overlapped those of their neighbors much more than expected by chance (Ibáñez 1991). Similar behavior was observed in a centrolenid frog, *Cochranella granulosa* (Ibáñez 1991). As in *Smilisca,* a male *C. granulosa* usually responds to the call of another male before that call has ended, resulting in partial overlap among calls of neighbors. This species breeds along streams where frog-eating bats are present, so this behavior probably is an antipredator strategy as well. Protection from predators comes at a cost in reduced attractiveness to females, however. Females of *C. granulosa* chose alternated calls over overlapped, out-of-phase calls in which the temporal structure of overlapped calls was obscured, but did not discriminate between alternated and in-phase overlapped calls (Ibáñez 1993).

Other species exhibit partial call overlap that is not related to protection from predators. For example, males of the Panamanian treefrog *Hyla ebraccata* usually respond to the multinote calls of their neighbors by placing their calls immediately after the end of the first male's introductory note. This results in the long introductory note of the second male overlapping one or more of the short secondary notes of the first male (fig. 7.2 E), effectively masking those notes (Wells and Schwartz 1984a). Experiments with females showed that they prefer the second masking call to the lead masked call when the calls are otherwise identical. It is not clear whether this represents an evolved interference tactic (Greenfield 1994b; Greenfield, Tourtellot, and Snedden 1997) or is simply a byproduct of timed responses to avoid overlap of introductory notes.

Males of the African frog *Kassina fusca* typically respond to calls of their neighbors very rapidly, so that more than 80% of all calls overlap. On average, about 21% of a lead call is overlapped by a follower call. Females exhibit a clear preference for follower calls when the degree of overlap is low, but switch to a preference for leader calls when the degree of overlap is high (Grafe 1999). These results suggest that males actively regulate the degree of overlap to correspond to female preferences. This was confirmed by experiments in which the degree of overlap in calls given in response to playbacks was nearly identical to that in natural interactions.

In some toads, the long trills given by one male stimulate calling by other males, which overlap their calls with those of their neighbors (as in fig. 7.16 E). This appears to be most common in species in which males call to attract females to the breeding site, but locate mates mainly by active searching (see chapter 9) and therefore are less likely to suffer the negative consequences of acoustic interference (Wells 1977b; Sullivan 1985a). In the only experiment performed with of a species that overlaps long calls, females of *Bufo americanus* preferred leader calls to follower calls in an overlapping pair, although this preference was affected by frequency differences as well (Howard and Palmer 1995).

Changes in Calling Rate

Male frogs usually call at faster rates in choruses than in isolation, and increases in calling rate have been demonstrated experimentally for many species (Wells 1988; Bendix and Narins 1999; Penna, Narins, and Feng 2005). In many cases, such changes result from antiphonal calling between males that can lead to relatively precise matching of calling rates of two interacting males. Such call matching also is seen in species with multinote calls. In *Hyla microcephala,* for example, there is a tendency for males to match the number of notes in their calls to those of their neighbors through note-by-note alternation (Schwartz and Wells 1985; Wells 1988; Wells and Taigen 1989). In the Asian rhacophorid frog *Philautus leucorhinus* and the Australian myobatrachid frog *Crinia georgiana,* males give a series of repeated notes before being answered by a nearby male (as in fig. 7.16 C). In both species, there is relatively precise matching of call note number, but addition of call notes by the responding male tends to level off at higher note rates (Arak 1983c; Gerhardt et al. 2000). Somewhat less precise call note matching was reported for *Kassina kuvangensis* (Grafe 2003). In contrast to the species discussed previously, males of species that do not call in dense choruses often show little or no response to playbacks of conspecific calls (Dubois 1977a; Greer and Wells 1980).

Although energetic costs (chapter 5) or risk of predation increase at high calling rates, females generally show a preference for high calling rates in two-choice experiments (Gerhardt 1988; Wells 1988; Gerhardt and Huber 2002; see chapter 8 for further discussion). Hence, the high calling rates of many species probably are a result of sexual competition. They derive in part from the tendency of many frogs to alternate their calls with those of other males, which leads to matching of calling rates by close neighbors. When males are presented with broadcast stimuli that greatly exceed their own spontaneous calling rates, they often cannot keep up. They tend to respond only to every second call, producing a calling rate about half that of the stimulus (Zelick and Narins 1985a; S. Moore et al. 1989; Klump and Gerhardt 1992; Bendix and Narins 1999; Grafe 2003).

Changes in Call Duration and Complexity

Frogs that have trilled calls often increase the duration of their calls in response to other males. This behavior has been demonstrated experimentally in *Hyla versicolor.* Males sometimes double call duration in response to the calls of other males, but they simultaneously reduce their calling rates, probably because high energetic costs make it impossible for males to produce long calls at high rates (Wells and Taigen 1986; Schwartz, Buchanan, and Gerhardt 2002; see also chapter 5). Females prefer both high calling rates and long calls, but prefer long calls at low rates to short calls at high rates (Klump and Gerhardt 1987). In natural choruses, background noise reduces the ability of females to discriminate among calls of different duration, and in such conditions, females tend to discriminate against only the shortest calls (Schwartz, Buchanan, and Gerhardt 2001). Consequently, as long as males calling together in one part of a pond roughly match one another in calling rate and call duration, they are likely to be equally attractive to females.

In many other species, males give single-note calls when calling alone, but add notes to their calls when calling in choruses (Wells 1988). In some species, a single type of note is repeated, as in *Rana catesbeiana* (Capranica 1968), *R. clamitans* (Wells 1978b; Ramer, Jenssen, and Hurst 1983; Bee and Perrill 1996), *R. virgatipes* (Given 1987), *R. septentrionalis* (Bevier et al. 2004), *Kassina kuvangensis* (Grafe 2003), and *Eupsophus emiliopugini* (Penna, Pottstock, and Velazquez 2005), although some species vary the structure of individual notes (Bevier et al. 2004; Suggs and Simmons 2005). Other species produce calls with distinct primary and secondary notes, and males tend to increase the number of secondary notes in their calls in response to the calls of other males or to experimental playbacks of calls (Wells 1988). This type of call is found in several Neotropical hylids, including species already mentioned, such as *Hyla ebraccata, H. microcephala, H. phlebodes, H. minuta,* and *Smilisca sila* (Fouquette 1960; Duellman 1970; Cardoso 1981b; Wells and Greer 1981; Tuttle and Ryan 1982; Schwartz and Wells 1984a, b, 1985; Wells and Schwartz 1984a). Similar calls are found in *Physalaemus pustulosus* (Rand and Ryan 1981; M. Ryan 1985b), several Australian myobatrachids (Ayre et al. 1984; Littlejohn and Harrison 1985; Gerhardt et al. 2000), a rhacophorid from Sri Lanka (Arak 1983c), and several ranid and hyperoliid frogs from Africa (Schiøtz 1967, 1999; Passmore 1977, 1978; Telford 1982; Backwell 1988; Pallet and Passmore 1988).

In two-choice playback experiments, females often exhibit a preference for complex, multinote calls over simple, single-note calls. This type of response has been documented in *Physalaemus pustulosus* (Rand and Ryan 1981*), Geocrinia victoriana* (Littlejohn and Harrison 1985), *Hyla ebraccata* (Wells and Schwartz 1984a), *H. microcephala* (Schwartz 1986), and *Hyperolius tuberilinguis* (Pallett and Passmore 1988). Females might prefer multinote calls because they indicate superior genetic quality in males that can sustain high levels of note production. Alternatively, a repetitive series of stereotyped click-like notes provides the best contrast with the continuous background noise of a multispecies frog chorus and therefore makes males more conspicuous to females (Schleidt 1973; S. Green and Marler 1979; D. Richards and Wiley 1980; Wells and Schwartz 1984a; Pallett and Passmore 1988). It also is possible that females are simply attracted to the longest calls, or those with the greatest total sound energy (G. Morris, Kerr, and Fullard 1978; Aiken 1982; Arak 1983a; Wells and Schwartz 1984a; Schwartz 1986, 1987b; Wells and Bard 1987). Males of these species probably would benefit from producing long, complex calls all of the time, but the high energetic cost of producing such calls and increased risk of predation probably makes this impossible (M. Ryan 1988a; Wells and Taigen 1989; Schwartz, Ressel, and Bevier 1995). An interesting question is why so many chorusing frogs tend to produce discontinuous calls consisting of repeated notes instead of long, continuous trills like those of many toads (*Bufo*). In addition to the energetic cost of continuous calling, Greenfield (1990) suggested that this pattern of calling produces acoustic windows of silence that enable a male to monitor the calling activity of his neighbors. This would be especially important in species that call in very dense choruses. Schwartz's (1987a) work on call alternation suggests that this explanation is applicable to frogs as well.

Changes in Call Intensity and Frequency Structure

Several studies have shown that males can alter the frequency structure of their advertisement or aggressive calls in response to the calls of other males, but the way in which frequency is altered differs among species. In *Leptodactylus albilabris,* males shifted the dominant frequency of their calls toward that of a call broadcast to them, either by raising or lowering dominant frequency, and they also increased the intensity of their calls in response to both advertisement and aggressive calls (Lopez et al. 1988). The shift in call frequency toward that of an opponent was interpreted as a possible mechanism to match the signal of an intruding male, possibly as a way of directing the signal toward that particular male. The change in call intensity could be advantageous in making a male more attractive to females or in delivering a stronger aggressive message to intruding males. The changes in call intensity and frequency can be constrained by the structure of the sound producing apparatus. Lopez et al. (1988) found that all of the males that showed an increase in call intensity also decreased call dominant frequency, so possibly changes in frequency are not in themselves adaptive.

Changes in call frequency also have been reported in several ranid frogs, including *Rana virgatipes* (Given 1999), *R. clamitans* (Bee and Perrill 1996), and *R. catesbeiana* (Bee and Bowling 2002; Bee 2002). In *R. virgatipes,* males give aggressive calls that are very similar in structure to advertisement calls, as they are in *R. clamitans,* but aggressive calls have secondary frequencies that are lower than those of advertisement calls. Males respond to playbacks of calls by lowering the secondary frequencies of their advertisement calls, which makes them more like aggressive calls (Given 1999).

In *R. clamitans,* males lowered the dominant frequency of their calls in response to playbacks of both single-note and multinote advertisement calls, and they also called at higher rates, produced longer notes, and decreased call amplitude (Bee and Perrill 1996). Bee, Perrill, and Owen (1999) demonstrated that males lower the dominant frequency of their calls more in response to low-frequency calls (350 Hz) than to calls with higher fundamental frequencies (400 and 450 Hz). Fundamental frequency is negatively correlated with body size, so these results suggest that males can use the frequencies of other males' calls to assess their body size. These results are consistent with earlier work by Ramer, Jenssen, and Hurst (1983), which showed that the level of aggressive responses by male green frogs differed in response to calls of large and small males.

The functional significance of this change in frequency is not yet clear. Bee, Perrill, and Owen (2000) tested two hypotheses to explain the significance of lowering the dominant frequency of calls: (1) The lower frequencies provide more accurate information about the size of the caller, or (2) the lower frequency provides deceptive information by making a male appear to be larger than he actually is. These authors found that calls given in response to playbacks were not more strongly correlated with male body size than were those given spontaneously, so the first hypothesis was not supported. Small males tended to reduce the dominant frequency of their calls more than did large males, so the possibility of deception remains a viable hypothesis. It also is possible that the change in frequency is correlated with some other change, such as the production of longer notes or changes in call intensity, and does not have an adaptive explanation. The magnitude of frequency alteration (about 20 Hz on average) is considerably smaller than the 50 or 100 Hz differences used by Bee, Perrill, and Owen (1999) to determine whether males can perceive differences in call frequency. It remains to be determined whether such small differences in dominant frequency elicit different behavioral responses from males. Bullfrogs (*R. catesbeiana*) exhibit similar changes in dominant frequency in response to other males, but lowering of dominant frequency does not appear to be related to fighting ability (Bee 2002).

Cricket frogs (*Acris crepitans*) also change the dominant frequency of their calls in response to calls of other males (Wagner 1989a, 1992). Larger males consistently won fights, and call dominant frequency was negatively correlated with body size. Males tended to retreat from broadcasts of low-frequency calls, but were more likely to attack speakers playing higher-frequency calls. Males also responded to low-frequency calls by lowering the dominant frequency of their own calls. This change in frequency gave males an advantage in aggressive interactions, but the changed frequency actually produced a less accurate correlation between body size and dominant frequency than did the unaltered frequencies. This suggests that the males do not alter call frequency to provide an honest indicator of body size. Wagner (1992) did find a positive correlation between the extent to which males lowered their call frequencies and the probability that they would initiate an attack (see also Burmeister et al. 2002). He therefore suggested that males alter the frequency of their calls to signal their fighting ability to opponents.

Chorus Leadership

There is a persistent idea in the anuran literature that certain individuals serve as leaders in choruses. An early proponent of this view was the Swedish naturalist Peter Kalm. Traveling in New Jersey in 1749, he reported that bullfrogs seemed to have "a captain among them. . . . When he begins to croak, all the others follow; and when he stops, the others are all silent" (Benson 1966, vol. 1, p. 297). Charles C. Abbott, a later naturalist who lived in the same region, disagreed with Kalm. Having carefully observed bullfrogs calling near his home, he reported that "the croaking of the 'captain' is not always the same individual. At times the initial croak would come from one side of the pond, then the other. . . This shows that not any one individual started and stopped the croaking of its companions" (Abbott 1885, 322–23).

Goin (1949) reported that *Pseudacris crucifer* choruses are organized into duets and trios, with certain individuals serving as chorus leaders. Subsequent authors have reported similar phenomena in other anurans (P. Anderson 1954; Hardy 1959; Bogert 1960; Brattstrom 1962a; Duellman 1967b; Brattstrom and Yarnell 1968; Wickler and Seibt 1974; Whitney and Krebs 1975b). Chorus leaders sometimes have been considered dominant individuals, and ordered sequences of calls have been characterized as hierarchies (Duellman 1967b; Brattstrom and Yarnell 1968; E. O. Wilson 1975). There is no real evidence that call-order is determined by aggressive interactions among individuals, nor is there evidence that choruses are analogous to dominance hierarchies in other animals.

Brattstrom and Yarnell (1968) reported that chorus leaders in *Physalaemus pustulosus* obtain more mates than other males, but subsequent work has refuted this (M. Ryan 1983b, 1985b). In fact, there is little convincing evidence that certain individuals consistently serve as chorus leaders. Most of the reports cited above are descriptive and provide little or no quantitative analysis of calling patterns. All are based on very brief observations, usually on a single night. In many choruses, certain males consistently call at higher rates than do others (Sullivan 1982a, 1983b; Wells and Taigen 1984; Given 1988a; Sullivan and Hinshaw 1990, 1992; Runkle et al. 1994; Jennions, Backwell, and Passmore 1995; Gerhardt, Dyson, and Tanner 1996; Zimmitti 1999; Bee et al. 2001; Tárano 2001; Friedl and Klump 2002; Schwartz, Buchanan, and Gerhardt 2002). These males sometimes tend to start calling bouts during short-term interactions with neighboring males (Whitney and Krebs 1975b), but in many species, leader-follower roles change frequently (e.g., Grafe 2003). Indeed, it has not been shown for any species of anuran that certain individuals serve as leaders of an entire chorus over long periods of time.

Acoustic Interactions between Males of Different Species

Although some species of anurans call in monospecific choruses, many call in aggregations of as many as 10 to 15 species, especially in the tropics (Duellman 1967a, 1978; Hödl 1977; Passmore 1978; Schlüter 1979, 1980a, b, c, 1981; Passmore and Telford 1981; Telford 1982; Schwartz and Wells 1983a, b, 1984a; Cardoso and Haddad 1992; Arzabe, de Carvalho, and Goes Costa 1998; Chek, Bogart, and Lougheed 2003). The presence of so many species calling together can lead to two problems for intraspecific communication. First, the calls of other species constitute noise that masks the vocalizations of conspecifics or obscure features of the calls needed for species recognition. Second, if calls of different species are sufficiently similar, then females might choose males of the wrong species as mates (Gerhardt 1994a, c). The problem of reproductive isolation in mixed-species choruses is discussed in the next section. Here I focus on problems of acoustic interference (see also Gerhardt and Schwartz 1995; Gerhardt and Huber 2002).

Littlejohn (1977) listed several ways in which acoustic interference between species could be minimized. One is spectral stratification, with each species using a different frequency band for communication. Another is spatial separation, either through aggregation of males into species-specific assemblages, or through use of different microhabitats for calling. A third is partitioning of calling time. Mistakes in species identification could be minimized by use of different coding patterns in advertisement calls, but this would have little effect on acoustic interference.

Spectral Separation

There are a number of examples in the literature of sympatric species using distinctly different frequency bands for broadcasting calls. For example, several species of *Eleutherodactylus* in Puerto Rico have calls with different dominant frequencies, so overlap between species is slight (Drewry and Rand 1983). Similar spectral stratification has been reported in anuran communities from South America, Australia, Asia, and Africa (Duellman 1967a, 1978; Dubois 1977a; Hödl 1977; Elzen and Kruelen 1979; Humphries 1979; Schlüter 1979, 1980a, b, c, 1981; Telford 1982; Garcia-Rutledge and Narins 2001). One interpretation of this pattern is that dominant frequencies of sympatric species have diverged, thereby enhancing the ability of each species to communicate in a noisy environment (Littlejohn 1977; W. Smith 1977; Drewry and Rand 1983). According to this view, each species has a unique "acoustic niche," the dimensions of the niche being shaped by acoustic competition among species (Duellman 1978; Duellman and Pyles 1983; Garcia-Rutledge and Narins 2001).

There are several problems with this interpretation. First, the argument implies that assemblages of breeding frogs are stable enough to allow selection to change frequency characteristics of calls. In fact, the number of species occurring together often differs from one site to another, even within a restricted geographic area (Crump 1974; Duellman 1990; Duellman and Thomas 1996; Arzabe, de Carvalho, and Goes Costa 1998), so it is not clear that any given assemblage represents a co-adapted community. Second, interspecific differences in dominant frequency are correlated with differences in body size, and many selective forces affect the evolution of body size. Third, there are many species in these assemblages that exhibit broad frequency overlap (Dubois 1977a; Hödl 1977; Humphries 1979; Schlüter 1979, 1980a, b, c, 1981; Telford 1982; Zelick and Narins 1982; Schwartz and Wells 1983a, b, 1984a; Garcia-Rutledge and Narins 2001). Finally, many species of frogs have broad auditory tuning curves (see discussion that follows) and are sensitive to sounds outside the frequency range of their own calls. Therefore, spectral separation of calls does not necessarily ensure a noise-free communication channel (Narins and Zelick 1988; Garcia-Rutledge and Narins 2001).

Most studies of spectral separation or "acoustic niche partitioning" in multispecies assemblages have not demonstrated statistically that spectral stratification occurs more frequently than expected by chance. Chek, Bogart, and Lougheed (2003) reanalyzed data from a number of these studies, along with previously unpublished data on Amazonian frog assemblages. They found statistical evidence for greater than expected call separation in only three of 11 assemblages studied. In most cases, separation was most apparent in dominant frequency, which probably is related to body size differences among species, but there was some evidence for separation by pulse rate in two assemblages. The evolutionary processes that have resulted in acoustic separation in these assemblages are not known. Overall, the analysis of Chek, Bogart, and Lougheed (2003) provides only weak support for the concept of acoustic niche partitioning in frogs.

Spatial Separation

Formation of species-specific aggregations within mixed-species choruses is frequently mentioned as a way of improving the efficiency of acoustic communication by polarizing the acoustic environment (Mecham 1961; Dubois 1977a; Hödl 1977; Littlejohn 1977; Passmore 1978; Telford 1982; Passmore and Carruthers 1995). Unfortunately, rigorous statistical analyses of spatial distributions of calling males are hard to find. Some clustering by species results from distinct preferences for calling sites in different microhabitats, on different types of plants, or at different heights in vegetation, but different species usually are within hearing range of each other. Often they are distributed in a mosaic, with heterospecific males calling only a few centimeters from one another (Fouquette 1960; Duellman 1967a; Hödl 1977; Littlejohn 1977; Passmore 1978; Bowker and Bowker 1979; Mac Nally 1979; Telford 1982; Schwartz and Wells 1983a, b, 1984a; Etges 1987; Garcia-Rutledge and Narins 2001).

Drewry and Rand (1983) reported that two Puerto Rican species, *Eleutherodactylus locustus* and *E. brittoni,* tended to use similar calling microhabitats where each species was found alone, but used different microhabitats when found in the same place. Unfortunately, they did not present a quantitative analysis of calling sites. Ptacek (1992) reported that the two species of North American gray treefrogs, *Hyla versicolor* and *H. chrysoscelis,* used a similar range of calling sites when each species was found alone in a pond. In ponds where both occurred, there was a tendency for males of *H. versicolor* to be found at more elevated sites and *H. chrysoscelis* closer to the ground or water. Even with these changes in spatial distribution, the calling sites of the two species overlapped broadly when they occurred in the same pond, and males sometimes respond to the calls of heterospecific males in mixed choruses. Males of *Hyla cinerea* were somewhat more likely to call from elevated perches in ponds where *H. gratiosa* was present than in ponds where it was not; *H. gratiosa* generally calls from the water surface (Höbel and Gerhardt 2003). In a study of two territorial ranids occupying the same pond, Given (1990) reported that choice of territories by males of the larger species, *Rana clamitans,* was not influenced by the presence of the smaller species, *R. virgatipes,* but there was some tendency for males of the latter species to avoid calling close to male green frogs. This behavior probably was related more to defense of oviposition sites than to acoustic interference. Acoustic interaction between the two species was rare.

Temporal Separation

When there is little spatial separation between species and call frequencies overlap, there can be considerable acoustic interference between species that can affect a male's ability to attract mates. The vocal repertoires of three sympatric Panamanian tree frogs, *Hyla ebraccata, H. microcephala,* and *H. phlebodes,* are very similar in both structure and function, and there is broad frequency overlap in their calls. Choruses of both *H. microcephala* and *H. phlebodes* can inhibit calling by *Hyla ebraccata* (Schwartz and Wells 1983a, b). Both species call in distinct bouts, and *H. ebraccata* calls mainly in the silent periods between bursts of heterospecific calls (fig. 7.19). Experimental playbacks of both a recorded chorus of *H. microcephala* calls and filtered noise of the appropriate frequency showed that *H. ebraccata* males were more likely to give aggressive calls and multinote calls during silent periods than during playbacks (fig. 7.20). Since

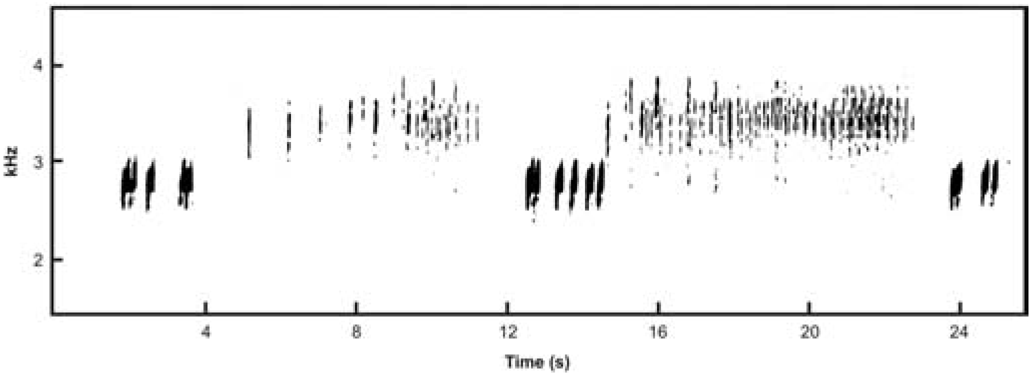

Fig. 7.19. Interaction between a chorus of *Hyla phlebodes* and several males of *H. ebraccata.* The calls of higher frequency are those of three or four *H. phlebodes* males calling in a group. The calls of lower frequency are those of several *H. ebraccata* males calling nearby. Note the lack of overlap in calls of the two species. From a recording by Kentwood D. Wells and Joshua J. Schwartz.

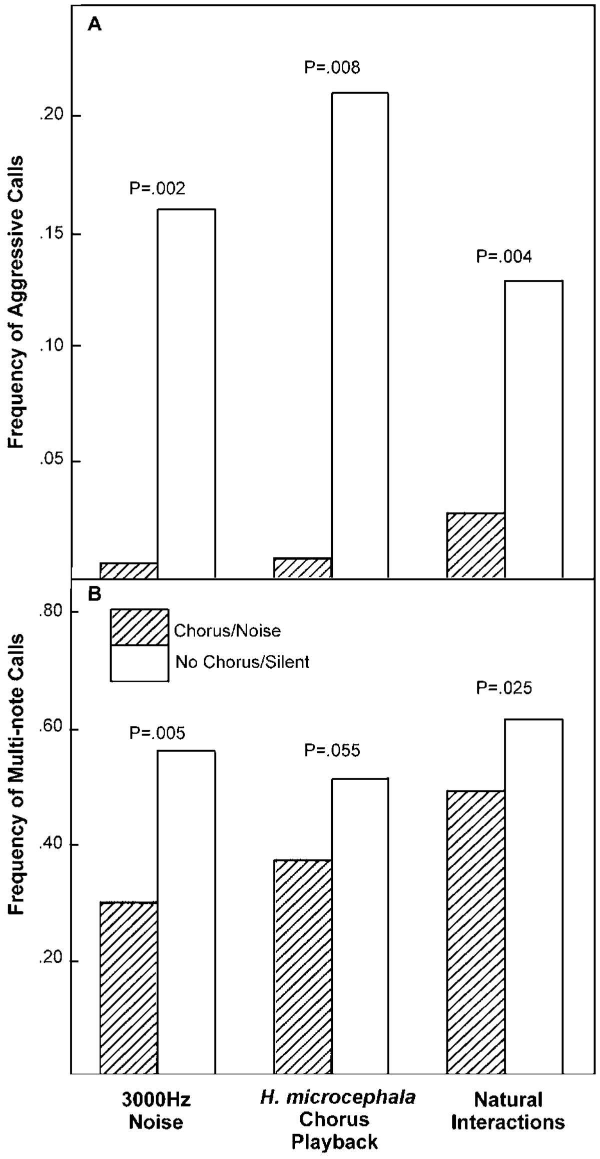

Fig. 7.20. Effect of acoustic interference on the calling of *Hyla ebraccata.* (A) Frequency of aggressive calls given by *H. ebraccata* during silent periods and during natural choruses of *H. microcephala,* during playbacks of a *H. microcephala* chorus, and during playbacks of filtered noise centered on the dominant frequency of the calls of *H. ebraccata.* (B) Frequency of multinote calls given by males of *H. ebraccata* in the same situations. The data are combined for all playback intensities between 80 and 104 dB SPL. Both aggressive calls and multinote calls are given in response to other males in the chorus, so these results show that background noise masks the calls of neighboring males. Plotted from data in Schwartz and Wells (1983a).

both types of calls are given in response to other males in the chorus, these experiments showed that background noise masks the calls of neighboring males.

All three species also give synchronized responses to individual heterospecific calls (Schwartz and Wells 1984a, b, 1985). Males of *H. microcephala* sometimes alternate individual call notes with those of *H. phlebodes;* when their calls are interrupted, they increase the interval between notes to avoid note overlap, just as they do in response to conspecific calls. *Hyla ebraccata* males are most responsive to sounds with a dominant frequency and duration similar to that of their own calls, although there was some response calls of different frequency and duration as well. Playback experiments with females of *H. ebraccata* showed that a chorus of *H. microcephala* calls makes it more difficult for females to orient to conspecific calls (Schwartz and Wells 1983b). In addition, females prefer conspecific calls free of interference to those overlapped by individual calls of *H. microcephala* (Schwartz and Wells 1984a). Ehret and Gerhardt (1980) and Gerhardt and Klump (1988a) obtained similar results by using synthetic masking noise in choice experiments with females of *Hyla cinerea.*

There are several other examples of one species shifting the timing of its calls to avoid overlap with those of other species, or males being completely inhibited by chorusing of heterospecifics. Males of *H. ebraccata* sometimes respond to the calls of *Scinax boulengeri,* which completely overlap the frequency range of their calls (personal observations). Males of *Eleutherodactylus coqui* are responsive to a range of frequencies outside those of their own calls and sometimes engage in vocal interactions with males of *E. portoricensis* (Zelick and Narins 1982). The Australian frog *Pseudophryne semimarmorata* is inhibited from calling by the much longer calls of *Geocrinia victoriana* (Littlejohn and Martin 1969). Similarly, the long calls of *Crinina parinsignifera* cause *C. signifera* males to stop calling and move away. The shorter calls of *C. signifera* have a less dramatic effect on *C. parinsignifera;* the latter shift the timing of their calls to avoid overlap with those of *C. signifera,* but they do not reduce overall calling rates (Mac Nally 1982; Littlejohn, Harrison, and Mac Nally 1985). On the other hand, Odendaal, Bull, and Telford (1986) found that *C. signifera* calls were much louder than those of sympatric *C. riparia,* and the former species often calls in dense choruses that produce continuous high background noise. They speculated that the noise generated by *C. signifera* prevents *C. riparia* from calling in the same habitats.

Similar examples of interspecific acoustic interference have been reported in birds (Cody and Brown 1969; Wickler 1972; Ficken, Ficken, and Hailman 1974; Bremond 1978; Popp, Ficken, and Reinartz 1985; Popp and Ficken 1987) and insects (Samways and Broughton 1976; Samways 1977a, b; Latimer 1981; Latimer and Broughton 1984; Bailey and Morris 1986; Greenfield 1988, 1990, 1993, 1997; Schatral 1990; Schatral and Yeoh 1990). There is even a report that calling by a diurnal tropical frog, *Dendrobates pumilio,* is inhibited by the loud sounds of cicadas (Páez, Bock, and

Rand 1993). In both birds and insects, the tendency to shift calls or songs in response to those of other species depends on the similarity of the heterospecific signals, especially the degree of frequency overlap. Furthermore, in orthopterans, males will alternate calls with males of other species only if they respond in this way to conspecific calls (Latimer and Broughton 1984). Hence, interactions between species probably are a by-product of intraspecific interactions. Consequently, discontinuous singers, which produce repeated chirps, are inhibited by continuous singers, which produce trills; only the former are "programmed" to produce their songs after those of a neighbor have ended (Greenfield 1990; Schatral 1990).

Interspecific Use of Aggressive Calls

Closely related species often have very similar aggressive calls, and in some cases these are used in interspecific communication. Defense of calling sites against heterospecific males has been reported in leptodactylids (Drewry 1970), myobatrachids (Pengilley 1971a; Mac Nally 1982, 1984a; Littlejohn, Harrison, and Mac Nally 1985) dendrobatids (Wells 1980a), and hylids (Paillette 1970b; Humphries 1979; Cardoso 1981b; Schwartz and Wells 1984a, b, 1985). Males of some species give aggressive calls in response to playbacks of heterospecific advertisement or aggressive calls (Gambs and Littlejohn 1979; Humphries 1979; Brzoska 1982; Mac Nally 1982; Littlejohn, Harrison, and Mac Nally 1985; Gerhardt 2001).

The three Panamanian tree frogs discussed earlier, *Hyla ebraccata, H. microcephala,* and *H. phlebodes* (fig. 7.21 top), have very similar vocal repertoires. In particular, the long aggressive calls of these species are much more similar to each other than are their advertisement calls (Schwartz and Wells 1984a). The similarity in the structure of aggressive calls in these three species (fig. 7.21 bottom) could result from descent from a common ancestor. *Hyla microcephala* and *H. phlebodes* are considered to be members of the *H. microcephala* species group, whereas *H. ebraccata* is a member of the *H. leucophyllata* species group. Cladistic analysis suggests that these species groups are relatively closely related (Duellman and Trueb 1983; Kaplan 1994; Duellman 2001). In playback experiments, males of *H. ebraccata* gave more aggressive calls in response to aggressive calls of *H. microcephala* and *H. phlebodes* than to advertisement calls of these species, although they were most responsive to conspecific aggressive calls (fig. 7.22). This indicates that males of *H. ebraccata* recognize the calls of all three species as aggressive calls, and indeed, males have been observed engaging in interspecific fights over calling sites (Schwartz and Wells 1984a). The high pulse repetition rate that characterizes the aggressive calls of all three species is the most important feature in eliciting aggressive responses from males (Wells and Schwartz 1984b).

Bottom: Sound spectrograms of long aggressive calls of *H. ebraccata* (left), *H. phlebodes* (center), and *H. microcephala* (right). Note overlap in both frequency and pulse rate among species. From recordings by the author.

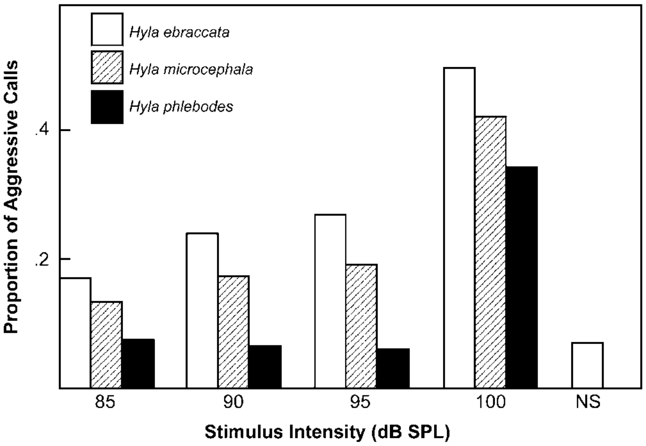

Fig. 7.22. Proportion of aggressive calls given by males of *Hyla ebraccata* to long aggressive calls of *H. ebraccata, H. microcephala,* and *H. phlebodes* at four different playback intensities. NS = no stimulus (silent) periods. Males of *H. ebraccata* were most responsive to conspecific calls and least responsive to those of *H. phlebodes.* After Schwartz & Wells (1984a).

Responses of Females to Conspecific and Heterospecific Calls

A major focus of the early work on anuran vocalizations was the role of calls in maintaining reproductive isolation between species, and this remains an active area of research today (see reviews by Gerhardt 1982, 1988, 1994 a, c; Gerhardt and Schwartz 1995; Gerhardt and Huber 2002). Traditionally, species recognition has been treated as a process distinct from sexual selection. Some authors, however, have treated species recognition and reproductive isolation as incidental effects of sexual selection (Thornhill and Alcock 1983; West Eberhard 1983). They argue that communication signals of two related species diverge in allopatry because of female preferences for certain types of calls. The species-specific nature of the resulting signals would be an incidental by-product of this preference, but the species would be reproductively isolated if they become sympatric. Others, most notably Paterson (1978, 1980, 1981, 1982, 1985), have argued that each species has a set of signals that constitute a Specific Mate Recognition System. Interspecific differences in call structure have been attributed to independent adaptation of signal structure to different environments, with sexual selection and interactions among species playing a relatively minor role (Passmore 1981).

From the point of view of a female frog trying to find a suitable mate, intraspecific mate choice (sexual selection) and species recognition are part of the same process of signal recognition (M. Ryan and Rand 1993b; Gerhardt 1994a, c; Gerhardt and Schwartz 1995). When a female enters a mixed-species chorus, she is confronted by an array of males calling to attract mates. Some of these are conspecifics, but many are not. The female's sensory system is selectively tuned to a certain range of values of each call feature, and those calls that provide the greatest sensory stimulation are most likely to elicit phonotaxis. Often the types of features that distinguish closely related species from one another, particularly differences in frequency and fine-temporal features such as pulse repetition rate, tend to be subject to stabilizing selection. That is, females generally exhibit preferences for average values of these traits over extreme values. These usually are relatively static call features that exhibit little variation within and among conspecifics in a chorus (Gerhardt 1991, 1994a, c; Castellano and Giacoma 1998; Giacoma and Castellano 2001). In contrast, as discussed in chapter 8, females often exhibit directional preferences for gross temporal features such as call intensity, calling rate, call duration, or call complexity. All of these features are quite variable within and among individuals and are subject to sexual selection. The net result of females exhibiting preferences for average values of some call traits and for extreme values of others is that they usually pick males of the same species. Within that subset of males in a mixed chorus, they often prefer individuals that invest a considerable effort in call production.

Under some circumstances, heterospecific calls, or certain features of heterospecific calls, can elicit phonotaxis by females (Gerhardt 1994a). When females have been presented only with heterospecific calls, they sometimes exhibit phonotaxis toward those calls (Martof 1961; Gerhardt 1974a, 1981b, 1994a; Gerhardt and Doherty 1988; Backwell and Jennions 1993; M. Ryan and Rand 1993b; Gerhardt and Schwartz 1995; Gerhardt 2001). Even filtered noise of the appropriate frequency can elicit phonotaxis in no-choice experiments (Ehret and Gerhardt 1980).

In a natural chorus, females might orient toward heterospecific calls if conspecific males are scarce. When many conspecifics are present, females can be expected to exhibit nearly perfect preferences for conspecific calls. Females are most likely to be attracted to heterospecific calls when those calls closely resemble conspecific calls in one or more key features. Calls that are less similar to conspecific calls are less likely to reach a threshold for sensory stimulation required to elicit female phonotaxis. It is possible that some heterospecific calls are so different from conspecific calls that they are simply ignored by females. Females also might actively avoid heterospecific calls although recent experimental studies have shown that females usually do not exhibit this type of avoidance behavior (Gerhardt, Dyson, Tanner, and Murphy 1994). There also have been experiments showing that females sometimes are more attracted to a conspecific call to which an element of a heterospecific call has been added than they are to normal conspecific calls (M. Ryan and Rand 1993a, c); this is discussed in more detail in the following.

Evidence for Species Recognition

Many of the pioneers of anuran acoustic research devoted much of their effort to documenting differences in call structure among closely related species and showing that these differences constitute important barriers to gene exchange between species (A. P. Blair 1941a, b, 1942; W. Blair 1955, 1956a, 1958a, b, d, 1964; Littlejohn 1959; Bogert 1960; Martof 1961; Mecham 1961). There have been many descriptive and statistical comparisons of the calls of sympatric anuran species (W. Blair 1958a, b, d; Bogert 1960; Littlejohn 1959, 1965; Fouquette 1960; Littlejohn and Martin 1965a; Duellman 1967a, 1978; Günther 1969; Channing 1976b; Hödl 1977; Passmore 1978; Schluter 1979, 1980a, b, c, 1981; Telford 1982; Drewry and Rand 1983; Duellman and Pyles 1983; Schwartz and Wells 1984a; Wollerman and Wiley 2002b). All of these have shown that sympatric species never have identical advertisement calls. In most cases, the calls of two species can be distinguished by more than one spectral or temporal feature.

There are many examples of cryptic or morphologically similar species of anurans that can be distinguished mainly by differences in their calls, or were first identified as separate species by differences in calls. These include several members of the *Rana pipiens* complex in North America (Hillis 1988), two treefrogs from Puerto Rico, *Eleutherodactylus coqui* and *E. portoricensis* (Thomas 1966), sympatric morphs of *Polypedates leucomystax* in Malaysia (Narins et al. 1998), morphologically similar species of *Breviceps* and *Hyperolius* in Africa (Minter 1997; Channing, Moyer, and Burger 2002), and many others. In some cases, groups of morphologically similar species are complexes of diploid and polyploid species, with the polyploids presumably being derived from the diploids. The latter include *Hyla chrysoscelis* (probably consisting of several separate diploid species) and *H. versicolor* (tetraploid) in North America (Ptacek, Gerhardt, and Sage 1994; Keller and Gerhardt 2001), diploid and tetraploid populations of green toads (*Bufo viridis*) in Europe (Castellano et al. 1998; Castellano, Giacoma, and Dujsebayeva 2000; Stöck 1998), species of *Xenopus* in Africa (Tymowska 1991), species of *Neobatrachus* in Australia (Roberts 1997), and species of *Phyllomedusa* in South America (Haddad, Pombal, and Batistic 1994).

When Charles M. Bogert published his 1960 review, the evidence that anuran calls were important for species recognition was largely circumstantial and based on qualitative comparisons of calls. The only attempt to test the hypothesis had been an experiment in which female *Pseudacris streckeri* were given a choice of conspecific calls and those of *P. clarki* (Littlejohn and Michaud 1959). The experiment showed conclusively that females were attracted only to the calls of their own species. Since then, many similar experiments have been conducted in both the field and laboratory (table 7.2). Some have suffered from a lack of statistical independence because multiple responses of the same females were included in the analysis. Whenever possible, I have reanalyzed the data to compare numbers of females choosing conspecific and heterospecific calls. The few cases in which females did not clearly discriminate between conspecific and heterospecific calls (Martof 1961; Awbrey 1968) probably failed because the test females were not yet ready to mate or were simply unresponsive to the test stimuli. Most investigators have tested females collected while already in amplexus to ensure a high degree of receptivity. Females collected in amplexus do not appear to be any less discriminating than those collected while approaching calling males (C. Murphy and Gerhardt 1996; Witte et al. 2000). In at least one species, gravid females that actually are ovulating are more receptive than those that are not (Lea, Halliday, and Dyson 2000). Gerhardt (1992a) and Gerhardt and Huber (2002) provide thorough reviews of techniques used in playback experiments.

Identification of Features Used in Species Recognition

Bogert (1960) cautioned against assuming that those features of calls that seem most distinct to human listeners are necessarily those most important to female frogs. Even when there are significant differences in various temporal features of calls, one cannot assume that all differences are equally important in species discrimination. Similarly, one cannot assume that calls differing in only one or two features are less likely to be distinguished by females than calls differing in many features. Duellman and Pyles (1983) performed a principal component analysis that combined seven spectral and temporal features of the calls of several Neotropical hylid species; they concluded that calls of related species are most similar when the species are not sympatric. Without knowing which features females use for call recognition, however, one cannot make any assumptions about their importance in preventing cross-species matings.

The best way to identify features used for call recognition is to alter calls experimentally, or use synthetic calls to systematically vary spectral and temporal features (Gerhardt 1988, 1992a, 2001; Gerhardt and Huber 2002). In an early experiment, Martof and Thompson (1964) found that major changes in call repetition rate, call intensity, and the temporal structure of call notes had relatively little effect on choice of calls by female *Pseudacris triseriata*. Females did discriminate against calls that deviated significantly from the average dominant frequency of conspecific calls, and they preferred a natural call to white noise. Unfortunately, Martof and Thompson did not use females captured in amplexus, so some of their results are questionable. More recent studies generally have found that females are relatively tolerant of small deviations in frequency or temporal features of calls, but major deviations from typical features of conspecific calls make synthetic calls less attractive to females (e.g., Kime et al. 1998; Witte, Ryan, and Wilczynski 2001; Bosch 2002b).

Loftus-Hills and Littlejohn (1971) were the first to use synthetic calls to investigate the basis of call discrimination in a pair of sympatric species. They presented females of two Australian frogs, *Litoria ewingii* and *L. verreauxii,* with calls differing in pulse repetition rate, but identical in all other temporal properties and dominant frequency. The difference in pulse rate was sufficient for effective discrimination by females of both species, even though this is not the only difference in the natural calls of these species (Littlejohn 1965). In a more detailed study, Straughan (1975) presented female *Pseudacris regilla* and *P. cadaverina* with synthetic calls differing in frequency, duration, pulse duration, and pulse repetition rate, all of which differ in natural calls of the two species. Only pulse repetition rate was important for species discrimination. Additional experiments with synthetic calls have established the importance of pulse repetition rate for species recognition in many species, including *Bufo woodhousii* (Sullivan and Leek 1987) and *Hyla microcephala* (Schwartz 1987b). In the latter species, differences in pulse repetition rate also are sufficient for females to distinguish advertisement calls from conspecific aggressive calls, a result obtained in experiments with *H. ebraccata* as well (Wells and Bard 1987).

Species Recognition in the *Hyla versicolor* Group

Carl Gerhardt and his colleagues have conducted detailed studies of call recognition in *Hyla versicolor* and *H. chrysoscelis* (Gerhardt 1978c, 1982, 1988; Gerhardt and Doherty 1988; Diekamp and Gerhardt 1995; Gerhardt, Dyson, and Tanner 1996; Gerhardt and Schul 1999; Schwartz, Buchanan, and Gerhardt 2001; Bush, Gerhardt, and Schul 2002; Schul and Bush 2002; see Gerhardt 2001 and Gerhardt and Huber 2002 for reviews). This system is an interesting one in which to study the evolution of call preferences, because the evolutionary history of the two species is well understood. *Hyla versicolor* is a tetraploid species derived from the diploid *H. chrysoscelis,* apparently more than once (Ptacek, Gerhardt, and Sage 1994).

At the same temperature, the calls of sympatric populations of these species have similar dominant frequencies and duration, but differ in pulse shape, pulse duration, and pulse repetition rate. The slower pulse rate of *H. versiolor* is a direct effect of polyploidy, as shown by the lower pulse rates of triploid and tetraploid males artificially produced in the laboratory (Keller and Gerhardt 2001). Differences in pulse rate alone are sufficient for females of each species to discriminate conspecific from heterospecific calls. Females also can use differences in pulse shape and pulse rise time to discriminate between conspecific and heterospecific calls, but these differences are of relativley minor importance compared to the large differences in pulse rate that females normally would encounter in the field. The responses of femaled are temperature-dependent. Pulse rate changes with temperature, and a female prefers calls with a pulse rate corresponding to that of conspecific calls at her own body temperature (Gerhardt 1978c). If the pulse-rate selectivity of females were not adjusted to changing temperature, then they might choose males of the wrong species, because the pulse rate of a warm *H. versicolor* is similar to that of a cool *H. chrysoscelis.*

The two species use somewhat different mechanisms to discern differences in pulse rate, with *H. chrysoscelis* using absolute pulse rate, whereas *H. versicolor* uses a combination of pulse duration and interpulse interval (Schul and Bush 2002). There also are differences in the responses of females of the two species to call frequency structure. Calls of both species have two distinct frequency bands, and females of both species prefer these calls to those lacking either the high or low frequency band (Gerhardt and Doherty 1988 Gerhardt 2001). Females of *H. versicolor* prefer calls with only the higher frequency present to those with only the lower frequency, but this is not true for *H. chrysoscelis* (Gerhardt, 2001). Hence, despite the fact that populations of the tetraploid *H. versicolor* clearly are derived from populations of diploid *H. chrysoscelis,* there has been evolutionary change in the mechanisms of call recognition in the derived species.

Species Recognition in the *Hyla cinerea* Group

Among the most detailed work on call recognition is the work of Gerhardt and others on *Hyla cinerea* (Gerhardt 1974b, 1976, 1978a, b, 1981b, 1982, 1987, 1988; Gerhardt and Mudry 1980; Megela Simmons 1988; Megela Simmons, Buxbaum, and Mirim 1993; Gerhardt, Allan, and Schwartz 1990; Allan and Megela Simmons 1994) and *H. gratiosa* (Gerhardt 1981a; Bodnar 1996; see Gerhart 2001 and Gerhardt and Huber 2002 for reviews). These species often breed at the same time and place as several other hylids of similar size (fig. 7.23), and *H. cinerea* and *H. gratiosa* are capable of producing viable and fertile hybrids. These species have similar calls, although each one differs from the others in both frequency and temporal structure (fig. 7.24). Gerhardt varied both spectral and temporal properties of calls and tested the responses of females to "standard" and altered synthetic signals. This allowed him to establish which features are important for call recognition and to determine how much each feature can be changed without reducing the effectiveness of the signal. The results can then be related

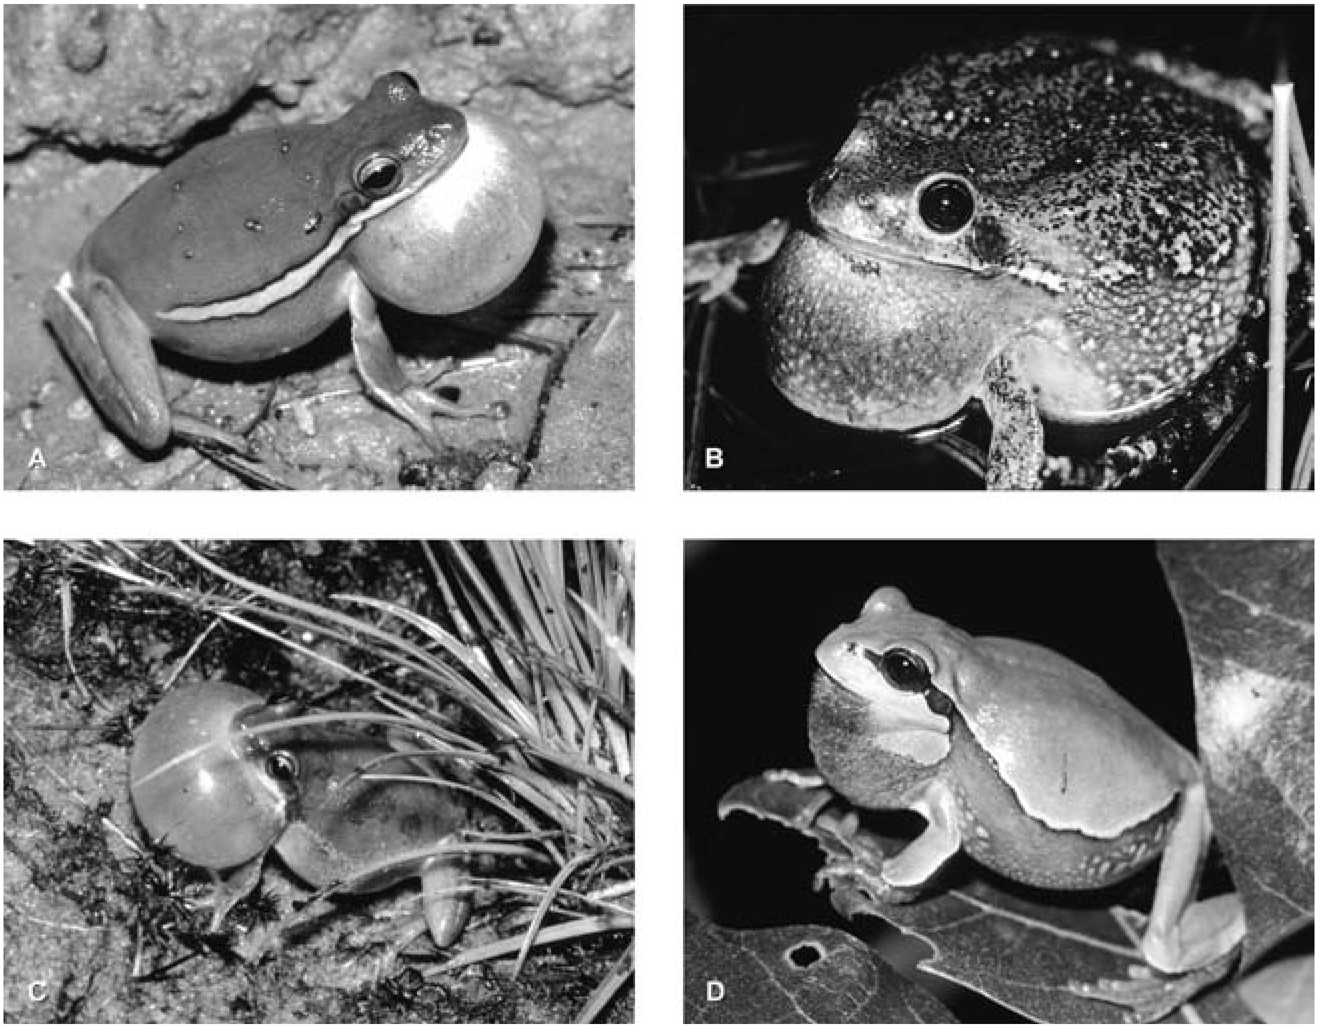

Fig. 7.23. Four mophologically similar treefrogs that sometimes occur together in breeding ponds in the southeastern United States. (A) *Hyla cinerea.* (B) *H. gratiosa.* (C) *H. squirella.* (D) *H. andersonii.* Photos by H. Carl Gerhardt (A, C) and Kentwood D. Wells (B, D).

to differences in the calls of sympatric species, as well as to differences between calls within the species' repertoire.

The advertisement calls of *H. cinerea* have a waveform periodicity of about 300/s. Females prefer standard calls to those with very high (900/s) and very low (below 100/s) periodicity, but do not discriminate between 300 and 450/s (Gerhardt 1978b). The calls of one sympatric species, *H. squirella,* overlap those of *H. cinerea* in frequency, but have a waveform periodicity of around 100–130/s; the difference in this fine temporal property apparently is sufficient for species discrimination. The calls of two other species, *H. andersonii* and *H. gratiosa,* have a periodicity of about 300 and 450/s respectively, so differences in this property alone would not allow *H. cinerea* females to distinguish the calls of these species from those of conspecifics.

The advertisement call of *H. cinerea* has a bimodal spectrum, with one energy peak at around 900 Hz and a second between 2,700 and 3,300 Hz. At low intensities, females do not discriminate between calls with both frequency peaks present and calls with only the 900 Hz component, but at higher intensities, they discriminate against calls with the high frequency component attenuated or missing (Gerhardt 1981b). Even at very low playback intensities, females prefer standard calls to those with the low frequency component attenuated by 12 dB (Gerhardt 1976, 1981b). Hence, the presence of both high and low frequency components is important for species recognition at close range, but low frequency sound is sufficient to attract females to a chorus from some distance away. When the low frequency peak of the call is varied, females prefer calls of average frequency (about 900 Hz) to those with lower (600–700 Hz) or higher (1100–1200 Hz) frequency peaks (Gerhardt 1982), except at very low temperatures (Gerhardt and Mudry 1980). If intermediate frequencies are added to stimulus calls, they be-

come less attractive to females (Gerhardt and Höbel 2005). These preferences are related to the tuning of the peripheral auditory system and have the effect of excluding calls falling within the frequency range of sympatric species (Gerhardt 1987; Gerhardt and Höbel 2005).

Experiments with *H. gratiosa* produced results qualitatively similar to those for *H. cinerea* (Gerhardt 1981a). Again, fine temporal properties alone are not sufficient to allow females to discriminate between conspecific calls and those of *H. cinerea.* The presence of a pulsed component at the beginning of the call is important to elicit phonotaxis in *H. gratiosa,* but not in *H. cinerea.* The presence of two spectral peaks also is important, but the optimum frequencies in these peaks differ from those of *H. cinerea.* Addition of components between the two spectral peaks in synthetic *H. gratiosa* calls has no effect on the attractiveness of the calls, whereas the attractiveness of *H. cinerea* calls is reduced when extra components are added. In fact, the optimum high frequency peak for *H. gratiosa* falls in the range of frequencies that reduces the attractiveness of *H. cinerea* calls when added to synthetic signals (Gerhardt 1974b). Alterations in the frequency and harmonic structure of calls can affect call recognition in this species as well, but their effect depends on how different call characteristics are combined (Bodnar 1996).

A number of general points can be made from the work on these two species. First, some species have very distinctive features in their calls that are irrelevant for species recognition, such as the pulsed component at the beginning of the call in *H. cinerea.* This demonstrates the need for careful experimental studies to confirm the functions of different call components. Second, there are differences in the way species-specific information is encoded in calls, even between closely related species. Hence one cannot generalize from one species to another and assume that certain spectral or temporal properties are always important for call recognition. Third, females probably recognize calls of their own species by responding to several different call characteristics in combination, and the way the characteristics are combined can affect the responses elicited. Finally, different properties can be responsible for the lack of phonotactic responses by females to different heterospecific calls. For example, the properties that lead females of *H. cinerea* to prefer their own species' calls over those of *H. squirella* are not the same as those that elicit greater phonotaxis to conspecific calls than to calls of *H. andersonii* or *H. gratiosa.*

Species Recognition in the Genus *Physalaemus*

Another anuran that has become a model system for studies of call recognition and the evolution of vocal signals is the leptodactylid frog *Physalaemus pustulosus* (M. Ryan 1985b; Wilczynski, Rand, and Ryan 1995; M. Ryan and Rand 2001). As discussed previously, this species has a call consisting of a whine note that decreases in frequency, sometimes followed by one or more noisy chuck notes (fig. 7.25). The whine alone is both necessary and sufficient to elicit phonotaxis by females, but females prefer calls with one or more chucks (Rand and Ryan 1981). The position of the chuck makes little difference to females; calls in which the chuck preceded the whine were as attractive as normal calls in which the chuck followed the whine (M. Ryan 1983a). In fact, experiments with synthetic calls showed that the chuck could be placed in any number of positions before or after the whine and still be as attractive as the normal whine-chuck call (Wilczynski, Rand, and Ryan 1999). If the frequency sweep of the whine was reversed, however, the call was less attractive to females. Frequency-modulated whines also were more attractive than were constant-frequency tones with frequencies encompassed by the whine. The direction of frequency modulation also affects the responses of males to calls; males gave relatively few responses to reversed whines over a wide range of playback intensities (G. Rose, Zelick, and Rand 1988; G. Rose and Rand 1991).

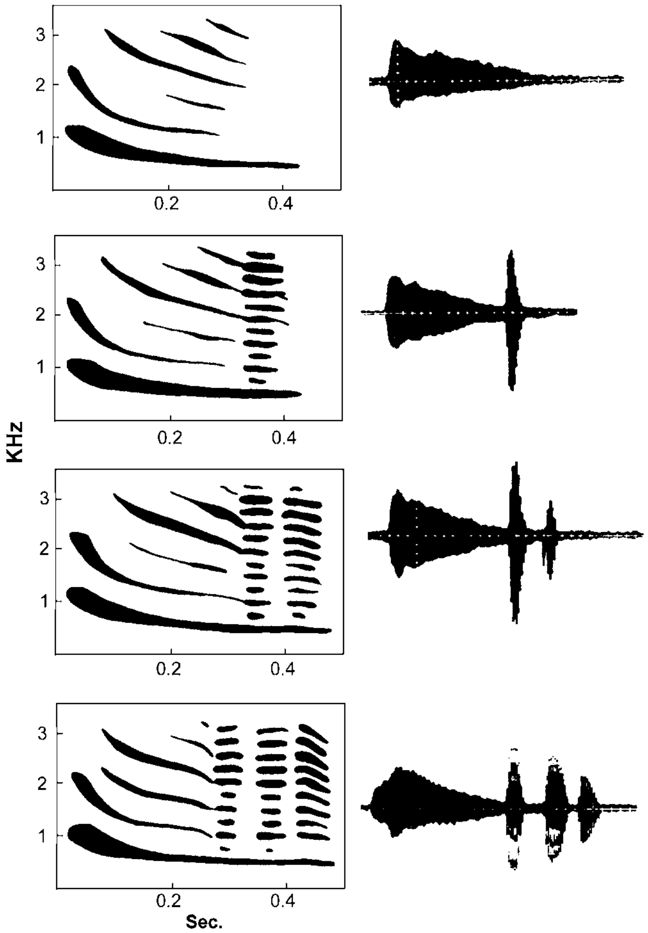

Fig. 7.25. Sound spectrograms (left) and oscillograms (right) of the whine advertisement calls of *Physalaemus pustulosus,* with increasing numbers of secondary chuck notes (top to bottom). After Ryan and Drewes (1990).

Other experiments showed that females responded strongly to calls that included the fundamental frequency of the whine (that is, the frequency determined by vibrations of the vocal cords), but not to calls containing only higher harmonics of the fundamental (Rand, Ryan, and Wilczynski 1992). Even a short segment of the whine was sufficient to elicit phonotaxis, although complete whines were more attractive than most partial whines. The chuck, which makes calls more attractive to females, can be altered in various ways without decreasing the responses of females. For example, females responded equally well to chucks with only the top or bottom half of the frequency range present, and they also responded to calls in which the chuck was replaced with a burst of white noise encompassing the same range of frequencies (Rand, Ryan, and Wilczynski 1992).

Tests of *Physalaemus pustulosus* females with calls of a number of other species in the genus demonstrated that they almost always chose conspecific whine notes over those of other species, despite considerable similarity in call structure within the genus (M. Ryan and Rand 1993b, 1995; Tárano and Ryan 2002). Furthermore, most heterospecific calls did not elicit phonotaxis even when paired with filtered noise, but a few heterospecific calls did elicit phonotaxis under these circumstances. Females also exhibited phonotaxis to synthetic calls arrayed along a gradient of intermediates between those of conspecifics and those of several other species, and the strength of their responses was related to how different the synthetic call was from a conspecific call (Ryan et al. 2003). This study and others (Kime et al. 1998) indicate that females will accept a relatively wide array of calls as long as their components are similar to those of conspecific calls. Nevertheless, when given a choice between such intermediates and conspecific calls, females consistently prefer the latter (M. Ryan and Rand 1995, 1999a,b, 2001). The evolution of call structure in this group has been unusually conservative, and many species have very similar whine calls (many of these are not sympatric with one another). This high degree of conservatism in call structure is paralleled by a high degree of similarity in the auditory tuning curves of the various species (Wilczynski, Rand, and Ryan 2001).

Members of the genus *Physalaemus* differ in the types of components added to the basic whine note. One species, *P. pustulatus,* has a pulsed component that precedes the whine note. Addition of this component to a *P. pustulosus* call rendered the call more attractive to females than a whine note

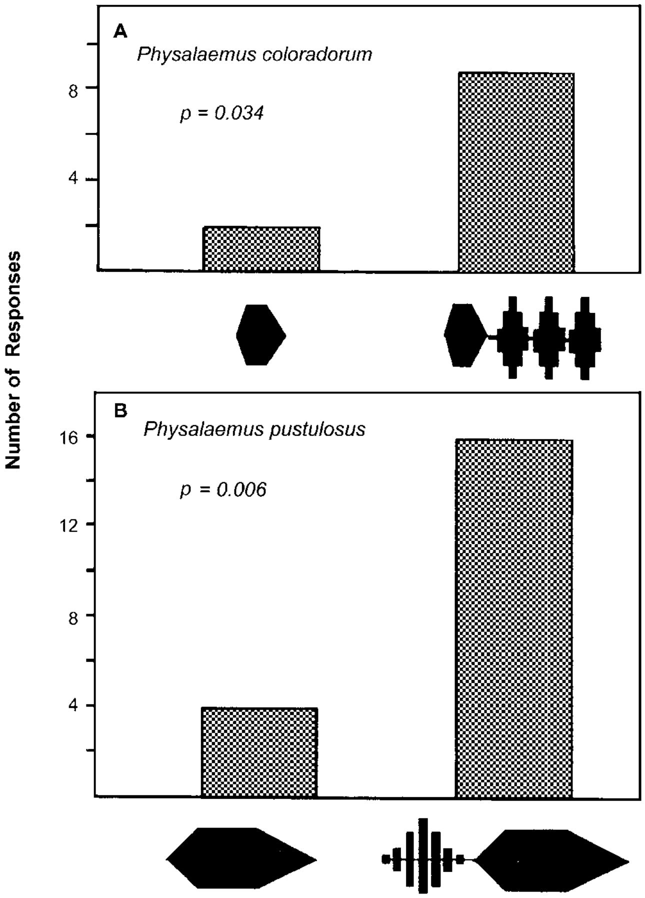

Fig. 7.26. Two examples of female responses to call elements from heterospecific calls in members of the *Physalaemus pustulosus* species group. (A) Responses of females of *P. coloradorum* to a conspecific call (left) and a conspecific call to which three chuck notes of *P. pustulosus* were added (right). (B) Responses of females of *P. pustulosus* to a conspecific call (left) and a conspecific call to which the amplitude-modulated prefix of another species, *P. pustulatus,* had been added (right). In both cases, females preferred the calls that had been made more complex by addition of heterospecific call elements. After Ryan and Rand (1993b).

alone, even though such calls are never given by this species (fig. 7.26 B). This suggests that the female sensory system has a pre-existing bias that would favor the evolution of this type of prefix if it were ever to arise by chance (M. Ryan and Rand 1993c). A similar response was obtained with females of another species, *P. coloradorum,* which does not produce chucks. Addition of a chuck from the call of *P. pustulosus* to the call of *P. coloradorum* made the latter more attractive to *P. coloradorum* females (fig. 7.26 A). In contrast, females of another species, *P. enesefae* did not exhibit the same type of pre-existing bias in favor of components of other species' calls when these were added to conspecific advertisement calls. They simply ignored these added components and were equally likely to choose modified and unmodified calls (Tárano and Ryan 2002). *Physalaemus enesefae* is rather distantly related to *P. pustulosus, P. pustulatus,* and *P. coloradorum,* all of which are in one clade within the genus. This suggests that the preference for complex calls has evolved within that clade, but not necessarily in the genus as a whole.

Hybridization and Hybrid Calls

Many closely related species of anurans exhibit a high degree of genetic compatibility. Because reproductive isolation is not always complete, interspecific hybridization is a regular, although not common, occurrence in anuran populations. Hybridization sometimes occurs in scattered locations throughout the ranges of two broadly sympatric species when the species breed in the same habitats (A. Blair 1941b, 1942; Cory and Manion 1955; Thornton 1955; Wasserman 1957; Mecham 1960, 1965; Zweifel 1968a; L. Brown 1970; Forester 1973; Jones 1973; Gerhardt, Guttman, and Karlin 1980; Green 1983; Sattler 1985; Anderson and Moler 1986; Lamb and Avise 1986; Schlefer et al. 1986; Haddad, Cardoso, and Castanho 1990; Oliveira et al. 1991; Gerhardt 1994a; Gerhardt Ptacek, Barrett, and Torke, 1994; Gerhardt and Schwartz 1995; Gergus, Malmos, and Sullivan 1999; D. Green and Parent 2003; Vines et al. 2003). Usually heterospecific matings are relatively rare in such situations, and hybrid individuals constitute only a small proportion of the adult population.

Hybridization sometimes also occurs in narrow zones where the boundaries of two largely allopatric species come into contact (W. Blair 1955; Henrich 1968; L. Brown and Guttman 1970; Littlejohn, Watson, and Loftus-Hills 1971; A. Martin 1972; Littlejohn and Watson 1973, 1983; Littlejohn and Roberts 1975; McDonnell, Gartside, and Littlejohn 1978; Woodruff 1978; J. Feder 1979; Sage and Selander 1979; Gartside 1980; D. Green 1983; Sullivan 1986a, 1995; Szymura and Barton 1986; Hillis 1988; Sullivan and Lamb 1988; Barton and Hewitt 1989; Sanderson, Szymura, and Barton 1992; Littlejohn 1993, 1999; Szymura 1993; Gerhardt and Schwartz 1995; Nürnberger et al. 1995; MacCallum et al. 1998; Kruuk, Gilchrist, and Barton 1999). Usually these zones occur when two relatively closely related species that have been separated geographically come back into contact, but postmating isolation (genetic incompatibility) is incomplete. Such parapatric hybrid zones (Woodruff 1973) can be stable for long periods of time.

Even if hybrid individuals are competitively inferior to both parental species, a hybrid population can be maintained in a narrow zone of overlap through continual mismatings between species. When two species come into contact in an ecotone between two different habitats, hybrid individuals might actually be better adapted to the ecotone than either parental species, although this has never been demonstrated conclusively for anurans. In that case, a self-maintaining hybrid population can develop in a zone separating allopatric populations of the parental species (Littlejohn and Watson 1973; Woodruff 1973; Green 1983; Littlejohn 1993, 1999). Sometimes hybridization can be favored if hybrid offspring are competitively superior in particular environments. For example, in ephemeral desert pools in Arizona, females of *Spea bombifrons* that mate with males of *S. multiplicata* produce tadpoles that develop more rapidly than do pure *S. bombifrons* larvae, an advantage in a drying pond. In contrast, matings between female *S. multiplicata* and male *S. bombifrons* produce offspring with longer development times and lower survival than pure *S. multiplicata* offspring (K. Pfenning and Simovich 2002).

Some instances of hybridization between broadly sympatric species occur when species that were previously isolated by habitat differences have been brought into contact by man-made habitat disturbance (Cory and Manion 1955; Thornton 1955; Wasserman 1957; Mecham 1960; L. Brown 1970; Schlefer et al. 1986; Lamb 1987). This is not necessarily true for parapatric hybrid zones. In either case, the chances of hybridization are greatest if one or more of the following conditions are met: (1) The advertisement calls of the two species are similar to one another, thereby increasing the probability that a female will move toward a heterospecific male; (2) males of one or both species typically obtain mates by active searching (see chapter 8) and are therefore likely to seize heterospecific females by mistake; (3) males of one species greatly outnumber males of the other species, so females have some difficulty locating conspecific males.

In some instances, hybridization can lead to formation of polyploid species and unsual reproductive systems. The best-known example is in a complex of European water frogs, the *Rana esculenta* complex. Hybridization between *Rana lessonae* and *R. ridibunda* in many separate locations has produced the *R. esculenta* phenotype, which often is competitively superior to the parental species (Berger 1977; Graf and Polls- Pelaz 1989). Usually the *R. esculenta* genotype occurs with *R. lessonae.* The *lessonae* genome is discarded before meiosis when *R. esculenta* females form eggs, and the remaining *ridibunda* genome is then duplicated. Females produce haploid eggs of the *ridibunda* genotype that then combine with *R. lessonae* sperm to reconstitute the *R. esculenta* genome. In populations where *R. esculenta* is associated with *R. ridibunda,* the *lessonae* genome usually is maintained in the eggs. In addition, some *R. esculenta* females produce both haploid and diploid eggs, and subsequent matings with a parental species yield some triploid offspring. Matings between males and females of the *R. esculenta* genotype normally produce inviable offspring of the *R. ridibunda* genotype, but production of viable *R. ridibunda* genotypes occurs occasionally. These are exclusively female and normally mate with males of *R. lessonae,* thereby reconstituting the *R. esculenta* genotype (Vorburger 2001).

The widespread success of the *Rana esculenta* genotype appears to be due mainly to competitive superiority of the hybrid phenotype. Theoretically, hybrids should be at some disadvantage because they are dependent on one of the parent species for successful reproduction. Yet in many populations, *R. esculenta* individuals outnumber the parental species. *Rana esculenta* tadpoles benefit from having an "all purpose" genotype that can they tolerate a wide range of physical conditions in ponds (Tunner and Nopp 1979). They also are superior competitors to the tadpoles of the parental species with which they most often are associated, *Rana lessonae* (Semlitsch and Reyer 1992b; Semlitsch 1993; see also chapter 15). If the *R. esculenta* genotype were to completely outcompete *R. lessonae* in a pond, then *R. esculenta* eventually would disappear, because they cannot reproduce themselves. Both forms continue to persist, however, through a combination of mating preferences by females for *R. lessonae* males and patterns of migration between neighboring populations (Hellriegel and Reyer 2000; Som, Anholt, and Reyer 2000). In addition, the sperm of hybrid *R. esculenta* males are less successful at fertilizing eggs than are those of parental genotypes, so the fitness advantage of the *R. esculenta* genotype is reduced (Reyer, Niederer, and Hettyey 2003).

Calls of Hybrid Males

The calls of hybrid males generally are intermediate in both spectral and temporal characteristics to calls of the parental species, although some features are more similar to calls of one parent than to those of the other (W. Blair 1955, 1956b, 1958b; Bogert 1960; Littlejohn and Oldham 1968; Zweifel 1968a; Littlejohn, Watson, and Loftus-Hills 1971; A. Martin 1972; Forester 1973; Littlejohn and Watson 1973; Gerhardt 1974c; Littlejohn and Roberts 1975; Littlejohn 1976; Brzoska 1980, 1982; Doherty and Gerhardt 1983; Schneider and Joermann 1988; Scroggie and Littlejohn 2005). In the *Rana esculenta* complex, however, calls of the hybrid form are not intermediate between those of the parental species, but have frequency components not found in either parental call (Wycherley, Doran, and Beebee 2002). This probably reflects the unusual genetic system in these frogs.

Several playback experiments have demonstrated that calls of hybrid males are less attractive to females of the parental species than are calls of conspecific males (Awbrey 1965; Gerhardt 1974c; Kruse 1981b; Höbel and Gerhardt 2003). However, the results are not as clear-cut as are those for the species discrimination tests described earlier. Some females are readily attracted to calls of hybrid males in the absence of conspecific calls, and they often fail to discriminate between hybrid and conspecific calls that are very similar (Gerhardt 1974c; Littlejohn and Watson 1976). Hybrid

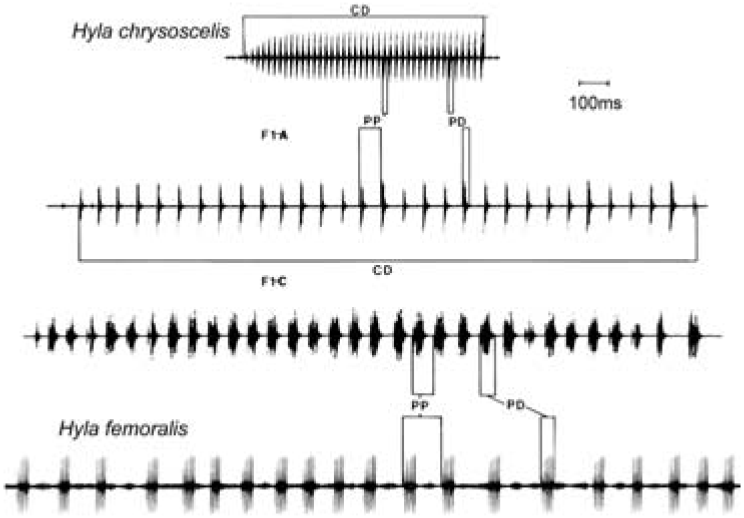

Fig. 7.27. Oscillograms of the advertisement calls of *Hyla chrysoscelis* (top), *H. femoralis* (bottom), and hybrids between the two species (middle). Hybrid calls like the one in the top middle figure were more similar in pulse structure to calls of *H. chrysoscelis* than to those of *H. femoralis.* Other calls, like that shown in the bottom middle figure, were more similar to *H. femoralis.* Abbreviations: CD = call duration; PD = pulse duration; PP = pulse period. After Doherty and Gerhardt (1984a).

males presumably are at a disadvantage when trying to attract mates in a large chorus of nonhybrid males, but the disadvantage is not absolute.

There is some evidence that hybrid females prefer the calls of hybrid males to those of the parental species. Mecham (1960) found several pairs of hybrid males and females in amplexus in mixed *Hyla cinerea-H. gratiosa* choruses, even though the number of hybrids in the choruses was small. Doherty and Gerhardt (1983, 1984a) showed that hybrid females produced by crossing *H. femoralis* and *H. chrysoscelis* preferred calls of hybrid males to those of *H. chrysoscelis.* They did not discriminate between hybrid calls and those of *H. femoralis,* which sometimes resembled hybrid calls in pulse repetition rate (fig. 7.27). However, when given a choice of synthetic calls with pulse repetition rates corresponding to the mean values for hybrids and *H. femoralis,* the hybrid females clearly preferred hybrid calls. Again, the situation in the *Rana esculenta* complex differs from other hybrid systems in that both *R. lessonae* females and *R. esculenta* females actively avoid mating with *R. esculenta* males. In this system, *R. lessonae* females have reduced fitness if they mate with *R. esculenta* males, because the *lessonae* genome eventually is discarded. *Rana esculenta* females avoid mating with *R. esculenta* males because matings between hybrids yield offspring with low viability (Abt and Reyer 1993; Roesli and Reyer 2000). Nevertheless, males of *R. esculenta* often acquire mates because they are very aggressive in competing for females (see chapter 8).

Character Displacement

If two species of frogs with very similar advertisement calls occur in sympatry, females might make frequent mistakes in choosing mates. If hybrid offspring have lower fitness than offspring of conspecific matings, then selection would favor individuals with calls least similar to those of the other species. The result might be divergence in the characteristics of calls in the zone of sympatry, a process known as reproductive character displacement or reinforcement (Littlejohn 1969, 1977, 1981, 1988, 1993, 1999; W. Blair 1974; Gerhardt and Schwartz 1995; Gerhardt and Huber 2002). If the calls of two species were more similar in allopatry than in sympatry, then this would be evidence of possible character displacement. It is possible that differences in the calls of many sympatric species of anurans have evolved through past reinforcement of slight differences in call characteristics, thereby enhancing their effectiveness in restricting interspecific gene exchange.

Despite extensive work on anuran vocalizations, convincing examples of reproductive character displacement have been elusive (W. Blair 1974; Gerhardt and Schwartz 1995; Littlejohn 1999; Gerhardt and Huber 2002). Many of the examples proposed by early workers can be explained as the result of clinal variation in call characteristics, incidental effects of differences in body size, or differences in the temperatures at which calls of different populations were recorded. Furthermore, the lack of evidence of character displacement among sympatric anurans could mean that the calls of different species diverged sufficiently in allopatry to ensure complete reproductive isolation when the species become sympatric. The difficulty in documenting reinforcement of call characteristics has led some workers to suggest that the process occurs very rarely, if at all (Paterson 1978, 1980, 1981, 1982; Passmore 1981; Telford 1982).

Nevertheless, there are several well-documented examples of character displacement in frog calls (Gerhardt and Schwartz 1995; Littlejohn 1999; Gerhardt and Huber 2002). The best known is the *Litoria ewingii* complex in eastern Australia (Littlejohn 1965, 1976). The calls of *L. ewingii* and *L. verreauxii* differ in pulse repetition rate both in allopatry and sympatry, but the differences are much greater in sympatry (fig. 7.28). In fact, the calls of *L. verreauxii* from populations sympatric with *L. ewingii* not only have much faster pulse repetition rates, but they also have less pronounced and more variable depths of amplitude modulation. Although females of both species readily discriminate between conspecific calls and those of sympatric congeners, *L. ewingii* females from a zone of sympatry cannot discriminate calls of sympatric *L. ewingii* from those of allopatric *L. verreauxii* (Littlejohn and Loftus-Hills 1968). On the other hand, the calls of sympatric and allopatric *L. verreauxii* are sufficiently different from each other that *L. verreauxii* females from a zone of sympatry prefer calls from their own population to allopatric calls. In fact, there appears to have been a shift in the way in which females recognize their own species' calls from a quantitative trait (pulse repetition rate) to a qualitative one (pulsed vs. unpulsed signals). The reduction in depth of amplitude modulation in populations sympatric with *L. ewingii* appears to be a result of increasing pulse rate (that is, the frogs have difficulty producing fully modulated calls at high pulse rates Gerhardt and Davis 1988).

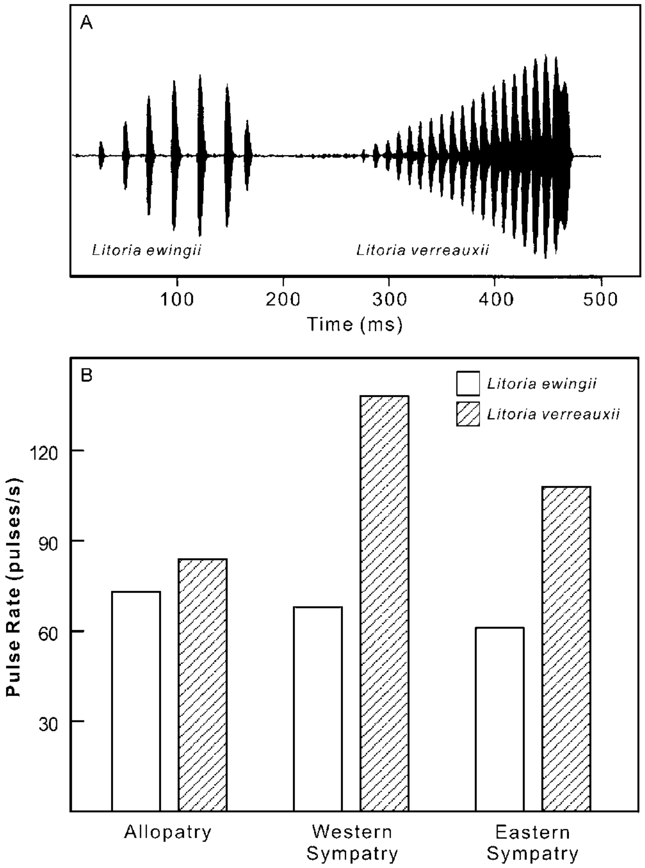

Fig. 7.28. (A) Oscillograms of the advertisement calls of two Australian treefrogs, *Litoria ewingii* and *L. verreauxii.* After Littlejohn (2001). (B) Mean pulse rates for the two species in areas of allopatry and western and eastern areas of sympatry at 10° C. The difference in pulse rate between the two species is much greater in sympatry than in allopatry, indicating the character displacement has occurred. Plotted from data in Littlejohn (1999).

Character displacement in pulse repetition rates also has been described in chorus frogs (*Pseudacris*) of the southeastern United States. Calls of *P. nigrita* have a relatively slow pulse repetition rate. Calls of *P. feriarum* sympatric with *P. nigrita* have much faster pulse rates. Allopatric populations have only slightly faster rates (Littlejohn 1960, 1969; Fouquette 1975), suggesting that character displacement has occurred. Furthermore, the calls of *P. feriarum,* an eastern species, are very different from those of *P. triseriata,* a western species. Female *P. triseriata* readily discriminate between calls from their own population and those of *P. feriarum,* but cannot discriminate between conspecific calls and those of allopatric *P. nigrita,* which have a very similar pulse rate (Littlejohn 1960). Unfortunately, the responses of females from sympatric populations of *P. feriarum* and *P. nigrita* have not been tested.

Ralin (1977) argued that character displacement has occurred in calls of *Hyla chrysoscelis* in sympatry with *H. versicolor.* He based this conclusion on differences in pulse repetition rate in sympatric and allopatric populations. Gerhardt (1982) found no differences in the relationship of pulse rate to temperature in *H. chrysoscelis* sympatric with *H. versicolor* in Missouri and allopatric populations, and therefore, no evidence of character displacement. Furthermore, the possibility of an east-west cline in pulse repetition rate in the calls of *H. chrysoscelis,* independent of the presence *of H. versicolor,* cannot be dismissed. The absence of obvious character displacement in these and other pairs of anuran species could be a result of character displacement having occurred in the responses of females rather than the structure of male calls. Gerhardt (1994b) reported that females of *H. chrysoscelis* from populations that were sympatric with *H. versicolor* were more selective in their preferences for conspecific calls than were females from far allopatric populations. In particular, preferences of females from far allopatric populations for calls with pulse repetition rates characteristic of conspecific calls could be weakened by making the calls longer, but this did not occur when females from sympatric populations were tested.

Several other studies also have shown that females are more discriminating in sympatry than in allopatry, and this form of character displacement actually could be more common than evolutionary changes in male calls. Females of two species of midwife toads, *Alytes obstetricans* and *A. cisternasii,* are more discriminating in sympatry than in allopatry, even though the calls of males do not differ between sympatric and allopatric populations (Márquez and Bosch 1997b). In spadefoot toads (*Spea multiplicata*), females from populations sympatric with *S. bombifrons* preferred average calling rates to high rates, whereas females from allopatric populations preferred high rates. Because the calling rate of *S. bombifrons* is higher than that of *S. multiplicata,* females of *S. multiplicata* in sympatry appear to avoid calling rates that are likely to overlap those of *S. bombifrons.* (K. Pfenning 2000). This appears to have resulted in reinforcement of call differences in areas of sympatry and a decrease in the frequency of hybridization over the last quarter century (K. Pfennig 2003). In *Hyla cinerea,* there were subtle differences in male calls in populations sympatric with *H. gratiosa* and allopatric populations, but the main difference was in responses of females. Again, females showed stronger discrimination against heterospecific calls in sympatric populations, although not all populations showed this pattern (Höbel and Gerhardt 2003).

The Evolution of Call Structure

As discussed in the previous sections, each species of anuran has a call that is distinct in one or more features from those of closely related species, and females consistently prefer the calls of conspecifics to heterospecifics. At the same time, it has long been recognized that the calls of closely related species often share certain basic structural characteristics. Presumably because these characteristics have been inherited from a common ancestor (Blair 1958a, c, 1962; McAlister 1959; Duellman 1970; A. Martin 1972; Nelson 1973; Zweifel 1985; Straughan and Heyer 1976; Tandy and Tandy 1976; Schneider, Hussein, and Akef 1986; Cocroft et al. 1990; M. Ryan and Drewes 1990; Cocroft and Ryan 1995; Gerhardt 2001; Gerhardt and Huber 2002). These similarities in call structure sometimes have been used to infer phylogenetic relationships among species or to place species within a genus into distinct species groups (Blair 1958a; Barrio 1965; Tandy and Keith 1972; C. Myers and Daly 1976; H. Zimmermann and Zimmermann 1988; Cocroft 1994). More recently, some investigators have used phylogenies derived independently from nonacoustic characters to map the evolution of call features as a means of unraveling patterns of call evolution (M. Ryan 1988a; M. Ryan and Drewes 1990; M. Ryan and Rand 1993a, c, 1995; Cocroft and Ryan 1995). I will briefly discuss three examples that have been particularly well studied.

The calls of North American species of toads (*Bufo*) are well known, and W. Martin (1971, 1972) studied morphological correlates of call production in detail. Some of these toads have traditionally been divided into two species groups. The *B. americanus* group includes *B. americanus, B. fowleri, B. hemiophrys, B. houstonensis, B. microscaphus, B. terrestris,* and *B. woodhousii;* the *B. cognatus* group includes *B. cognatus, B. compactilis,* and *B. speciosus* (W. Blair 1972; Maxson, Song, and Lopata 1981). Examination of the calls of these species, placed in a phylogenetic context, reveals major differences in call structure between the two species groups (fig. 7.29). All of these toads produce relatively long trills composed of regularly repeated pulses (fig. 7.29 A), but they differ in pulse repetition rate, call duration, and calling rate. There also are differences in dominant frequency as a result of difference in body size (Cocroft and Ryan 1995). The most distinctive difference is in the internal structure of the calls. The members of the *B. cognatus* group have pulses with internal amplitude modulation (fig. 7.29 B). These are produced by vibrations of arytenoid valves, which are absent in the *B. americanus* group. Because the outgroup species, *B. valliceps,* also has internal amplitude modulation, it appear that this is the ancestral condition for this clade of toads, with the loss of internal modulation being a derived condition.

A similar phylogenetic analysis of the calls of chorus frogs in the genus *Pseudacris* revealed considerable congruence between phylogeny and call structure (fig. 7.30). Cocroft (1994) found that *Pseudacris crucifer,* a species that often has been placed in the genus *Hyla,* appears to be a basal member of the *Pseudacris* clade, an interpretation consistent with electrophoretic work by Hedges (1986). It has a tone-like call, similar in basic structure (fig. 7.30 A) and pulse shape (fig. 7.30 B) to the calls of *P. ornata* and *P. streckeri,* two species that have long been considered close relatives. Most other *Pseudacris* have trilled calls (fig. 7.30 A), with a distinctly different pulse shape (fig. 7.30 B). *Pseudacris ocularis,* a tiny species that is morphologically distinct from other members of the genus and has been placed in various genera, including its own genus, appears to arise between these two major clades and has a two-part call with notes similar to both groups (Cocroft and Ryan 1995). One interesting pattern that has not been analyzed in detail is the evolution of aggressive calls. *Pseudacris crucifer* has a trilled

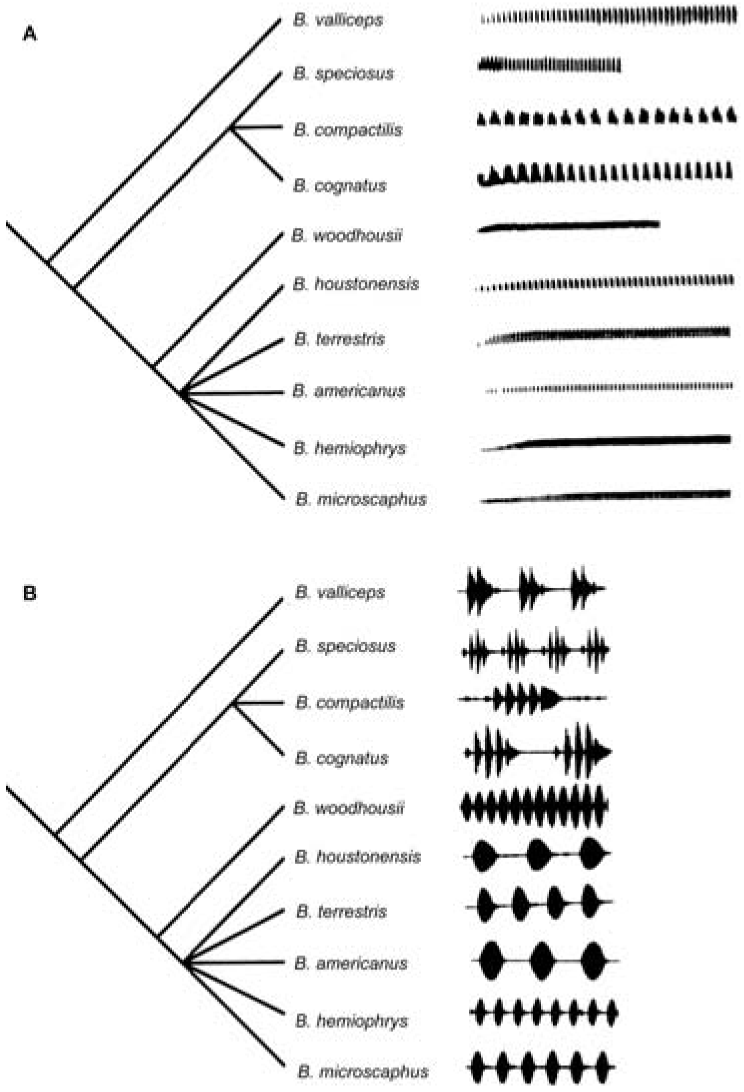

Fig. 7.29. Phylogenetic analysis of call evolution in North American toads (*Bufo*). (A) Sound spectrograms of the first second of calls of each species at about 18° C. Frequency scale omitted to facilitate comparison of overall call structure. (B) Oscillograms showing waveform and pulse structure of calls. The *Bufo americanus* group (bottom half) lacks internal amplitude modulation of pulses. From Cocroft and Ryan (1995).

aggressive call similar to the advertisement calls of other *Pseudacris* (Schwartz 1989), as does *Pseudacris regilla* (Allan 1973). Owen (2003) documented the occurrence of trilled aggressive calls in *P. feriarum* from North Carolina, *P. triseriata* from Indiana, *P. brachyphona* from West Virginia, and *P. streckeri illinoiensis* from Illinois, suggesting that this type of aggressive call is widespread in the genus.

A third group that has been investigated in considerable detail is the Neotropical leptodactylid genus *Physalaemus*. Members of this genus have similar frequency-modulated calls with a pronounced harmonic structure. These vary in duration and in the shape of the call envelope, but many species have rather similar dominant frequencies (fig. 7.31). Most species produce whine-like notes alone or in doublets, but a few add other components to the call. Both *P. pustulosus* and *P. petersi* produce secondary chucks. These are short notes with a wide frequency spectrum, but the chucks have a somewhat different structure in the two species (M. Ryan and Drewes 1990). The hypothesized phylogeny of the *P. pustulosus* species group, to which both of these species belong, has changed several times as new data have become available (Cannatella and Duellman 1984; M. Ryan and Rand 1993c, 1995), making it somewhat difficult to interpret patterns of call evolution. If *P. pustulosus* and *P. pe-*

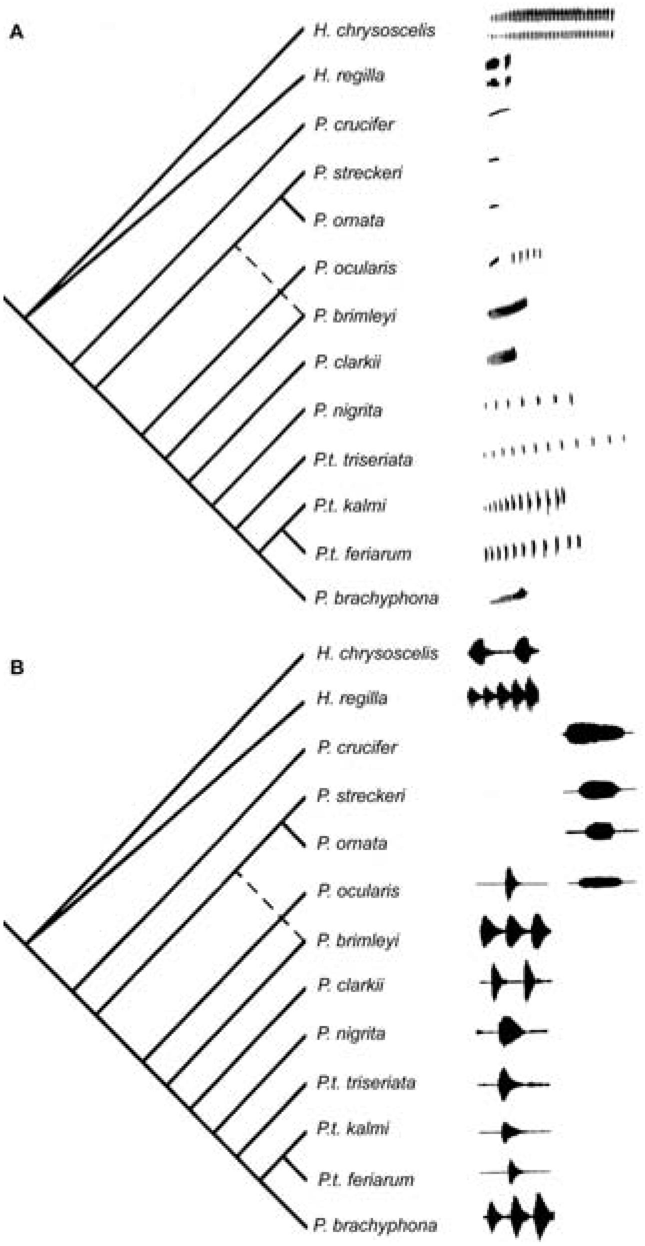

Fig. 7.30. Phylogenetic analysis of call evolution in North American chorus frogs (*Pseudacris*) and related species of *Hyla.* (A) Sound spectrograms of the calls of each species, not all recorded at the same temperature. Time scale is the same for each call. Frequency scale omitted to facilitate comparison of overall call structure. (B) Oscillograms showing waveforms and pulse structure of calls. Calls in the first column represent 30 ms in the middle of the call. The second column shows the amplitude envelope for pure-tone calls. tersi are sister species (Cannatella and Duellman 1984; M. Ryan and Rand 1995), then the chuck notes could have evolved once in a common ancestor; if they are not, then evolution of the chuck would have occurred twice (fig. 7.32). *Physalaemus pustulatus* adds a pulsed prefix to its call (fig. 7.31). This appears to be a uniquely derived trait that is absent in its closest relative, *P. coloradorum,* and all other members of the genus (M. Ryan and Drewes 1990; M. Ryan and Rand 1993a, c).

M. Ryan and Rand (1995, 1999b) went beyond mapping of calls of *Physalaemus* onto cladograms to examine the evolution of call structure in this genus. They also used the phylogeny of the group to estimate characteristics of the calls of the ancestors of extant species (fig. 7.33). They then tested responses of *Physalaemus pustulosus* females to the calls of both the extant and "ancestral" species. In general, they found that females showed strong discrimination between conspecific calls and those of other extant species, but showed less discrimination between conspecific calls and those of their immediate ancestors. Many females did respond to heterospecific calls and even to the hypothetical calls of ancestral species when given a choice between heterospecific calls and white noise, even when the calls presented were those of fairly distantly related species. These results indicate that females recognize a broad range of calls as appropriate signals, but they show strong discrimination against most of these when conspecific calls are available. The tendency of females to respond to heterospecific calls in the absence of conspecific calls was related to the quantitative similarity in call characteristics, but not necessarily to phylogenetic similarity. The estimates of ancestral call characteristics varied depending on the exact model of phylogeny reconstruction that was used (Losos 1999; M. Ryan and Rand 1999a), but most of these differences did not appear to be important to females (M. Ryan and Rand, 1999a).

Major changes in call structure within clades of frogs are correlated with morphological changes in the structures that produce the calls. For example, all members of the *Physalaemus pustulosus* group have fibrous masses in their vocal cords, but only those that have a firm attachment between the fibrous mass and the cricoid cartilage produce chuck notes when the fibrous mass vibrates in the airstream passing through the larynx. In addition, the fibrous mass is much larger in *P. pustulosus* and in other species that produce complex calls than in species that lack chuck notes (Boul and Ryan 2004). Other morphological changes in the larynx can have major effects on call structure as well. One example already mentioned in the loss of arytenoid valves in the *Bufo americanus* species group, resulting in the loss of internal amplitude modulation of pulses (W. Martin 1972). Differences in call note duration and pulse repetition rate could be correlated with differences in the size of the laryngeal muscles (McClelland, Wilczynski, and Rand 1997), as well as physiological changes in aerobic capacity, enzyme activities, muscle fiber type, contractile properties, and blood supply (McLister, Stevens, and Bogart 1995; R. Marsh 1999; see also chapter 5). Presumably the neural programs controlling call production and the timing of muscle contrac-

Bracketed figures show derived call characters, including a secondary chuck note in *P. pustulosus,* a "squawk" at the end of the call of *P. freibergi,* double-note call in *P. coloradorum,* and amplitude-modulated prefix in *P. pustulatus.* After Ryan and Rand (1993b).

tion must undergo changes as well, although this has not been thoroughly studied in a phylogenetic context.

The Anatomy and Neurobiology of Call Recognition

To understand how sounds influence the behavior of anurans, it is important to know something about how sounds are perceived by these animals. The perceptual world of a frog is not the same as that of a human observer and vocal signals are not necessarily interpreted by the anuran auditory system in the same way as they would be by our own. Morphological or physiological constraints imposed by the auditory system can be important in shaping the evolution of anuran vocal communication (M. Ryan 1986a, 1988a, 1990; Gerhardt 1987, 1988; M. Ryan and Rand 1990;

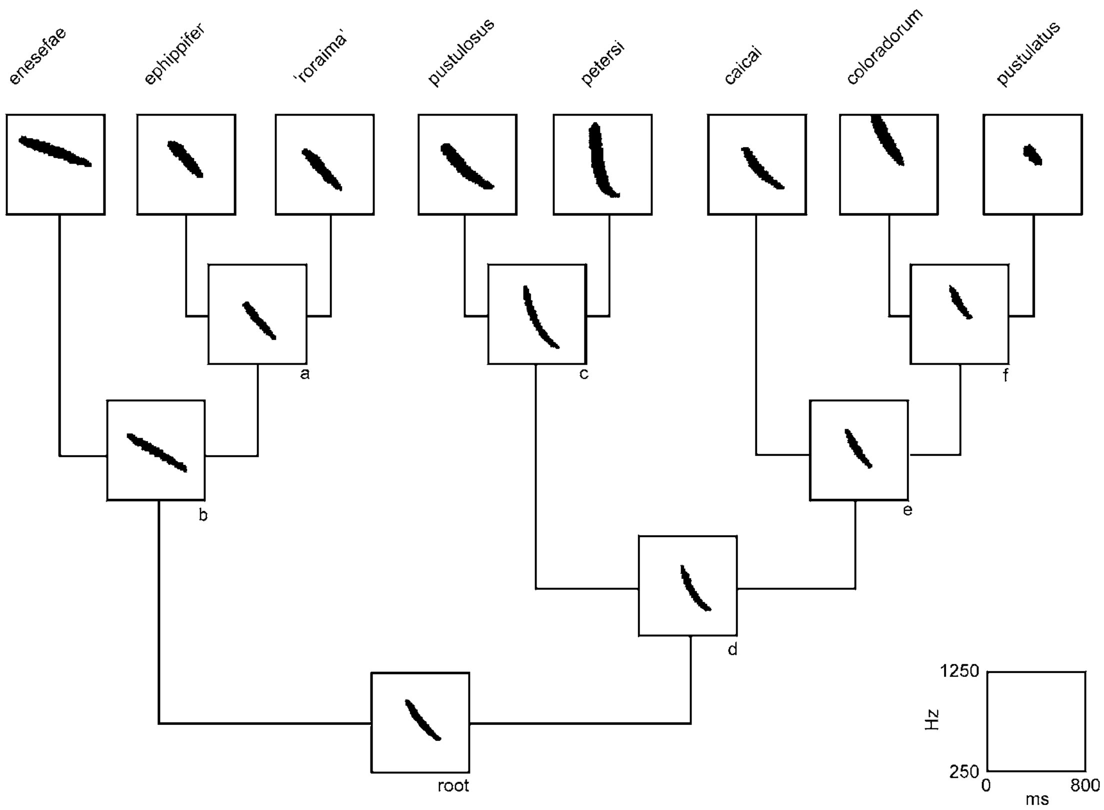

Fig. 7.33. Basic structure of whine calls of the genus *Physalaemus,* with inferred ancestral calls (a–f). Sound spectrograms show synthetic models of calls used in playback experiments with females. After Ryan and Rand (1999).

M. Ryan, Fox, Wilczynski, and Rand 1990; M. Ryan and Keddy-Hector 1992). The following section reviews the anatomy and physiology of the anuran auditory system, especially as it relates to behaviorally relevant aspects of sound perception and call recognition. This has been an active field of research for decades, but an exhaustive review of anuran neuroanatomy and neurophysiology is beyond the scope of this book. Several books (Fritzsch et al. 1988; Gerhardt and Huber 2002; M. Ryan 2001; Narins and Feng 2007) and a review by Smotherman and Narins (2004) provide detailed reviews of work in this field, and several earlier reviews are useful as well (Capranica 1976a, b, 1977; Capranica and Moffat 1983; Capranica and Rose 1983; Wilczynski and Capranica 1984).

Anatomy and Function of the Middle Ear

The anuran ear consists of two major parts, the middle ear and the inner ear (fig. 7.34). The tympanic membrane is flush with the outside of the frog's head and is not recessed in a cavity as in mammals, so there is no outer ear. The middle ear provides the mechanical linkage between the external environment and the fluid-filled cavities of the inner ear, while the inner ear contains the sensory structures that translate mechanical stimulation into nerve impulses that then travel to the brain. While the basic principle of sound reception in anurans is similar to that in other vertebrates, the details of anatomical structure are quite different in some respects. Anurans have more than one system for picking up acoustic stimuli from the environment and more than one type of sensory organ to translate these inputs into nerve impulses (E. Lewis and Narins 1999; Smotherman and Narins 2004).

The Tympanic Ear

The tympanum, or eardrum, provides the major input of airborne sound into the auditory system of most anurans (fig. 7.34). The tympanum is a thin membrane supported by a bony or cartilage ring. Variation in the size of the tympanic membrane appears to be correlated with differences in auditory sensitivity, both within and between species, with frogs having larger tympana also exhibiting greater sensitivity (Fox 1995). In addition, larger tympana are sensitive to lower frequency sounds, both within and between species (Hetherington 1992a, b). This can lead to sexual differences in frequency sensitivity, as in the bullfrog (*Rana catesbeiana*), a species in which males have much larger tympana (Hetherington 1994).

The inner surface of the tympanum is in contact with the

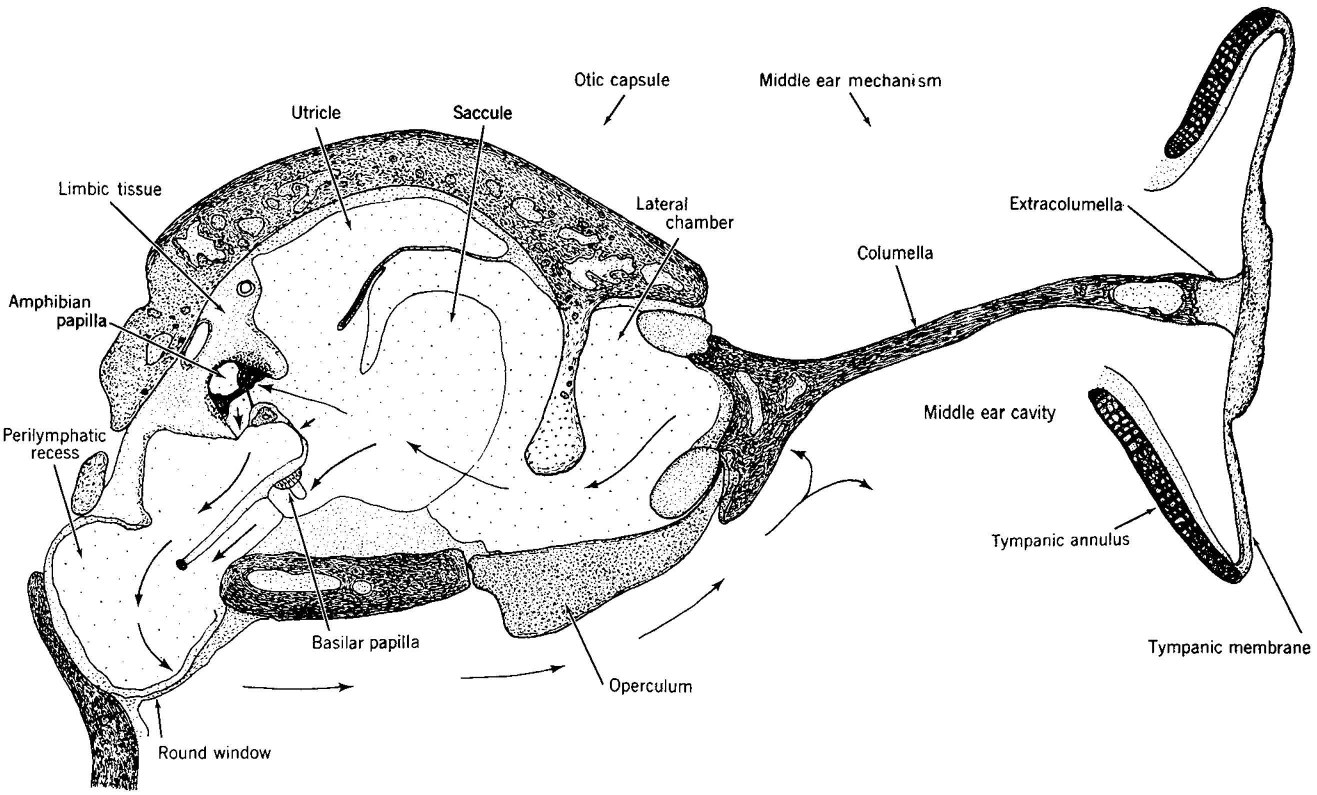

Fig. 7.34. Cross-section of the anuran middle ear, showing important structures involved in sound transmission and perception. From Wever (1985).

extracolumella (also called the extrastapes or plectrum), a structure usually composed of cartilage that links the tympanum with the bony columella (stapes). The columella in turn serves as the mechanical link to the inner ear (fig. 7.34). The outer part of the columella passes through an air-filled chamber that has a direct open connection to the buccal cavity through the eustachian tube. Hence, pressure changes in the buccal cavity can affect the pressure on the inner surface of the tympanum. In most anurans, the medial portion of the columella passes through connective tissue and muscle before reaching its connection with the inner ear. This condition contrasts with that of mammals, in which the entire middle ear cavity is filled with air (Wever 1985; Jaslow, Hetherington, and Lombard 1988; Smotherman and Narins 2004).

The medial end of the columella (columellar or stapedial footplate), usually composed of cartilage, rests in the oval window of the otic capsule, the bony structure that protects the inner ear. Vibrations of the tympanum are transmitted by the stapes through this window to the fluid in the inner ear (M. Jørgensen and Kanneworff 1998). This sets up currents that stimulate the sensory structures in the inner ear (Purgue and Narins 2000). Measurements of tympanic vibrations by means of laser interferometry in several anuran species have shown that the tympanum is not finely tuned to particular frequencies, but shows a relatively flat response over a broad range of frequencies. In *Rana pipiens,* sensitivity falls off rapidly below 650 Hz, and the tympanum shows very little response to frequencies below 300 Hz. Sensitivity also decreases at frequencies above 1,200 Hz, but high frequencies are transmitted if the intensity of the sound is sufficiently high (Wilczynski, Resler, and Capranica 1987). Removal of the tympanum causes a substantial decrease of hearing sensitivity at high frequencies (Lombard and Straughan 1974). In frogs with tympanic ears, the tympanum appears to be the major route for acoustic input underwater as well as in air, at least at relatively high frequencies in the range of most anuran advertisement calls (Hetherington and Lombard 1982). Hearing sensitivity underwater is similar to that in air (Lombard, Fay, and Werner 1981), so frogs that call underwater, such as *Rana aurora, R. cascadae,* or *R. palustris,* should have little difficulty detecting conspecific calls.

Although the tympanic ear is the major means of detecting airborne sounds in most anurans, it is not essential for effective sound reception, even at relatively high frequencies. In fact, reduction of various elements of the tympanic ear has occurred repeatedly in anuran evolution (Jaslow, Hetherington, and Lombard 1988). Some species, such as the microhylid *Koloula pulchra,* lack a tympanum and part of the extrastapes, but retain the stapes and middle ear cavity. Others, such as the leptodactylid *Telmatobius exsul,* have lost the tympanum and middle ear cavity, but retain most of the middle ear bones. Still others have lost all of the tympanic ear structures. This condition is found in representatives of at least 11 anuran families, including all of the Sooglossidae and various species of bufonids (*Atelopus* and some *Bufo, Nectophryne,* and *Melanophryniscus*), myobatrachids (*Pseudophryne, Crinia*), and in *Hemisus.* Loss of tympanic ears has not occurred only in voiceless frogs (discussed in a previous section). In fact, many earless frogs have advertisement calls with frequencies in the same range as species with normal tympanic ears (i.e., dominant frequencies above 1 kHz). Behavioral and neurophysiological studies of earless frogs and those lacking a tympanum have shown that acoustic communication and frequency sensitivity are similar to those of normal anurans (Pengilley 1971a; Loftus-Hills 1973a, b; Jaslow 1979; Hill and Robertson 1981; Nussbaum, Jaslow, and Watson 1982; Robertson 1984, 1986b; Crump 1988; Jaslow, Hetherington, and Lombard 1988; Cocroft et al. 1990; Jaslow and Lombard 1996; Lindquist and Hetherington 1996; Lindquist, Hetherington, and Volman 1998). Hence, there must be alternative routes for acoustic input in earless frogs and perhaps other anurans as well (see the following).

The Opercularis System

One extratympanic pathway for sound reception that is sensitive mainly to low frequency input is the opercularis system, which is unique to amphibians. This system is always present in anurans, even in species that lack a tympanic ear. It is present in most urodeles as well, but is absent from some neotenic groups (proteids, amphiumids, and cryptobranchids; Wever 1985; Jaslow, Hetherington, and Lombard 1988). The operculum is a cartilage disk that sits in the oval window adjacent to the stapedial footplate (fig. 7.34). It is attached to the opercularis muscle, which inserts on the suprascapula (Hetherington, Jaslow, and Lombard 1986). The operculum articulates with the stapedial footplate, often sitting in a notch within the footplate. Lombard and Straughan (1974) suggested that interlocking of the operculum and stapes by action of the opercularis muscle would modify the frequency response of the tympanic ear by increasing its sensitivity to low frequency sound. When they removed the opercularis muscle, sensitivity to frequencies below 1 kHz was greatly reduced. They proposed a dual input system, with frequencies below 1 kHz being received mainly by the opercularis system and those above 1 kHz being received mainly by the tympanic system. Changes in the tension of the opercularis muscle would modify the sensitivity of the combined system to high and low frequencies. More recent work by Hetherington, Jaslow, and Lombard (1986) largely refuted this hypothesis by showing that the two systems articulate in such a way that the operculum and stapes move independently.

A second hypothesis to explain the function of the opercularis system was proposed by Wever (1979, 1985). He suggested that contraction of the opercularis muscle when the frog is vocalizing would cause the operculum to lock the stapedial footplate in place, reducing movement of the stapes and thereby greatly reducing the sensitivity of the tympanic ear. This would serve as a mechanism to protect the auditory system from the loud sound of the frog's own voice. Recent authors have offered several lines of evidence to refute Wever's hypothesis. First, the independent movement of the two systems suggests a lock mechanism is unlikely. Second, the opercularis muscle is made up mainly of tonic fibers, not the fast twitch fibers required for rapid contraction. In fact, it is a very slowly contracting muscle that appears to remain in tonic contraction whenever a frog is sitting on the ground (Becker and Lombard 1977; Hetherington and Lombard 1983; Hetherington, Jaslow, and Lombard 1986; Hetherington 1987).

Hetherington (1988a) argued that the opercularis system functions primarily in detection of vibrations at frequencies below 200 Hz. The tonic contraction of the muscle ensures a rigid connection between the operculum and the pectoral girdle that is well suited for transmission of low-frequency vibrations. This explanation is applicable to amphibians in general; many urodeles are sensitive to low frequency vibrations even though they lack a tympanic ear (Wever 1978, 1985; Ross and Smith 1979). The hypotheses of Lombard and Straughan (1974) and Wever (1979, 1985) do not provide a functional explanation for the opercularis system in nonvocalizing amphibians. In anurans, the opercularis muscle has a vertical orientation when the frog is sitting in a normal posture, and this probably enhances transmission of vertical displacements of the pectoral girdle. If the opercularis muscle is removed, responses of inner ear receptors to vibrations are greatly reduced (Hetherington 1985). Recent work by Mason and Narins (2002) has shown that greater coupling occurs between the operculum and the footplate than previously thought. They revived Weaver's protective hypothesis and argued that the operculum is not the major avenue for detection of ground-borne vibrations afterall. They also suggested that the role of the operculum in amphibians remains unresolved.

Other Extratympanic Pathways

Although Lombard and Straughan's original concept of separate input channels for high and low frequency sounds seems to be an oversimplification, there is considerable evidence of extratympanic pathways for airborne sound and not just ground-borne vibrations. Wilczynski, Resler, and Capranica (1987) found that both tympanic and extratympanic pathways are important for sound reception in *Rana catesbeiana*. At frequencies below about 900 Hz, auditory nerve fibers were about equally sensitive to tympanic and extratympanic input, but at higher frequencies, sensitivity to tympanic input was much greater. However, over a fairly broad frequency range (about 300 to 1,200 Hz), inner ear responses probably reflect an interaction between tympanic and extratympanic transmission. The precise nature of extratympanic inputs of airborne sounds is unknown. The opercularis system could be involved, as suggested by Lombard and Straughan's (1974) experiments, but this has not been definitively demonstrated (Wilczynski, Resler, and Capranica 1987; Jaslow, Hetherington, and Lombard 1988). Another possibility is that sound is simply transmitted through the tissues of the head, a pathway that is likely to be more effective underwater than in air.

Still another route was suggested by work with *Eleutherodactylus coqui* by Narins, Ehret, and Tautz (1988). They found that the body wall adjacent to the lungs vibrates in response to frequencies within the range of the advertisement call. Since the lungs have an open connection to the middle ear cavity through the buccal cavity and eustachian tubes, these vibrations could be directly transmitted to the auditory system through changes in air pressure in these cavities (fig. 7.35). Subsequent work showed that sounds of about 1 kHz, the frequency of the introductory co note of this species, are transmitted via the lung channel more effectively than are sounds around 2 kHz, the frequency of the qui note (Ehret et al. 1990). Other species of frogs exhibit significant transmission of sound via the lung-ear pathway, suggesting this is an important component of hearing in many anurans (Hetherington 1992a, b; Ehret, Werth, and Kamada 1994), including those that lack a tympanic ear (Lindquist, Hetherington, and Volman 1998; Hetherington and Lindquist 1999) and those that call underwater (Christensen-Dalsgaard and Elepfandt 1995). This is particularly true of small-bodied species, in which the movements of the body wall in response to sound can actually exceed those of the tympanic membrane (Hetherington 1992a). This allowed for the retention of vocal communication in small-bodied anurans that have undergone a reduction or loss of the tympanic ear (Hetherington 1992b). In some species, the body wall over the lungs vibrates in response to lower frequency sound than does the tympanum, but in others, frequency-sensitivity is similar (Ehret, Werth, and Kamada 1994). Input from the lung pathway is thought to be particularly significant for detecting the direction of a sound source (see "Sound Localization" in the following).

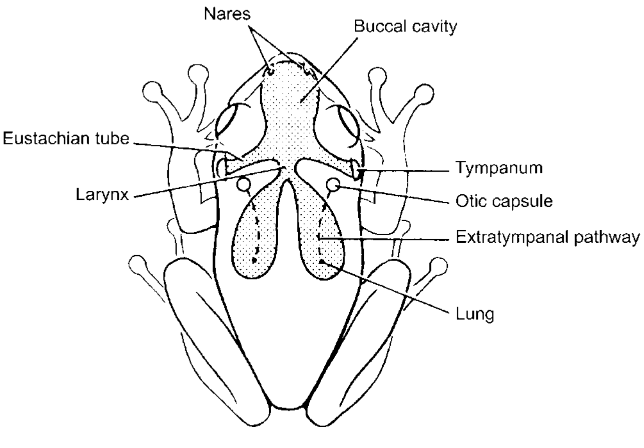

Fig. 7.35. Diagram of possible pathways for sound transmission in *Eleutherodactylus coqui*. Vibrations of the body wall over the lungs are transmitted to the ears via the larynx, buccal cavity, and Eustachian tubes. Sound also may be transmitted through the body to the otic capsule. After Narins et al. (1988).

Anatomy and Function of the Inner Ear

The anuran inner ear is contained within the otic capsule (fig. 7.34) and consists of a number of fluid-filled chambers (the endolymphatic or membranous labyrinth) within which the sensory organs are located. The bony labyrinth of the otic capsule surrounds these sacs, and the space between the membranous and bony labyrinth is filled with fluid as well (the perilymphatic system). The perilymphatic system is important for hearing because it receives vibrations from the middle ear and transmits them to the fluid-filled chambers of the membranous labyrinth (E. Lewis and Narins 1999; Purgue and Narins 2000). The dorsal parts of the otic labyrinth make up the vestibular system for detecting motion and maintaining balance. The ventral part contains four sensory organs, each of which is innervated by a branch of the auditory nerve (VIIIth cranial nerve; fig. 7.36). One of these, the lagena, is mainly a gravity receptor involved in maintaining equilibrium (Caston, Precht, and Blanks 1977). It does not appear to play a role in detecting communication signals (Feng, Narins, and Capranica 1975; Baird and Lewis 1986; M. Jørgensen and Christensen-Dalsgaard 1991). The three remaining organs, the saccule, amphibian papilla, and basilar papilla, are sensitive to vibrations, to airborne sounds, or to both (Wilczynski and Capranica 1984; Wever 1985; E. Lewis and Lombard 1988; Zakon and Wilczynski 1988; M. Jørgensen and Chistensen-Dalsgaard 1991; Yu, Lewis, and Feld 1991; Christensen-Dalsgaard and Narins 1993; Christensen-Dalsgaard and Jørgensen 1996; E. Lewis and Narins 1999).

Saccule

The function of the saccule varies among the major vertebrate groups. In fish, it is primarily an acoustic organ, while in birds and mammals it is mainly involved in vestibular function (Fay and Popper 1985). The saccule of amphibians

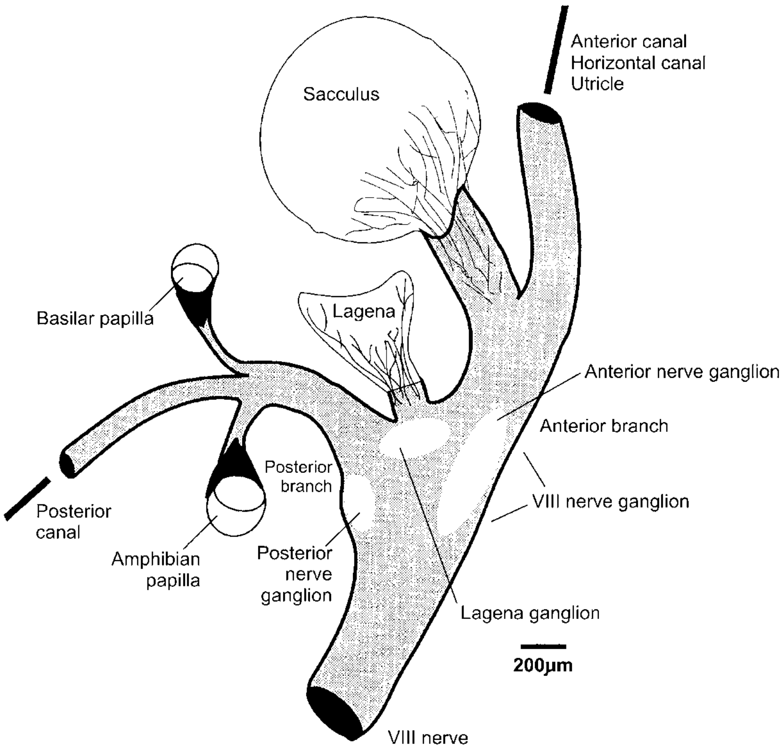

Fig. 7.36. Diagram of peripheral innervation of the right VIII nerve of *Rana pipiens* in ventromedial view, showing major sound-receiving organs. After Simmons et al. (1992).

is extraordinarily sensitive to substrate-borne vibrations, particularly frequencies below 100 Hz (Koyama et al. 1982; E. Lewis, Leverenz, and Koyama 1982; E. Lewis 1983; Narins and Lewis 1984; Christensen-Dalsgaard and Jørgensen 1988, 1996; E. Lewis and Lombard 1988; M. Jørgensen and Christensen-Dalsgaard 1991; Yu, Lewis, and Feld 1991; Christensen-Dalsgaard and Narins 1993; Smotherman and Narins 2004). Central processing of vibrational information takes place in the midbrain in the same region where acoustic cues are processed (Walkowiak 1980a; Comer and Grobstein 1981; Fuzessery and Feng 1982; Christensen-Dalsgaard and Jørgensen 1989).

This seismic sense probably is used by most anurans to detect the approach of predators. However, it also functions in the detection of substrate-borne signals produced by frogs that call underground (E. Lewis and Narins 1985) and perhaps vibrations produced by frogs calling in the water (Walkowiak and Munz 1985). The saccule also is capable of detecting low-frequency airborne sounds, and the best excitatory frequencies of neurons innervating the saccule are similar for vibrations and sound (Moffat and Capranica 1976; M. Jørgensen and Christensen-Dalsgaard 1991; Yu, Lewis, and Feld 1991; Christensen-Dalsgaard and Narins 1993; Christensen-Dalsgaard and Jørgensen 1996). Because the tympanum does not transmit sound effectively at such low frequencies, it is possible that the saccule is an important receptor for sound transmitted through extra-tympanic pathways, such as the bones of the skull and the lungs.

Amphibian Papilla

The amphibian papilla is an organ located in a chamber called the amphibian papillar recess (fig. 7.34). It is found in all three groups of extant amphibians and is unique to these groups, providing evidence for the monophyly of modern amphibians (Wever 1985; E. Lewis and Lombard 1988). Amphibian papillar fibers in the VIIIth nerve are sensitive mainly to frequencies between 100 Hz and 1,200 to 1,400 Hz. Most species have two distinct populations of fibers innervating the amphibian papilla. One group is tuned to frequencies below about 500 Hz and can be inhibited by simultaneous presentation of sounds just above the best frequency of the neuron, a phenomenon known as two-tone inhibition (Capranica and Moffat 1980). The other is a group of fibers tuned to midfrequency sounds (500–1,200 Hz), which cannot be inhibited by higher frequencies. These two types of fibers have been found in various ranids, bufonids, hylids, and leptodactylids (Feng, Narins, and Capranica 1975; Narins and Capranica 1980; Capranica and Moffat 1983; Wilczynski and Capranica 1984; Zakon and

Wilczynski 1988), but only the lower frequency population was present in *Scaphiopus couchii* (Capranica and Moffat 1975). Recent work has shown that the amphibian papilla also is sensitive to vibrations at frequencies overlapping and slightly above the sensitivity of the saccule (M. Jørgensen and Christensen-Dalsgaard 1991; Yu, Lewis, and Feld 1991; Christensen-Dalsgaard and Narins 1993; Christensen-Dalsgaard and Jørgensen 1996).

The amphibian papilla shows a tonotopic organization, with sensory hair cells sensitive to different frequencies distributed on different parts of the papilla. This change in frequency sensitivity is correlated with morphological differences in hair cells from different regions of the organ (Simmons, Bertolotto, and Narins 1994). Hair cells are found in a patch at the rostral end of the papilla and on a long, S-shaped caudal extension (fig. 7.37 A). In general, neurons tuned to the lowest frequencies innervate cells at the rostral end of the papilla; this is the inhibitable population of low-frequency fibers described above. The range of the amphibian papilla extends into higher frequencies in a caudal direction (fig. 7.37 B), with the S-shaped extension giving rise to the population of noninhibitable, midfrequency fibers (E. Lewis, Leverenz, and Koyama 1982; E. Lewis, Baird, Leverenz, and Koyama 1982; Wilczynski and Capranica 1984; E. Lewis and Lombard 1988; Zakon and Wilczynski 1988). In primitive anurans, such as *Ascaphus,* the caudal extension is absent and sensitivity of the amphibian papilla to frequencies above 500 Hz is poor. In pelobatids, this part of the papilla is small, perhaps accounting for the lack of midfrequency, noninhibitable fibers. In more derived anurans, the caudal extension is longer, extending the range of the amphibian papilla to frequencies between 700 and 1,400 Hz (E. Lewis 1981). There is considerable morphological diversity among species of derived anurans that parallels the diversity of call frequencies used by different species (M. Ryan 1986a). Even within closely related species, such as the monophyletic assemblage of frogs in the genus *Eleutherodactylus* on Puerto Rico, there is considerable diversification in the form of this organ, suggesting that changes in the structure of the auditory system have accompanied divergence in the structure of advertisement calls (E. Lewis, Hecht, and Narins 1992).

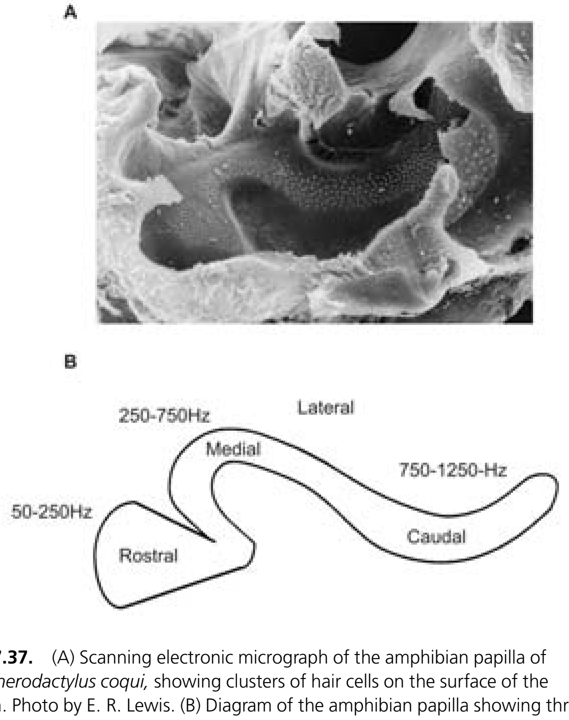

Fig. 7.37. (A) Scanning electronic micrograph of the amphibian papilla of *Eleutherodactylus coqui,* showing clusters of hair cells on the surface of the organ. Photo by E. R. Lewis. (B) Diagram of the amphibian papilla showing three regions of different frequency sensitivity. After Smotherman and Narins (1999).

The tuning of the amphibian papilla appears to be based on a mechanism similar to that found in the cochlea of the mammalian ear, although the system in amphibians has evolved completely independently. In mammals, a basilar membrane runs the length of the coiled cochlea and supports the sensory hair cells. Mechanical stimulation of the basilar membrane near its base sets up a traveling wave that moves along the membrane to its apex. Because the thickness and mass of the membrane change along its length, both the velocity and wavelength of the traveling wave change. Maximum excitation of hair cells at different places along the basilar membrane is a function of the frequency of sound being transmitted. This provides a mechanical filter that allows the ear to make fine-scale frequency discriminations (Fay and Popper 1985). An analogous traveling wave filter has been proposed for amphibians, possibly supported by the tectoral membrane that overlies the hair cells in the amphibian papilla (Capranica and Moffat 1977; Hillery and Narins 1984; E. Lewis and Lombard 1988). Like the mammalian basilar membrane, the thickness of the tectoral membrane varies, with the most massive portion being over the low-frequency hair cells at the rostral end of the papilla (Wever 1973; E. Lewis 1976; Shofner and Feng 1983, 1984). Although the details of how such a traveling wave filter actually works is not yet fully understood (E. Lewis and Lombard 1988; Zakon and Wilczynski 1988; E. Lewis, Hecht, and Narins 1992), it appears that the amphibian papilla shows a remarkable degree of functional convergence with the mammalian auditory system.

Basilar Papilla

The basilar papilla is a small organ that sits in a chamber (the basilar papillar recess) opening to the saccule (fig. 7.34). There has been some debate about whether or not the basilar papilla in amphibians is homologous to auditory organs in reptiles, birds and mammals, or is an independently derived structure (E. Lewis and Lombard 1988; Smotherman and Narins 2004). All anurans have a basilar papilla, as do primitive urodeles, but it is absent in most derived urodeles and most caecilians. Basilar papillar fibers in the VIIIth nerve are most sensitive to high frequency sounds above 1,000 Hz (Feng, Narins, and Capranica 1975; E. Lewis, Leverenz, and Koyama 1982; Wilczynski and Capranica 1984; Zakon and Wilczynski 1988). All fibers innervating the basilar papilla usually have best frequencies within about 100 Hz of each other and effectively are tuned to the same frequency. The basilar papilla functions as a mechanical resonator, with tuning characteristics that depend in part on the size of the organ. The size of the basilar papilla generally increases with body size both within and between species, and larger basilar papillae are tuned to lower frequencies. Consequently, larger frogs generally are most sensitive to lower frequencies (within the range above 1,000 Hz) than are smaller frogs (Wilczynski and Capranica 1984; Zakon and Wilczynski 1988). This is true for comparisons between species (Loftus-Hills 1973a; Walkowiak, Capranica, and Schneider 1981; Wilczynski, McClelland, and Rand 1993), between sexes that differ in body size within species (Narins and Capranica 1976, 1980; Wilczynski, Zakon, and Brenowitz 1984; Wilczynski, Keddy-Hector, and Ryan 1992; McClelland, Wilczynski, and Rand 1997), and between same-sex individuals of different body size (Shofner and Feng 1981, 1984; Wilczynski, Zakon, and Brenowitz 1984; Shofner 1988; Zakon and Wilczynski 1988; Keddy-Hector, Wilczynski, and Ryan 1992).

Central Auditory Pathways

Most of our understanding of central auditory pathways in anurans comes from studies of ranid frogs, with limited information on certain parts of the brain from other families. The nonneurobiologist can easily become lost in the complex interconnections of different regions of the brain, and I will not attempt a detailed summary here. Instead, I will simply describe the main features of auditory pathways in ascending order from the medulla (hindbrain) to the diencephalon (midbrain) and telencephalon (forebrain), with a brief mention of features that are important for understanding neural processing of acoustic signals. Detailed descriptions of anatomy and wiring diagrams of connections between major brain centers can be found in E. Lewis, Leverenz, and Koyama (1980), Wilczynski (1981, 1988), Wilczynski and Capranica (1984), Feng (1986a, b), Neary (1988), Will (1988), Will and Fritzsch (1988), and J. C. Hall (1994).

Fibers from the VIIIth nerve enter the medulla in the posterior part of the brain (fig. 7.38) and terminate in the dorsolateral nucleus (also called the dorsal medullary nucleus or dorsal acoustic nucleus). Fibers from the basilar papilla and amphibian papilla project to different regions of this nucleus, and there is separation of the low and midfrequency fibers from the amphibian papilla as well. Cells in the dorsolateral nucleus receive inputs from both ears through connections between the nuclei on each side of the brain (Feng and Capranica 1976; Wilczynski and Capranica 1984; Fuzessery 1988). From the dorsolateral nuclei there are nerve projections to the superior olivary nuclei, located at the base of the medulla, and to both sides of the torus semicircularis in the midbrain. The latter seems to be homologous to the inferior colliculus in the mammalian brain and is a major center for processing of acoustic signals and the integration of other sensory information (Wilczynski 1981, 1988; Wilczynski and Capranica 1984; J. C. Hall 1994; Walkowiak and Luksch 1994). The torus becomes sensitive to conspecific acoustic signals shortly after metamorphosis. As the frog develops and grows, neurons in the torus exhibit a gradual downward shift in the frequencies to which they are most sensitive, as well as a sharpening of frequency tuning (Boatright-Horowitz and Simmons 1995) and changes in their response to amplitude-modulated (Boatright-Horowitz, Garabedian, Odabashian, and Simmons 1999).

The main ascending connections from the torus terminate in the central thalamic nucleus of the diencephalon. Auditory sensitivity also is present in several other nuclei in this region, receiving inputs from the central thalamic nucleus and directly from the torus as well (Neary 1974, 1988; Mudry, Constantine-Paton, and Capranica 1977). Several areas of the forebrain (telencephalon) exhibit acoustic sensitivity, including the striatum, medial pallium, and preoptic area. These receive connections from several nuclei in the diencephalon and directly from the torus (Wilczynski and Northcutt 1977, 1983; Gruberg and Udin 1978; Mudry and Capranica 1980; Neary 1988). Some of these areas are linked to motor centers of the brain and provide a link between the perception of calls and call production (R. Schmidt 1966, 1968b, 1973a, 1974, 1984; Knorr 1976; Wada and Gorbman 1977; Urano and Gorbman 1981; Aitken and Capranica 1984; Wetzel, Haerter, and Kelly 1985; Neary 1988; Schneider 1988; Walkowiak and Luksch 1994), as well as phonotactic responses by females (R. Schmidt 1969, 1971; Walkowiak and Luksch 1994). There are at least three pathways between the torus, auditory centers of the diencephalon, and the hypothalamus. These pathways provide a link between the auditory system and the center for hormonal control of reproductive behavior (Urano and Gorbman 1981; Brzoska and Obert 1980; Ball 1981; Neary 1988; Neary and Wilczynski 1986; Wilczynski and Allison 1989; Allison and Wilczynski 1991; Wilczynski 1992; Wilczynski 1993).

Processing of Acoustic Signals

So far, I have discussed only the basic structure of the auditory system and the major peripheral and central auditory pathways, but not the way in which this system actually processes acoustic signals. Processing of acoustic information involves at least three major steps: (1) detection of the signal, (2) recognition of key properties of signals that distinguish them from other sounds in the environment, and (3) accurate localization of the signaler. Behavioral experiments have shown that anurans can localize the source of acoustic signals and generally are quite selective in their responses to acoustic stimuli. Selectivity in females usually is tested by presenting them with a choice of two or more sounds and observing their phonotactic responses, as discussed in a previous section (Gerhardt 1992a). In most experiments, male frogs are presented with recorded calls. Either an evoked vocal response or a reduction in calling during the stimulus is then measured (Capranica 1965; Paillette 1970a; Loftus-Hills 1973b; Narins and Capranica 1978; Narins 1982a; Walkowiak and Brzoska 1982; Zelick and Narins 1982; Megela and Capranica 1983; Schwartz and Wells 1983a, b, 1984; Megela Simmons 1984; Wells and Schwartz 1984a, b; Sullivan and Leek 1986; Allan and Megela Simmons 1994). These experiments have demonstrated that anurans are capable of fine-scale discrimination between conspecific and heterospecific calls and between different types of calls within their own species' repertoire. Discrimination between calls can be based on differences in frequency structure, temporal structure, or both (Gerhardt 1988; Walkowiak 1988b; Brenowitz, Rose, and Adler 2001).

Processing in the Frequency Domain: Peripheral Tuning

Because the anuran tympanum has a relatively flat frequency response over a broad range of frequencies, the middle ear provides little frequency selectivity. It simply acts as a low-pass filter, cutting off frequencies above a certain range, but transmitting those below that range at similar amplitudes. In general, cut-off frequencies at the high end tend to decrease as body size and tympanum size increase. Hence, in a relatively small species, *Hyla cinerea,* there is rapid attenuation of frequencies above 3,500 Hz. For larger species, such as *Bufo americanus* and *Rana pipiens,* the cut-off is between 1,200 and 1,800 Hz (Moffat and Capranica 1978; Capranica and Moffat 1983; Wilczynski, Resler, and Capranica 1987).

The inner ear exhibits a greater degree of frequency selectivity. As previously discussed, nerve fibers innervating the basilar and amphibian papillae are tuned to different frequency ranges. Individual fibers have V-shaped tuning curves; that is, each fiber has a characteristic best frequency to which it responds at the lowest sound intensity threshold. Different populations of nerve fibers are tuned to different frequencies (fig. 7.39 A). This type of tuning is not unique to anurans, but is characteristic of all vertebrate auditory systems. The sharpness of tuning of individual nerve fibers in anurans is not very different from that found in mammals (Wilczynski and Capranica 1984). When responses of fibers from several individuals are pooled, the range of frequency sensitivity in the population can be determined (fig. 7.39 B). Because of structural characteristics of the two auditory organs discussed above, individual amphibian papillar fibers show a wide range of best frequencies within and between individuals, whereas basilar papillar fibers exhibit little variation within individuals, but differ in best frequencies among individuals of different size (Zakon and Wilczynski 1988).

In general, peaks of sensitivity in the inner ear roughly correspond to the distribution of energy in the species' own calls (Gerhardt and Schwartz 2001). This was first demonstrated in Capranica's (1965) studies of bullfrogs (*Rana catesbeiana*). Calls with energy in two bands, one at around 200 Hz and another at 1,500 Hz, were most effective in eliciting vocal responses from males, and this represents the natural distribution of energy in bullfrog calls. Similarly, in *Hyla cinerea,* advertisement calls have two major bands of energy at about 900 Hz and 3,000 Hz, and calls with both frequency bands present are most effective in eliciting phonotactic responses from females (Gerhardt 1981b, 1987). In both cases, the low frequency energy in the call corresponds to peak sensitivities of amphibian papillar fibers, while the high frequency bands correspond to peak sensitivities of

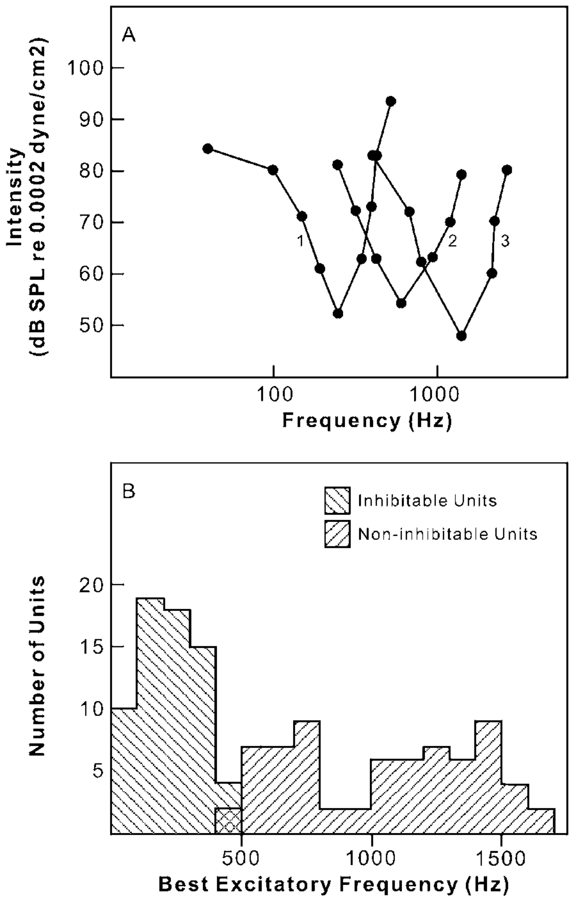

Fig. 7.39. (A) V-shaped tuning curves of three populations of nerve fibers of the bullfrog (*Rana catesbeiana*). Frequencies are plotted on a logarithmic scale. The low-frequency population has a best excitatory frequency (BEF) of about 250 HZ, the mid-frequency population has a BEF of about 600 HZ, and the high-frequency population has a BEF of about 1400 HZ. The low and mid-frequency populations are derived from the amphibian papilla, while the high-frequency population is derived from the basilar papilla. (B) Histogram of best excitatory frequencies of individual eighth nerve fibers. After Feng, Narins, and Capranica (1975).

basilar papillar fibers (Frischkopf, Capranica, and Goldstein 1968; Feng, Narins, and Capranica 1975; Capranica and Moffat 1983). Behavioral responses to different frequencies in *H. cinerea* are closely matched to sensitivity peaks in behaviorally derived audiograms of total hearing sensitivity for this species (Megela Simmons, Moss, and Daniel 1985). This is less true for bullfrogs, which exhibit relatively poor sensitivity to 200 Hz sounds, even though these are effective in eliciting vocal responses (Megela Simmons, Moss, and Daniel 1985). Furthermore, these frogs are not deaf to sounds outside the frequency range of their calls, but in fact are sensitive to a relatively broad range of frequencies (Capranica 1992).

In *Rana catesbeiana* and *Hyla cinerea,* co-activation of both the amphibian and basilar papilla seems to be necessary to elicit a maximum behavioral response to a call, but this clearly is not the case for many anurans. Most small frogs have relatively high-frequency calls that fall outside the range of the amphibian papilla and therefore excite only the basilar papilla (e.g., Hödl, Amezquita, and Narins 2004). In contrast, a few species, such as *Physalaemus pustulosus* and *Eleutherodactylus coqui,* have calls or call components falling only within the range of the amphibian papilla (Narins 1983; M. Ryan 1985b; G. Rose, Zelick, and Rand 1988). In species with high frequency calls, there generally is a good match between the tuning of basilar papillar fibers in the VIIIth nerve and the dominant frequency of the call (Capranica 1976a, b; Wilczynski, Zakon, and Brenowitz 1984; Zakon and Wilczynski 1988; Bosch and Boyero 2003a). The tuning of the basilar papilla is related to body size, so there often is parallel geographic or altitudinal variation in body size, dominant frequency of the call, and frequency sensitivity of the ear (Capranica, Frischkopf, and Nevo 1973; Nevo and Schneider 1976; Nevo and Capranica 1985; Narins and Smith 1986; M. Ryan 1988a). There is evidence from studies of *Acris crepitans* that the evolution of call frequency and basilar papilla sensitivity has been independent of body size. The result is a closer match between call frequencies and tuning of the auditory system than expected from interpopulation differences in body size alone (M. Ryan and Wilczynski 1988; Keddy-Hector, Wilczynski, and Ryan 1992; Wilczynski, Keddy-Hector, and Ryan 1992).

In some species, there is evidence of sexual dimorphism in peripheral auditory tuning that is related at least in part to differences in body size (Zakon and Wilczynski 1988). For example, in *Eleutherodactylus coqui,* amphibian papillar fibers of both males and females exhibit sensitivity to frequencies in the range of the "co" note (about 1,000 Hz). Excitation of this organ alone is sufficient to elicit a vocal response from males (Narins 1983). Males seem to pay little attention to the higher frequency "qui" note, which falls within the range of the basilar papilla (Narins and Capranica 1976, 1978, 1980). Females, on the other hand, are attracted to this note, but are little influenced by the co note. Females have a population of basilar papillar fibers that are well tuned to the frequency of the qui note (about 2,000 Hz). Males, on the other hand, are smaller than females and have many basilar papillar fibers tuned to frequencies above 3,000 Hz, well above the frequency range of any conspecific calls (fig. 7.40).

Similar sexual dimorphism has been found in the tuning of basilar papilla fibers in *Pseudacris crucifer* (Wilczynski, Zakon, and Brenowitz 1984) and other hylids (McClelland, Wilczynski, and Rand 1997). In these cases, the result is that ears of females are well matched to the average frequency of the call, whereas males have peak sensitivity at higher frequencies. In many species, however, the match between basilar papilla tuning and call frequency is not perfect. In several species, including *Physalaemus pustulosus* and *Acris*

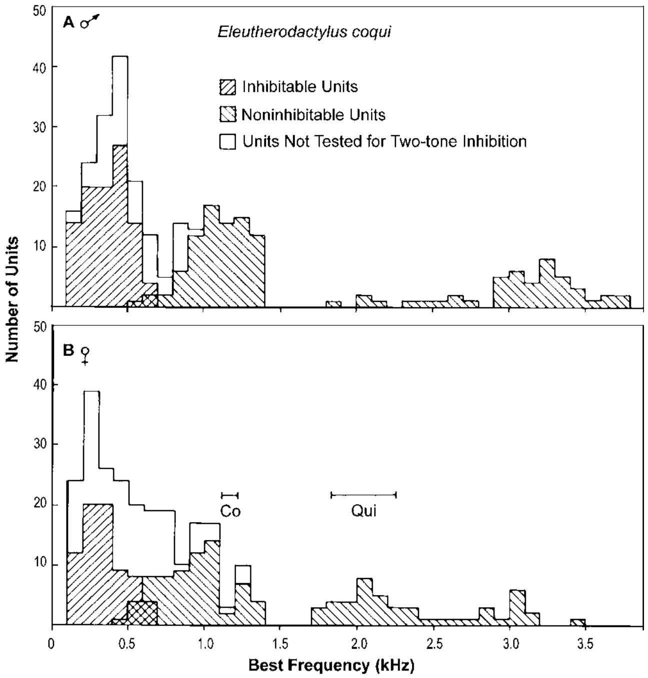

Fig. 7.40. Sexual dimorphism in tuning of peripheral auditory system in *Eleutherodactylus coqui.* Nerve fibers with best excitable frequencies below 1.5 kHz are derived from the amphibian papilla, while those above 2 kHz are derived from the basilar papilla. The latter exhibit sexual differences in tuning, with males having fibers tuned to higher frequencies. After Narins and Capranica (1976).

crepitans, the basilar papilla of females is tuned to slightly lower frequencies than the average frequency of male calls in the same population (Gerhardt and Schwartz 2001). One possible explanation for this is that tuning of the auditory system represents a trade-off between long-distance and short-distance communication (Sun et al. 2000). This is because high frequencies in calls exhibit greater attenuation with distance than do low frequencies, so an ear tuned to lower than average frequency could be adapted to detect calls at a distance. It also is possible that auditory tuning and call frequency structure are subject to different evolutionary constraints, and any deviation from a theoretical optimum or perfect match does not reflect an adaptive response.

It is important not to read too much into a match, or lack of a match, between the average dominant frequencies of male calls in a population and average best frequencies in the tuning curves of females. The tuning curves of frogs are not very sharp, but exhibit a fairly broad range of frequency sensitivity. The match between the tuning curves of females and male calls could be sufficient to bias choices of females toward conspecific calls and away from heterospecific calls that differ significantly in frequency structure. It is not clear, however, that this can account for choices that females make among conspecific calls differing by a few hundred Hertz in dominant frequency. This is especially true for species with high-frequency calls. Because of the structure of the basilar papilla, female frogs are expected to have relatively poor intensity-independent discrimination of frequencies that stimulate only that organ (Zakon and Wilczynski 1988; Gerhardt and Schwartz 2001).

Schwartz and Gerhardt (1998) found relatively poor frequency discrimination in female spring peepers (*Pseudacris crucifer*), especially in the absence of background noise. Furthermore, the choices of individual females that were tested several times often were not consistent. This is the only study in which the tuning curves of individual females have been determined after testing their behavior in playback experiments. The results showed that a female's preference for call dominant frequency was not correlated with best excitatory frequency, as determined from multi-unit recordings in the brain. This calls into question adaptive explanations for female preferences based on average best excitatory frequencies for whole populations (e.g., Sun et al. 2000; see further discussion of female choice in chapter 8).

Processing in the Frequency Domain: Central Nervous System

Tuning of the peripheral auditory system is only the first step in frequency processing. Further processing and integration of frequency information takes place in the auditory centers of the brain. Most of our knowledge of frequency processing in the brain is derived from studies of the response characteristics of individual neurons. We know a good deal about tuning characteristics of these neurons and how they respond to changes in frequency, but we know less about how information from neurons with different response characteristics is integrated. We also know relatively little about where this integration takes place, how the nervous system actually recognizes different types of calls, or how behavioral responses to calls are regulated (Fuzessery 1988). Therefore, only a brief outline of frequency processing in the central nervous system will be given here.

Most neurons in the dorsolateral nucleus seem to reflect the tuning characteristics of the VIIIth nerve fibers that terminate there. Cells in this region exhibit the V-shaped tuning curves characteristic of VIIIth nerve fibers, and the same three populations of fibers tuned to low, middle, and high frequencies can be identified. Hence, it appears that relatively little additional processing occurs at this level (Feng and Capranica 1976; Fuzessery and Feng 1981, 1983a; Fuzessery 1988). Many of these characteristics also are found in neurons of the superior olivary nucleus, but there also is evidence of neuronal interactions at this level that result in a sharpening of frequency sensitivity (Fuzessery 1988).

This sharpening of frequency tuning continues in the torus, where the majority of neurons exhibit single best frequencies like those at lower levels. However, other neurons in the torus exhibit a variety of responses not seen at lower levels. Some show little evidence of narrow tuning, but respond to a wide range of frequencies. Others have a bimodal response to two distinct frequencies, but are inhibited by or unresponsive to frequencies in between. Still others exhibit maximal responses to specific combinations of frequencies (Loftus-Hills 1971; Walkowiak 1980a; Hermes et al. 1981, 1982; Fuzessery and Feng 1982; Fuzessery 1988; Diekamp and Gerhardt 1992). Hence, in the torus we find the first evidence of an ability to selectively respond to sounds with complex frequency structure.

Further processing almost certainly occurs in higher brain centers as well, but our knowledge of frequency processing in the diencephalon and telencephalon is very incomplete and is based mostly on studies of *Rana pipiens*. In this species, some cells in the thalamus are highly selective in their responses to tone combinations, giving maximum responses to combinations corresponding to the distribution of energy in the advertisement call (Mudry, Constantine-Paton, and Capranica 1977; Fuzessery and Feng 1983b; J. C. Hall 1994). Mudry (1978) found evidence of similar selective responses to tone combinations in *Rana catesbeiana* and *Hyla cinerea* (cited in Capranica and Moffat 1983; Capranica and Rose 1983). In all three of these species, the excitatory tone combinations result in stimulation of both the amphibian and basilar papilla. How applicable these results are to anurans in general, particularly those with only a single frequency band in the call, is not yet known.

Processing in the Time Domain

The early work of Capranica and his colleagues focused almost exclusively on the frequency-tuning characteristics of the anuran auditory system. They were especially concerned with identifying potential "mating call detectors" in the brain that might function as a matched frequency filter to recognize biologically relevant sounds (e.g., Capranica and Moffat 1983). Textbook accounts often stop at this point, giving the misleading impression that processing of acoustic signals is simply a matter of recognizing the distribution of sound energy in the calls (e.g., Hopkins 1983; Duellman and Trueb 1986). While much of this early neurobiological work was being done, however, a large body of behavioral evidence was accumulating showing that recognition of conspecific calls and discrimination between different calls within a species' repertoire often is based on temporal features of the calls and not just frequency structure (see Gerhardt 1988, 1994a, c; Gerhardt and Schwartz 1995; Gerhardt and Huber 2002; and previous sections of this chapter). Consequently, in the 1980s investigators began to consider ways in which temporal features of calls are processed (Capranica and Rose 1983; Walkowiak 1988a; J. C. Hall 1994; Brenowitz, Rose, and Alder 2001; Gerhardt and Huber 2002; Narins and Feng 2006).

In contrast to the frequency selectivity of the peripheral auditory system, VIIIth nerve fibers are not tuned to particular rates of amplitude modulation (Feng, Hall, and Siddique 1991). Instead, the nerve simply fires in synchrony with amplitude modulated signals up to a certain rate (Walkowiak 1988a). To date, most species tested have been those with relatively low rates of amplitude modulation in their calls (less than 150 pulses/s). These species exhibit a cut-off rate at about 100–150 Hz (Capranica and Moffat 1975; Capranica and Rose 1983; G. Rose and Capranica 1983, 1985; Walkowiak 1984, 1988a). In the green treefrog (*Hyla cinerea*), however, rates of amplitude modulation within calls are much higher (260–300 Hz), and the auditory neurons of this species are capable of tracking such modulation (Klump et al. 2004). This is not surprising, because we know from behavioral experiments that some species with much higher pulse rates can distinguish between calls on the basis of pulse rate alone. For example, *Hyla microcephala* females exhibit a clear preference for calls of 225 pulses/s over those with pulse rates of 95, 150, or 325 pulses/s (Schwartz 1987b). It would be interesting to know the cut-off rate for VIIIth nerve synchrony in this species. It should be noted that these tropical frogs are active at a higher temperature (about 26° C) than temperate zone species tested previously (usually at around 20° C), and the ability to synchronize with an amplitude-modulated signal is very likely to be temperature dependent.

Most neurons in the acoustic nuclei of the medulla (dorsolateral nucleus and superior olivary nucleus) exhibit the same low-pass characteristics found in VIIIth nerve fibers, but are unselective in their responses to AM rates within the appropriate range. However, some cells appear to be selectively tuned to specific AM rates (Walkowiak 1988a; Condon, Chang, and Feng 1991), a trend that becomes more pronounced in the torus and probably continues in high brain centers such as the thalamus (J. C. Hall and Feng 1986, 1987; Walkowiak 1988a). The torus has been the site of the most intensive studies of temporal processing. Single-cell recordings in ranids, bufonids, hylids, and leptodactylids have all yielded similar results. Several types of neurons have been identified in the torus, each with a distinct response to AM signals (fig. 7.41). Some cells are tuned to specific rates of amplitude modulation, often approximating the rate of the species' advertisement call. However, the occurrence of AM-tuned units in the midbrain does not appear to be a specific adaptation of anurans for detecting conspecific calls, but rather a general property of vertebrate brains (G. Rose 1986). Furthermore, not all toral cells are AM-tuned. Many are nonselective, responding equally well to a wide range of amplitude-modulated signals. Still others act as high or low-pass filters, responding only to AM rates above or below a certain level. Finally, some units are suppressed

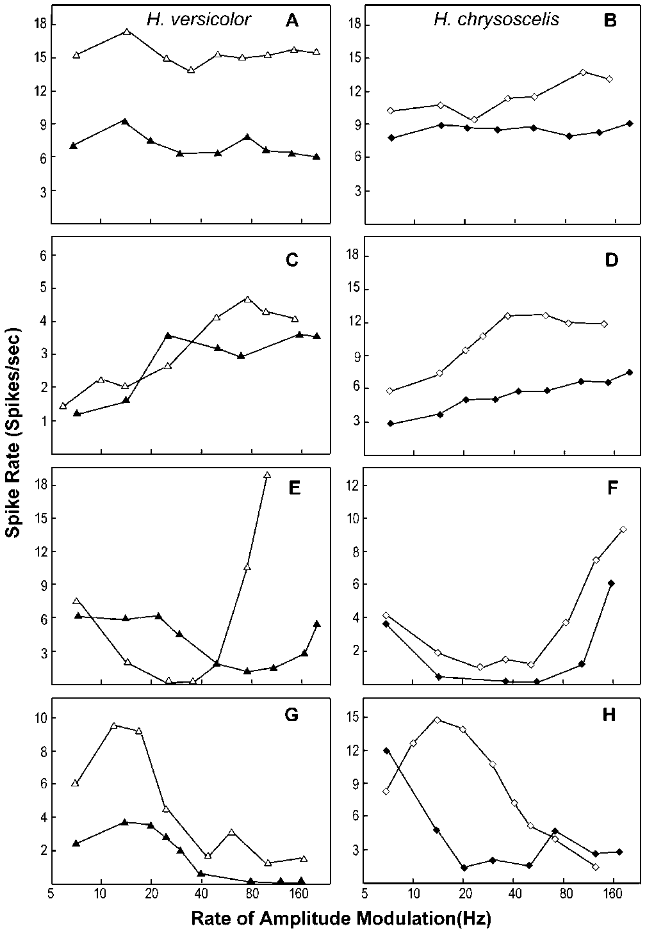

Fig. 7.41. Iso-intensity spike rates of single units of the torus semicircularis of two species of treefrogs, *Hyla versicolor* and *H. chrysoscelis,* as a function of the rate of amplitude modulation of a white-noise sitimulus. The two types of symbols indicate recordings from different neurons. Some units show nonselective responses to amplitude-modulated stimuli (A, B). AM high-pass units (C, D) respond strongly to high rates of amplitude modulation. Band-suppression units (E, F) respond to high and low rates of modulation, but less strongly to intermediate rates. Low-pass units (G, H) respond primarily to low rates of amplitude modulation. Not shown are band-pass units that respond to a range of intermediate AM rates. After G. Rose, Brenowitz, and Capranica (1985).

by certain AM rates (Capranica and Rose 1983; G. Rose and Capranica 1983, 1984, 1985; Walkowiak 1984, 1988a; Capranica, Rose, and Brenowitz 1985; G. Rose, Brenowitz, and Capranica 1985; Epping and Eggermont 1986a, b; J. C. Hall 1994; Penna, Lin, and Feng 1997). Responses to rates of amplitude modulation in the torus are temperature-dependent (Brenowitz, Rose, and Capranica 1985; G. Rose, Brenowitz, and Capranica 1985), which probably accounts in part for temperature-dependent changes in behavioral preferences for pulse rate observed in some treefrogs (Gerhardt 1978c; Gerhardt and Doherty 1988). Neurons in the torus also are selectively responsive to intrapulse amplitude modulation, pulse duration, pulse shape, and call duration (Penna, Lin, and Feng 1997; Alder and Rose 2000).

Long-term Temporal Integration

Recent work in which synthetic calls were played to *Pseudacris regilla* has shown that cells in the torus integrate the temporal characteristics of calls, especially pulse repetition rate, over relatively long periods of time (on the order of hundreds of milliseconds). This type of long-term temporal integration enables the frogs to discriminate between advertisement and aggressive calls that differ mainly in pulse rate (Alder and Rose 1998; Brenowitz, Rose, and Aldler 2001; G. Rose and Brenowitz 2002). Long-term temporal integration also has been demonstrated in *Rana pipiens.* Specifically, neurons in the torus that were most sensitive to relatively high pulse repetition rates (40–50 pulses/s in this species) required a threshold number of pulses to be presented before they could respond to the stimulus. Once the neurons began to respond, responses continued as long as the stimulus continued, so responses were greater to longer stimuli. At pulse rates above those to which the neurons were most sensitive, neural responses were reduced, apparently because they did not have sufficient time to recover between pulses.

The need for female frogs to perform long-term integration of male signals to detect the appropriate pulse rate of conspecific advertisement calls could drive the evolution of call structure and calling behavior in males. In amplitude-modulated calls consisting of trains of repeated pulses, long calls contain more pulses repeated at the appropriate rate than do short calls, and females might prefer males that give longer calls. Such preferences could be considered to result from sensory exploitation (M. Ryan 1990), with males exploiting a pre-existing sensory mechanism (long-term integration of pulse rate) to make their calls more attractive (Alder and Rose 2000; G. Rose et al. 2002).

Female preferences for long calls have been demonstrated in a number of species, including *Hyla versicolor* (Klump and Gerhardt 1987; see also chapter 8). In that species, males respond to the presence of females by greatly lengthening their calls beyond the duration of normal advertisement calls. As discussed in a previous section of this chapter, males of other species make similar adjustments in their calls when females are detected nearby, often giving longer trains of pulses or repeating a pulsed call at a higher rate, as in *Hyla ebraccata* and *H. microcephala.* In *H. ebraccata,* females prefer calls with the largest number of pulses repeated at the pulse rate of the advertisement call. Hence, they prefer single-note advertisement calls to aggressive calls of the same duration; the latter have much higher pulse rates. They also prefer aggressive calls to which secondary notes have been added to those consisting only of the introductory note. Secondary notes have the same pulse rate as do advertisement calls. Multi-note advertisement calls with long primary notes and short secondary notes of the same pulse rate were about as attractive to females as a continuous single-note call of the same duration calls (Wells and Bard 1987), a result that supports the temporal integration model of Brenowitz, Rose, and Adler (2001).

Processing of Signals in Noise

Most of the neurobiological studies discussed above have involved testing of individuals under ideal experimental conditions, with pure tones or AM stimuli being delivered directly to the auditory system. However, frogs in the real world frequently communicate in a very noisy environment, in which conspecific calls, calls of other species, and nonbiological sources of noise all reduce their ability to detect and recognize calls of other individuals (Narins and Zelick 1988; Wollerman 1999). Frogs exhibit a variety of behavioral strategies to reduce the effects of background noise, including a remarkable ability to detect even very brief periods of quiet and insert their own calls in those periods (Schwartz and Wells 1983a, b; Zelick and Narins 1983). These behavioral responses were discussed in more detail in the section on chorusing interactions.

The main effect of noise on the auditory system is to reduce the sensitivity of individual nerve fibers and to saturate the auditory system so that signals of interest cannot be distinguished from background noise. Such physiological masking is not limited to simultaneous exposure to the signal and to noise; exposure to loud noise can reduce the sensitivity of the ear for time period after the exposure ceases (Megela and Capranica 1982; Zelick and Narins 1985b). Hence a major difficulty for animals trying to communicate in noise is to make accurate intensity discriminations that allow them to pick out relevant signals from the background. One way of accomplishing this is to increase the thresholds of individual neurons to avoid overloading the system. An auditory nerve fiber fires at an increasing rate as the sound pressure level of a stimulus increases, up to a certain point at which the fiber is saturated and firing at its maximum rate. Hence, differences in firing rate can be used to code differences in signal intensity. In *Eleutherodactylus coqui,* Narins (1987) found a shift in the relationship between intensity and firing rate in the presence of broadband noise, effectively decreasing the sensitivity of the lowest threshold fibers and avoiding complete saturation of the auditory system. This would allow the frog to make intensity discriminations needed for signal detection even at high noise levels. Signal detection also is enhanced because individual neurons tuned to the same frequency have a wide range of intensity thresholds. Hence, at high noise levels, the most sensitive fibers become saturated, but higher thresholds units are still able to detect the signal (Capranica and Moffat 1975; Feng 1982; Narins and Zelick 1988).

The tuning of peripheral auditory nerve fibers to frequencies near those of conspecific calls, and the sharpening of that tuning in the central nervous system, enable a frog to extract signals from noise more effectively than would be possible if all fibers were broadly tuned. However, this alone is not sufficient, because background noise in a chorus often has energy concentrated around the frequency of the frog's own call (Gerhardt and Klump 1988a; Narins and Zelick 1988). Nerve fibers differ in their capacity to reject noise near the frequency of the signal being detected, so the behavioral effects of masking depend on both the frequency and intensity of the masking sound (Ehret and Gerhardt 1980; Narins 1982b). In general, frequency selectivity is greatest at low frequencies, where tuning curves of auditory nerve fibers are relatively narrow, and gradually decreases at higher frequencies (Ehret and Capranica 1980), a pattern found in many vertebrates. However, using a behavioral technique, Moss and Megela Simmons (1986) found that the ability of *Hyla cinerea* to extract signals from noise is greatest at frequencies similar to those in the advertisement call. In contrast, *Rana catesbeiana* exhibits its greatest capacity to reject noise at around 900 Hz, a frequency not present in the advertisement call. This suggests that matching of frequency selectivity to the spectrum of the advertisement call is not a general feature of all anuran auditory systems (Megela Simmons 1988).

Chorus noise often obscures key temporal features of calls used in call recognition, so even if the call can be detected, discrimination between calls is impaired (Schwartz and Wells 1983a, b; Schwartz 1987a; Gerhardt and Klump 1988a; Schwartz and Gerhardt 1989). This masking effect is somewhat reduced if the signal and interfering noise come from different directions, but the improvement is relatively small (Schwartz and Gerhardt 1989). Narins and Zelick (1988) suggested that the ability to detect specific temporal features such as pulse rate in the presence of background noise should be enhanced by AM-selective neurons, because they are keyed to a particular temporal pattern not present in the random fluctuations of the chorus sound.

Sound Localization

Once a female frog has detected and recognized a conspecific call, she still is faced with the task of locating the calling male. The same is true for a male trying to locate an intruder in his territory. Often this is made more difficult by the types of calling sites chosen by males, which often are hidden in dense vegetation or located in tree holes or burrows that distort the directional cues available to the receiver. Yet frogs clearly do manage to locate one another, and often do so very quickly in a natural chorus. Several behavioral studies have demonstrated that frogs can accurately locate a speaker broadcasting conspecific calls and can do so in both the horizontal and vertical planes (Feng, Gerhardt, and Capranica 1976; Rheinlaender et al. 1979;

Gerhardt and Rheinlaender 1980; Passmore et al. 1984; Rheinlaender and Klump 1988; M. Jørgensen and Gerhardt 1991). In some species, the female will move her head from side to side before orienting her body toward the sound source, but other species do not exhibit head-scanning behavior (M. Jørgensen and Gerhardt 1991). The frog then jumps toward the sound source, often with some error that is corrected for on the next jump. The result is a characteristic zigzag pattern of approach to the speaker. Rheinlaender et al. (1979) showed that scanning with the head before jumping improves the accuracy of approach to the speaker. Both ears are required for sound localization, and covering one tympanum with grease causes the frog to turn in a circle (Feng, Gerhardt, and Capranica 1976). These early studies demonstrated that a frog could determine whether a sound was coming from the left or right of its head, but did not demonstrate an ability to discriminate between different angles of sound incidence. Later work by Klump and Gerhardt (1989) showed *that Hyla gratiosa* females are capable of true angle discrimination.

All of the frogs tested so far for sound localization ability are very small species, and one, *Colostethus flotator,* is one of the world's smallest frogs, with a distance between the ears of less than 5 mm (Gerhardt and Rheinlaender 1980). This presents a serious problem for sound localization, because the small distance between the ears makes it nearly impossible for frogs to make use of the two types of cues usually employed by vertebrates to locate sounds: differences in the intensity of sound reaching the two ears and differences in time of arrival. The paradox of sound localization by such small animals is partially resolved if one assumes that localization is not based simply on comparisons of input from the two ears, but also on comparison of input to the two sides of the tympanum. In other words, the anuran ear seems to function as a pressure gradient system that compares sound waves reaching the two sides of the tympanum through different pathways (Rheinlaender, Walkowiak, and Gerhardt 1981).

Research on the directionality of hearing in frogs is highly technical, much of it focused on the effects of sound source direction on responses of neurons in the peripheral auditory system or in higher brain centers. Only a brief summary will be given here (for a more detailed review, see Gerhardt and Huber 2002). The middle ear cavity is open to the buccal cavity through the Eustachian tube, so several routes to the inside of the tympanic membrane are possible. Potential routes include the ear on the other side of the head, the skin over the lungs, and other as yet unknown extratympanic pathways such as the tissues of the head (Rheinlaender, Walkowiak, and Gerhardt 1981; Pinder and Palmer 1983; Vlaming, Aertsen, and Epping 1984; Aertsen et al. 1986; Michelsen, Jørgensen, and Christensen-Dalsgaard 1986; Wilczynski, Resler, and Capranica 1987; Eggermont 1988; Narins, Ehret, and Tautz 1988; M. Jørgensen 1991; M. Jørgensen, Schmitz, and Christensen-Dalsgaard 1991; Ehret, Werth, and Kamada 1994). The tympanum is inherently directional in its responses to sound. Directionality varies with sound frequency, but in most species studied to date, peak directionality does not correspond precisely to the dominant frequency of the advertisement call (M. Jørgensen 1991; M. Jørgensen and Gerhardt 1991; M. Jørgensen, Schmitz, and Christensen-Dalsgaard 1991; Wang, Ludwig, and Narins 1996). The directionality of tympanic responses appears to be enhanced by input from extratympanic pathways, such as the lungs (M. Jørgensen 1991; M. Jørgensen, Schmitz, and Christensen-Dalsgaard 1991; Wang, Ludwig, and Narins 1996), but it is not clear whether this actually enhances the ability of a frog to locate a sound source. The responses of neurons in the auditory nerve and higher brain centers also are sensitive to changes in the direction of a sound source. This sensitivity can affect both their frequency response and responses to temporal patterns such as amplitude modulation (Feng 1981; Feng and Capranica 1976, 1978; Schmitz, White, and Narins 1992; White, Schmitz, and Narins 1992; Gooler et al. 1993; Xu, Gooler, and Feng 1994, 1996; Schwartz and Gerhardt 1995; Wang, Ludwig, and Narins 1996). What is not yet fully understood is how directional information from the two ears is integrated in the brain to allow a frog to locate a calling male.

Summary and Conclusions

In most anurans, sound is produced when the trunk muscles force air through the larynx into the buccal cavity and vocal sac. Both the trunk muscles and laryngeal muscles of male frogs exhibit morphological, physiological, and biochemical features that enhance their aerobic capacity and make them well suited for long periods of sustained activity. Furthermore, variation in morphological, physiological, and biochemical features of muscles parallels variation in calling activity among species (see chapter 5). Electromyographic studies have shown that in some species with slow pulse repetition rates, the trunk muscles are involved in production of individual call pulses. In two of these species, *Hyla versicolor* and *H. chrysoscelis,* differences in the biochemical and contractile properties of the trunk muscles parallel differences in pulse rate. We also know next to nothing about the physiological characteristics of vocal sac musculature or the role of these muscles in sound production, although there is evidence that these muscles are unusually elastic in some species. The size and shape of the vocal sac in relation to the wavelength of sound being radiated affect the efficiency with which metabolic energy is converted into acoustic energy, but again, little comparative work has been done on calling efficiency. Some frogs lack vocal sacs and use other modes of communication in aggressive interactions or in attracting mates, but the behavior of most voiceless anurans has not been studied in the field.

Anuran vocal repertoires can be divided into several functional types of calls, including advertisement calls, courtship calls, aggressive calls, release calls, and distress or defensive calls. Advertisement calls are either simple, single-note calls, or complex calls consisting of one or more types of repeated notes. Complex calls of some species appear to have attractive and aversive elements combined into one call, so a male can convey separate messages to males and females simultaneously. In other species, males alter the temporal structure of part of the advertisement call, turning it into a call that functions mainly in male-male aggressive interactions. Aggressive calls of most frogs are readily distinguished from advertisement calls of the same species, but there is no temporal structure that is common to aggressive calls of all species. Some frogs have more than one type of aggressive call used in long-range and short-range encounters, or they have graded aggressive calls that change gradually as frogs approach one another. The function of graded aggressive calls is not yet clear, but they could enable a male to convey a more precise message about his aggressive motivation, or they might be used in assessing the qualities of an opponent. Graded calls also could allow a male to gradually shift from attractive to aversive calls by dropping elements that are attractive to females only when immediately threatened by a competitor.

Several features of the physical environment potentially influence the evolution of anuran calls and calling behavior, but this aspect of vocal communication is only beginning to be explored. Although there have been suggestions that the frequency structure of bird songs is adapted for transmission through particular habitats, there is little evidence that this is true for anurans. Nevertheless, the height of the caller above the ground, the density of vegetation surrounding his calling site, and other aspects of the physical environment will affect the attenuation of different frequencies in a frog's call and thereby affect the way a signal is perceived by other individuals. Some authors have suggested that frogs breeding in open country have louder calls than do those breeding in forests, but there has not been a systematic attempt to test this hypothesis.

The evolution of calls also can be affected by background noise derived from the physical environment. For example, the sound of running water, particularly near waterfalls or torrents, can mask frog calls; highly repetitive calls or narrowly tuned calls can be effective in counteracting acoustic masking. Problems of sound transmission through air are most severe near the ground, particularly for species calling from burrows. However, at least one species, *Leptodactylus albilabris,* is highly sensitive to substrate-born vibrations and apparently can use the ground as a relatively noise-free channel for acoustic communication. The extent to which this is true for other burrowing frogs needs to be investigated.

The biological environment also has a major effect on the evolution of vocal communication. Some bats and several other types of predators can use the calls of frogs to locate prey, and the presence of these predators could affect the structure of a frog's call, the temporal pattern of calling behavior, and the nature of the calling site. Many frogs call in dense choruses of both conspecific and heterospecific individuals. Often these are incidental aggregations around choice breeding sites, but individuals also could derive various benefits from being in an aggregation, including greater protection from predators or a greater chance of attracting females. However, the costs and benefits of chorusing behavior are poorly understood for most species.

One major cost of calling in either a group of conspecifics or a mixed-species chorus is acoustic interference from other calling males. Such interference reduces a female's ability to perceive and locate individual calling males, and it makes advertisement of a male's territory to other males more difficult. At the intraspecific level, most chorusing frogs exhibit adaptations to reduce acoustic interference and increase the distinctiveness and detectability of their own calls. These include matching the calling rate of neighboring males, timing calls to avoid overlap with the calls of other individuals, and changes in the complexity or duration of advertisement calls in response to those of other males. Experiments with females of a few species have shown that males usually alter their vocalizations in choruses in ways that enhance their ability to attract mates, but the dynamics of chorusing behavior need to be studied in much more detail. Most playback experiments with females have been conducted in highly simplified acoustic environments, and the ways in which females detect signals in the complex environment of a natural chorus is not well understood. Consequently, the relationship between socially mediated changes in the calling behavior of males and their mating success has scarcely been explored (see chapter 8).

Many of the behavioral adaptations for avoiding acoustic interference at the intraspecific level extend to interspecific interactions as well. For example, frogs often are inhibited from calling by the calls of other species with a similar frequency structure. Individuals can avoid interference by calling in silent intervals between bouts of calling by other species, or they alter the timing of their calls in response to individual calls. The effectiveness of heterospecific calls in eliciting such responses is a function of the similarity of spectral and temporal features of calls. Some frogs also engage in aggressive interactions with other species and use aggressive calls for interspecific communication. Again, the effectiveness of calls in repelling heterospecific males depends on the similarity of the calls of the two species.

Mixed-species choruses also present problems to females searching for mates, because they must correctly identify males of their own species from a cacophony of different advertisement calls. The role of vocalizations in reproductive isolation and the identification of properties important for call recognition are perhaps the best studied aspects of anuran communication. Choice experiments with many species have shown that female anurans generally have no difficulty distinguishing conspecific calls from those of other species. The use of synthetic calls to systematically vary individual properties of calls has been an effective way to identify call properties critical for species recognition. These experiments have revealed that some species-specific features of calls are irrelevant to females, and that females of closely related species often use quite different properties to discriminate against calls of other species. A major challenge for future investigators is to determine how females integrate information about different properties of calls when choosing a mate in a natural chorus.

Despite the species-specific nature of anuran calls, closely related species often share basic structural characteristics of their calls that have been inherited from a common ancestor. These similarities have been used to identify higher-order relationships among groups of species, or to reconstruct the phylogeny of a particular clade. The use of independently generated phylogenies to examine the evolution of call structure promises to be an important approach for future investigators. Limited evidence for a few groups, including North American toads (*Bufo*) and chorus frogs (*Pseudacris*) suggests that changes in call structure often are congruent with phylogenies based on morphological or molecular characters. As with any study based on phylogenetic evolution, however, our understanding of call evolution will only be as good as the phylogenetic hypothesis used to examine it. Changes in the proposed phylogenetic relationships of closely related species, such as those that have occurred several times for the genus *Physalaemus,* can change conclusions about the evolution of call structure. Studies that couple phylogenetic studies of call evolution with investigations of changes in the morphology and physiology of the call-producing apparatus would be particularly useful.

The structure and function of the anuran auditory system has been a major focus of research for many years, but our understanding of how acoustic signals are processed is still very incomplete. We know a good deal about frequency response characteristics of the peripheral auditory system and the role of the amphibian and basilar papillae in sound reception. We also have a considerable amount of information on the frequency selectivity of individual neurons in the medulla and midbrain acoustic centers, but considerably less about frequency processing at higher levels. Although many behavioral studies have shown that species recognition and discrimination among call types within a species' repertoire often is based on temporal features of the calls, there were few studies of temporal processing until the 1980s. These studies have shown relatively little temporal selectivity in the peripheral auditory system, but some selectivity for specific rates of amplitude modulation in the midbrain and perhaps in higher auditory centers as well. However, much of our understanding of sound processing in the central nervous system is based on studies of a limited number of ranids, bufonids, and hylids. We have no information on temporal processing in species that have calls with extremely high rates of amplitude modulation. Unfortunately, many anurans with calls of this type are very small and not ideal subjects for neurophysiological work. Nevertheless, the diversity of call structures in anurans presents a challenge for future studies of the neurophysiological correlates of call recognition. We also know very little about how frequency and time information are integrated in the brain, but the early concept of a single "mating call detector" in the brain seems to be an oversimplification.

The ability of female frogs to locate calling males in a chorus or artificial sound sources has been well established. It is now generally accepted that sound localization involves a pressure-gradient system in which inputs from two sides of each tympanic membrane are compared. These inputs come not only from sound impinging directly on the tympanum, but from extratympanic pathways such as the ear on the opposite side of the head, the lungs, and perhaps the bones and tissues of the head. Both the peripheral and central auditory systems exhibit inherent directional responses, but the way in which directional information from the two ears is integrated to allow for accurate sound localization is not yet understood.

Chapter 8 Mating Systems and Sexual Selection in Anurans

It is surprising that these animals have not acquired more strongly marked sexual characters; for, though cold-blooded, their passions are strong. . . . An unfortunate female toad [is sometimes found] dead and smothered from having been so closely embraced by three or four males. Frogs have been observed . . . fighting all day long during the breeding season.

Among almost all animals there is a struggle between the males for possession of the female. . . . Females have the opportunity of selecting one out of several males, on the supposition that their mental capacity suffices for the exercise of a choice.
—Charles Darwin, *The Descent of Man and Selection in Relation to Sex* (2nd ed., 1874)

In 1871, Charles Darwin published his second most famous book, *The Descent of Man, and Selection in Relation to Sex*. Although his discussion of human evolution was the most controversial part of the book, more than half the book was devoted to animal behavior and Darwin's theory of sexual selection. This has been one of his most lasting contributions to biology, and was the starting point for all modern investigations of sexual selection and the evolution of mating systems. Darwin first proposed the theory of sexual selection to explain the evolution of morphological traits in animals that did not appear to be products of natural selection. He noted that male animals often are larger than females, more brightly colored, or endowed with special weapons used in competition for mates. He argued that such traits, which he called secondary sex characters, often decrease the survivorship of males, either because they are more vulnerable to predators, or because they kill or injure each other in fights. Nevertheless, if such traits enhance a male's ability to acquire mates, then they will be favored by sexual selection.

Darwin recognized two components of sexual selection that could lead to the evolution of secondary sex characters or differences in body size between males and females. The first was the relatively uncontroversial observation that males often fight among themselves for possession of females, leading to selection for weapons and fighting ability. The second was female choice, which involved females comparing the traits of potential mates and selecting those that were the most attractive. Many of Darwin's contemporaries were skeptical that female choice occurred in nature, in part because Darwin attributed to animals a sense of beauty like that of humans. Although a few investigators studied sexual selection and female choice, especially in birds, the subject was largely neglected until the second half of the 20th century (Cronin 1992). Sexual selection, and specifically female choice, is now among the most active areas of research in behavioral ecology and evolutionary biology (Andersson 1994).

Darwin had relatively little to say about amphibians in his book, although he did note that male frogs sometimes fight among themselves for possession of females, and he suggested that the calls of frogs are analogous to the songs of birds, and probably evolved through sexual selection. One of the few investigators in the early twentieth century who addressed questions of sexual selection and mate choice in anurans was G. Kingsley Noble. He published a pioneering study of the behavior of *Hyla andersonii* in the Pine Barrens of New Jersey (Noble and Noble 1923), and he contributed to studies of the mating behavior of other frogs (Noble and Aronson 1942). He also devoted a chapter of his book on *The Biology of the Amphibia* (1931) to secondary sex characters. Serious study of the mating systems of anurans began with the publication of several studies of territoriality and mate choice in frogs (Emlen 1968, 1976; Heusser 1969d; Wiewandt 1969; Wells 1977c, 1978b; R. D. Howard 1978a; Fellers 1979a, b) and a review of anuran social behavior (Wells, 1977b). Since then, anurans have become important model organisms for testing hypotheses about sexual selection and mate choice (Arak 1983a; M. Ryan 1985b, 1991; Gerhardt 1988, 1994a; Halliday and Tejedo 1995; B. K. Sullivan, Ryan, and Verrell 1995; Grafe, Spieler, and König 1999; Gerhardt and Huber 2002).

Mating Systems and Sexual Selection

The process of sexual selection takes place in the context of particular mating systems. These encompass the array of behavioral tactics used by individuals to acquire mates. Most studies have focused mainly on the mating systems of male animals, but sexual selection can operate on traits of females as well. Females also can vary in their choosiness, depending on the relative costs and benefits of selecting particular males as mates (Jennions and Petrie 1997). In general, males are subject to more intense sexual selection than are females because of differences in the way each sex invests energy in the production of gametes. Females usually produce eggs that are provisioned with large yolk reserves to support the growth and development of the embryos, and some provide additional nutritional resources to embryos retained inside the body (chapter 10) or to young after they have hatched (chapter 11). Males, on the other hand, produce sperm that are supplied with only enough energy to get them to the eggs. This means that the cost of sperm production generally is lower than the cost of egg production, even when males produce millions of sperm, and they usually have sufficient sperm supplies to fertilize the eggs of many females. This difference in parental investment in gametes means that the reproductive success of males usually is limited by the number of mates they can acquire, whereas the reproductive success of females tends to be limited by energy availability (Trivers 1972). This disparity in parental investment means that the potential reproductive rate of males usually exceeds that of females, and females then become a limiting resource and the object of competition among males (Clutton-Brock and Vincent 1991; Clutton-Brock and Parker 1992; G. Parker and Simmons 1996). Traits that enhance the ability of males to locate, attract, capture, or retain possession of females will be favored by sexual selection, as will traits that reduce the amount of time between successive matings (Arnold and Duvall 1994).

In general, male animals adjust their mate-locating tactics to the spatial and temporal distribution of females (Emlen and Oring 1977; Arnold and Duvall 1994). When females are highly dispersed, males often have little choice but to search over wide areas for mates. This type of mating system is common in reptiles that have large home ranges, such as widely foraging lizards and snakes (Wells 2001b), and it occurs in some pond-breeding salamanders and newts as well (see chapter 9). Mate searching is uncommon in anurans, which are relatively sedentary (chapter 6) and usually adopt the more efficient tactic of calling to attract females. Although males of some tropical forest frogs call from widely separated locations to attract females, most anurans are moderately to highly aggregated at terrestrial calling sites or aquatic breeding sites. The form of the mating system that results is partly a product of the temporal availability of females.

Temporal Patterns of Reproduction in Anurans

Most anurans can be classified as either explosive or prolonged breeders, although these actually represent two ends of a continuum from single night breeding in some desert species that use ephemeral rain pools to year-round breeding in some tropical anurans (Wells 1977b). Variation in the temporal pattern of breeding appears to be related mainly to abiotic factors, such as the seasonal distribution of rainfall and the permanence of bodies of water used for reproduction, but biotic factors such as predation, competition, and foraging opportunities can be important as well (Lucas, Howard, and Palmer 1996; McCauley et al. 2000).

Breeding Patterns in Temperate-Zone Frogs

Most temperate-zone anurans live in seasonal environments in which breeding activities are restricted to warm months with sufficient rain to fill breeding ponds. Many temperate-zone ranids and bufonids breed explosively in early spring, often in temporary ponds that disappear by late summer. The precise duration of the breeding period varies both within and among species, with some populations completing breeding activity in only three or four nights. In other cases, males may be present in a pond for several weeks, but with actual breeding activity concentrated into a few peak nights (e.g., Lodé, Holveck, and Lesbarrères 2005).

In cold-water breeders, explosive breeding enables females to clump eggs into huge communal masses that reduce heat loss (J. Moore 1939; R. Savage 1961; Herreid and Kinney 1967; Hassinger 1970; Licht 1971; Beattie 1980; R. D.

Howard 1980; Caldwell 1986a) and increase development rate (Waldman 1982a). Early synchronous breeding also allows tadpoles to develop before populations of aquatic predators become well established. For example, ambystomatid salamanders often breed in the same ponds as *Rana sylvatica* and lay eggs at the same time. The wood frog eggs develop more quickly, so tadpoles are mobile before the salamander larvae are large enough to eat them (Wilbur 1972). In other areas, the major predators are aquatic insect larvae, and populations do not reach high levels until summer (see chapters 13 and 14). Heusser (1970) suggested that synchronous breeding in some European ranids is advantageous because late eggs are likely to be consumed by early-hatching conspecific tadpoles. The same was found to be true for North American wood frogs (*Rana sylvatica;* Petranka and Thomas 1995; see Crump 1992 and chapter 12 for a general discussion of cannibalism in tadpoles).

Many temperate-zone frogs in both the northern and southern hemispheres have spring or summer breeding periods lasting two to three months (Wells 1977b). Breeding activity often is more or less continuous, although there are some nights on which activity is greater than on others (R. D. Howard 1978a; Ritke, Babb, and Ritke 1992; Henzi et al. 1995). Others have long breeding seasons divided into short breeding periods, producing a pattern similar to that of explosive breeders that breed only once each year. For example, a population of southern leopard frogs (*Rana sphenocephala*) breeding in a temporary pond in Mississippi formed several short breeding aggregations over a period of several months, with breeding episodes sometimes separated by a month or two. Eggs were laid only when water in the pond was high, and each period of egg laying lasted less than three days (Doody and Young 1995). Similar episodic breeding triggered by rainfall has been reported for *Bufo calamita* in Europe, with some populations having as many as nine distinct calling periods during a three-month breeding season (Banks and Beebee 1986; Sinsch 1988d; Denton and Beebee 1993a).

Northern populations of the European water frogs (the hybrid *Rana esculenta* and its associated parental species, usually *R. lessonae*) generally have one short breeding period (Forselius 1963). Southern populations have a series of short breeding periods (Rühmekorf 1958a; Heusser 1961; Günther 1969; M. Smith 1969; Wahl 1969; van Gelder and Hoedemaekers 1971; Blankenhorn 1974, 1977). Some discoglossids and bombinatorids have a series of short breeding periods (Knoepffler 1962; Lörcher 1969; Heinzmann 1970; Akef and Schneider 1985; Reading and Clarke 1988), but the proximate control of reproductive activity differs from that of ranids. In the ranids, periodic reproduction appears to be a facultative response to changing temperature (Obert 1975), whereas in the discoglossids and bombinatorids, it is controlled by an endogenous hormonal cycle that is independent of temperature (Obert 1973, 1974, 1977). Nevertheless, populations of midwife toads (*Alytes*) at high elevations or in arid regions often have only a single short breeding season, imposed by environmental conditions (Angelier and Angelier 1964; Márquez 1992).

Breeding Patterns in Tropical Frogs

In tropical and subtropical regions, conditions often are suitable for anuran reproduction for many months, even for species that breed in temporary ponds. Many species breed more or less continuously during long rainy seasons, but the number of frogs at a breeding site varies with rainfall (Berry 1964; Inger and Bacon 1968; Crump 1974; Wells 1977b; M. Ryan 1985b; Aichinger 1987a; Cardoso and Haddad 1992; Donnelly and Guyer 1994; Moreira and Barreto 1997; Pröhl 1997a; Arzabe et al. 1998; Bastos and Haddad 1999; Bertoluci and Rodrigues 2002; Vaira 2005). This pattern is characteristic of Neotropical species such as *Hyla ebraccata, H. microcephala, Physalaemus pustulosus,* and many others (M. Ryan 1985b; Schwartz and Wells 1985; Donnelly and Guyer 1994; Arzabe, Carvalho, and Goes Costa 1998; D. Marsh 2000). Sometimes closely related species have very different breeding patterns. For example, in Panama, *Scinax boulengeri* breeds in relatively permanent water and is active throughout the rainy season, whereas a congeneric species, *S. rubra,* forms explosive mating aggregations in temporary pools only after heavy rains (Bourne 1992; Bevier 1997a). Terrestrial breeders that do not depend on standing water for reproduction sometimes breed for most of the year in wet tropical climates, or they reproduce mostly in the rainy season (Donnelly 1989c, 1999; Praderio and Robinson 1990; Moreira and Lima 1991; Townsend and Stewart 1994; Pröhl 1997a; Brooke, Alford, and Schwarzkopf 2000).

Many aquatic-breeding tropical frogs form explosive mating aggregations after heavy rains, as described previously for *Scinax rubra.* The large canopy-dwelling hylids *Trachycephalus* (=*Phrynohyas*) *venulosus* and *Phrynohyas coriaceus* often appear in ponds at the onset of the rainy season, engage in a brief burst of reproduction, and then disappear for the rest of the year (Rivero and Esteves 1969; Zimmerman and Hödl 1983), although in the Cerrado of Brazil, *T. venulosus* engaged in repeated bouts of reproduction after heavy rains (Rodrigues, Uetanabaro, and Lopes 2005). Other species form explosive mating aggregations in shallow rain pools, including the Costa Rican hylid *Hyla pseudopuma* (M. Crump and Townsend 1990), the Australian hylids *Litoria chloris* and *L. xanthomera* (Morrison, Hero, and Smith 2001), the Brazilian microhylid *Chiasmocleis shudikarensis* (Zimmerman and Bogart 1988), a variety of anurans from the Brazilian Pantanal (Prado, Uetanabaro, and Haddad 2005), and the golden toad of Costa Rica, *Bufo periglenes* (now apparently extinct; Jacobson and Vandenberg 1991). Two other Neotropical toads, *Bufo alatus* (formerly *B. typhonius*) and *B. dapsilis,* are explosive breeders, but are not restricted to temporary rain pools. The former breeds in pools in permanent streams, while the latter breeds in shallow pools at the edges of streams (Wells 1979; Zimmerman and Bogart 1988). Explosive breeding in *B. alatus* probably swamps potential predators of eggs and tadpoles, including tadpoles of another frog, *Leptodactylus pentadactylus* (Wells 1979).

Breeding Patterns in Desert and Savanna Frogs

Most anurans from arid or semiarid regions have explosive breeding periods because they use ephemeral rain pools for reproduction. The short life of the breeding pools places a premium on rapid oviposition, so males and females typically arrive at ponds immediately after heavy rains, engage in a frenzy of mating activity for a few nights, and then leave. In some species, males attend several different choruses in one year, but females usually breed only once. This type of breeding behavior is characteristic of desert-dwelling anurans in many families, including bufonids, pelobatids, microhylids, hylids, ranids, leptodactylids, and myobatrachids (Poynton 1964b; Wager 1965; Main 1968; Channing 1976b; Wells 1977b; Cei 1980; B. K. Sullivan 1989a; Krupa 1994), as well as temperate-zone anurans from more mesic areas with irregular rainfall patterns (Greenberg and Tanner 2004). Some anurans from tropical savannas also have a single explosive breeding period, or a series of explosive breeding periods, depending on the persistence of aquatic breeding sites (Balinsky 1969; Barbault 1972; Grobler 1972; Channing, du Preez, and Passmore 1994; Rödel 1996).

Geographic Variation in Breeding Phenology and Mating Systems

Temporal patterns of breeding appear to be relatively flexible in many anurans, and it can be misleading to consider a particular temporal pattern as being a fixed species-specific trait. Variation in temporal patterns of breeding can, in turn, result in considerable variation in mating systems, even among populations of the same species. In some North American toads, the length of the breeding season is quite variable, depending on local weather conditions (Kagarise Sherman 1980; B. K. Sullivan 1982a, 1985b, 1986b, 1989a; Woodward 1982b, c; Wagner and Sullivan 1992). For example, some populations of American toads (*Bufo americanus*) complete their breeding activities in less than three days (R. D. Howard 1988b; Howard and Young 1998), but others remain at a breeding site for up to five weeks (Forester and Thompson 1998). The behavior of males in some choruses is like that of typical explosive breeders, but in others it more closely resembles that of prolonged breeders. Geographic variation has been reported in the mating systems of both *Bufo calamita* and *B. bufo* in Europe. In most regions, the former has a long breeding season (Rühmekorf 1958a; Heusser and Miesterhans 1969; Beebee 1979c, 1983; Sinsch 1988d) and a mating system that has been compared to a lek (Arak 1983b; 1988a, b). In Spain, the same species has an explosive breeding season and exhibits behavior typical of other explosive-breeding toads (Tejedo 1988). The northern subspecies of the common European toad, *B. bufo bufo,* has an explosive breeding season throughout its range (R. Savage 1934; W. Jungfer 1943; Eibl-Eibesfeldt 1950; Heusser 1960, 1961, 1963, 1968b, d, 1969a; N. Davies and Halliday 1977, 1978, 1979; Gittins, Parker, and Slater 1980; Hemelaar 1983; Loman and Madsen 1986; Höglund and Robertson 1987). The southern subspecies, *B. bufo spinosus,* has a long breeding season and a mating system very different from that of its explosive-breeding relatives (Hotz 1970; Dolce 1976; Sofianidou and Schneider 1985). Some geographic variation in length of the breeding period has been reported in the European spadefoot toads, *Pelobates fuscus* and *P. cultripes,* but most populations have relatively long breeding periods (> three weeks; Nöllert 1984; Lizana, Márquez, and Martin-Sanchez 1994; Eggert and Guyétant 2003). Geographic variation probably is common in widely distributed temperate-zone anurans, with breeding seasons becoming shorter with increases in latitude, altitude, or habitat aridity.

Geographic variation probably occurs in widely distributed tropical species as well, but has not been as thoroughly documented. In Panama, *Leptodactylus pentadactylus* is a prolonged breeder, with males often being found in low-density choruses or calling alone (Breder 1946; personal observations), but Rivero and Esteves (1969) described an explosive aggregation of the same species in Venezuela. *Physalaemus cuvieri,* which is common throughout much of Brazil, calls more or less continuously for six to eight months in the relatively mild climate of southern Brazil. In the hotter, drier regions of central Brazil, the same species calls for only about four months and does so sporadically after heavy rains in semiarid regions of northeastern Brazil (Moreira and Barreto 1997). Again, as in temperate-zone frogs, increasing habitat aridity or decreased pond hydroperiod tends to produce a shorter and less predictable breeding season in tropical frogs. Some species even exhibit different breeding patterns in different ponds in close proximity to one another. For example, in Brazil, *Scinax eurydice* was found calling for six months in a permanent pond, but for only one month in a temporary pond about one km away (Arzabe, Carvalho, and Goes Costa 1998).

Implications of Prolonged and Explosive Breeding

Variation in the temporal pattern of reproduction has important implications for the operation of sexual selection in anuran mating systems and the way in which males allocate their time and energy for reproduction. One predicted difference between prolonged and explosive breeders is that the opportunity for female choice should be more limited in explosive breeding aggregations because of the high densities of competing males. In general, male-male competition is expected to be the most important determinant of variation in male mating success in explosive breeders. In contrast, when the breeding period is prolonged, females arrive asynchronously, and direct competition among males for individual females is expected to be rare. Females should be able to compare males before selecting their mates (Wells 1977b). Recent research has largely supported these predictions (Arak 1983a; B. K. Sullivan et al. 1995). Nevertheless, females sometimes can choose mates in low-density choruses, even when the breeding season is relatively short (B. K. Sullivan and Sullivan 1985; B. K. Sullivan, 1989b, 1992; Wagner and Sullivan, 1992; K. Pfennig 1998, 2000).

Because of the highly synchronized nature of explosive breeding aggregations, males are expected to have relatively few opportunities to compete for mates, because many females will be mating simultaneously (Wells 1977b). Indeed, males of explosive-breeding species seldom obtain more than three matings in a season, and usually less than 5% obtain more than one (B. K. Sullivan, Ryan, and Verrell 1995). Multiple mating opportunities are more common in prolonged breeders (fig. 8.1), and in some species, a single male can mate more than 15 times in a breeding season of three to six months (Murphy 1994a; Dyson, Bush, and Halliday (1998). The major determinant of the intensity of sexual selection operating on male traits is variation in male mating success (Wade 1979; Wade and Arnold 1980; S. Arnold 1983a; S. Arnold and Wade 1984a, b; S. Arnold and Duvall 1994). Consequently, the opportunity for sexual selection to operate on male traits should be more limited in explosive breeders than in prolonged breeders.

This prediction is complicated by variation in the operational sex ratio, defined as the number of males relative to the number of females in breeding aggregations. In explosive mating aggregations, males often outnumber females by as much as 10 to 1 on any given night, and the total number of males visiting a pond throughout the breeding period usually exceeds the total number of females. This means that many males fail to mate at all. Consequently, the opportunity for sexual selection to operate on male traits can be high even when only a few males mate more than once (B. K. Sullivan, Ryan, and Verrell 1995). Studies of two species of toads that have short breeding periods, *Bufo woodhousii* and *B. valliceps*, showed that the opportunity for sexual selection was correlated with the seasonal operational sex ratio for different populations (fig. 8.2). When the sex ratio was strongly biased in favor of males, the opportunity for sexual selection on male traits increased. In species with prolonged breeding periods, sex ratios also tend to be biased toward an excess of males (B. K. Sullivan, Ryan, and Verrell 1995; Lüddecke 2001; Eggert and Guyétant 2003). This bias, coupled with the ability of some males to obtain multiple matings, will tend to produce even greater variance in male mating success and further increase the intensity of sexual selection on male traits.

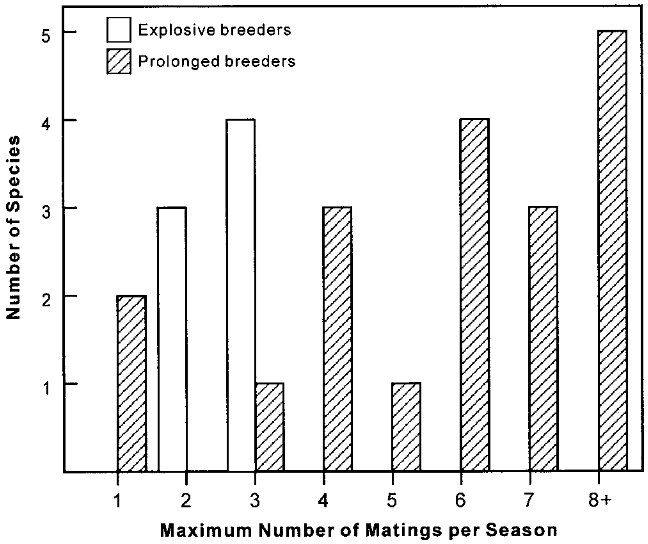

Fig. 8.1. Maximum number of matings obtained by individual males in a single breeding season in explosive and prolonged breeding anurans. Each species is represented only once. The two prolonged-breeding species with only a single mating per season are both from studies with very small sample sizes. Plotted from data summarized in Kluge (1981) and B. K. Sullivan, Ryan, and Verrell (1995) and additional data from Roithmair (1992), Dyson, Henzi, Halliday, and Barrett (1998), and Pröhl and Hödl (1999).

Variation in the duration of breeding seasons also has implications for the way in which males allocate their time and energy to reproduction (Wells 1977b; Arak 1983a). Explosive breeding places a premium on rapid location of mates, because females are available for such a short time. Males can afford to use a lot of energy searching for mates and struggling over females, even if this leaves them largely drained of energy reserves at the end of the breeding period. In contrast, prolonged breeders must husband their resources to last much longer, especially if a male's mating success is determined in part by how long he can remain at the breeding site. Male frogs can conserve their energy reserves in several ways. One is to use inexpensive forms of mate-locating behavior, such as assuming a satellite role near a calling male (Arak 1983a). A second is to call mostly when females are likely to be present (Woolbright 1985a; Bevier

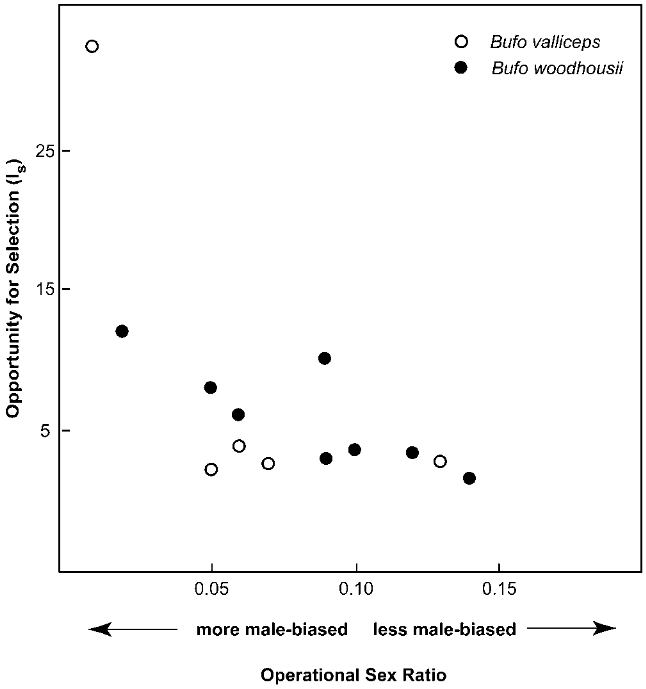

Fig. 8.2. Relationship of the operational sex ratio to the opportunity for sexual selection in males for two species of toads, *Bufo valliceps* and *Bufo woodhousii.* The operational sex ratio was measured as the ratio of the number of females to the number of males in a chorus. The opportunity for sexual selection (I_s = variance in male mating success/squared mean mating success) is an indicator of the potential strength of sexual selection on male traits that are related to mating success. After B. K. Sullivan, Ryan, and Verrell (1995).

1997a). A third is to call in bouts separated by silent periods (Schwartz et al. 1995). Alternatively, males can replace depleted energy reserves by leaving the breeding area periodically to feed (Fellers 1979b; Greer and Wells 1980; Kagarise Sherman 1980; Arak 1983a; Woodward 1982b; Godwin and Roble 1983; M. Ryan 1983b). Nevertheless, male frogs often deplete a significant proportion of their energy reserves by the end of the breeding season (Jenssen 1972; Wells 1978b; Mac Nally 1981; Arak 1983a; Given 1988a; Ressel 1993; Eggert and Guyétant 2003; see also chapter 5). In some cases, the ability of individual males to remain in a chorus is limited by energy reserves (C. Murphy 1994a, b).

As expected, explosive breeders tend to deplete their energy reserves more quickly than do prolonged breeders (Halliday and Tejedo 1995). Daily changes in body mass in the explosive-breeding toad *Bufo bufo* were greater than in *B. calamita,* a prolonged breeder (Arak 1983a). Explosive-breeding wood frogs (*Rana sylvatica*) deplete their trunk-muscle glycogen reserves more quickly than do prolonged-breeding green frogs (*Rana clamitans*), even though wood frogs begin the season with much larger reserves (fig. 8.3). Male wood frogs usually spend only a few nights at the breeding pond, whereas male green frogs can be present every night for up to two months. Green frogs conserve their energy reserves in part by calling at much lower rates than do male wood frogs. They also feed throughout the breeding season to supplement stored energy reserves, something that wood frogs cannot do because of the low temperatures at their breeding ponds (Wells and Bevier 1997; Wells 2001a). In *Scinax rubra,* a tropical hylid with an explosive breeding period, males call at higher rates and for more hours per night than do males of *S. boulengeri,* a prolonged breeder, and they deplete their energy reserves much more quickly. These differences are reflected in the much longer chorus attendance of *S. boulengeri* males. This species further reduces energy expenditures by calling at high rates only early in the evening, when females are most likely to be present, and then sharply reducing calling rates for the rest of the night (Bevier 1997a).

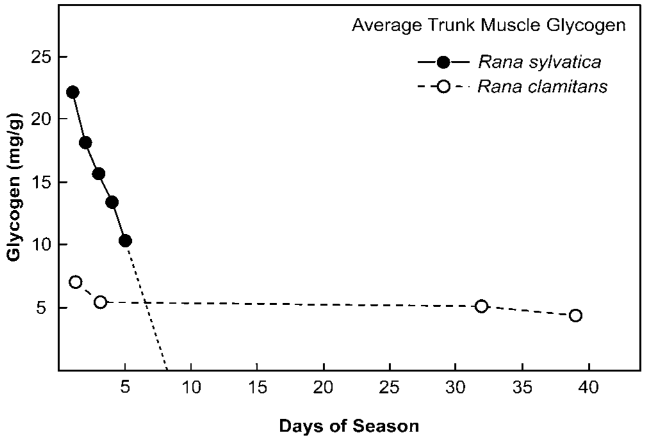

Fig. 8.3. Relative rates of depletion of glycogen reserves in the trunk muscles of males of the explosive-breeding wood frog (*Rana sylvatica*) and the prolonged-breeding green frog (*Rana clamitans*). Wood frogs exhaust their glycogen reserves within a few days, whereas green frogs maintain low levels of glycogen in their muscles throughout the breeding season. From Wells (2001).

Scramble Competition Mating Systems

The distinction between explosive and prolonged breeders does not, in itself, determine the precise tactics used by males to acquire mates, but the temporal pattern of breeding provides the framework for the evolution of mating systems. The mating systems of most anurans fall into one of three categories: (1) scramble competition, (2) choruses and leks; and (3) resource defense (Wells 1977b; Arak 1983a; B. K. Sullivan, Ryan, and Verrell 1995). Most anurans with very short breeding periods fall into the first category, but one must keep in mind that the distinctions among these mating systems are somewhat artificial. In reality, the mating tactics of male anurans exhibit a considerable degree of plasticity and tend to grade into one another, even within a single species (see the following "Plasticity in Anuran Mating Sys-

Fig. 8.4. A dense explosive mating aggregation of American toads (*Bufo americanus*), with many pairs in amplexus and single males searching for females. Photo by Kentwood D. Wells.

tems"). Some anurans, especially those that do not lay their eggs in water, have mating systems that do not fit conveniently into any of these categories. Rather than engaging in debates about whether a particular species fits an arbitrary set of criteria used to define a particular type of mating system, it is more informative to describe the full range of variation seen in anuran mating systems. The following discussion focuses mainly on the behavior of males and its effect on male mating success. The role of female choice is discussed in a later section.

Scramble Competition in Aquatic Mating Aggregations

A number of well-studied species of anurans in Europe and North America form explosive mating aggregations and exhibit classic scramble competition. These include *Rana temporaria, R. dalmatina, R. sylvatica, Bufo americanus, B. bufo,* and several other species of *Bufo, Scaphiopus,* and *Spea.* Similar mating systems are found in anurans in these and other families around the world. The typical pattern for most explosive breeders is for males to gather in very dense choruses (fig. 8.4). They tend to arrive at breeding ponds somewhat earlier than females and often greatly outnumber them (fig. 8.5). Males typically search for females in the water or on land around the breeding site (R. Savage 1961; Wells 1977b, 1979; N. Davies and Halliday 1979; R. D. Howard 1980, 1988b; Kagarise Sherman 1980; Berven 1981; Kruse 1981a; R. D. Howard and Kluge 1985; B. K. Sullivan 1985b; Elmberg 1986; Loman and Madsen 1986; Okuno 1986; Höglund and Robertson 1987, 1988; Tejedo 1988, 1992c, 1993a; Ryser 1989a; Telford and van Sickle 1989; Woolbright, Greene, and Rapp 1990; Jacobson and Vandenberg 1991; Lizana, Márquez, and Martin-Sanchez 1994; Tarkhnishvili 1994; Tsuji and Kawamichi 1996a, b; Forester and Thompson 1998; R. D. Howard and Young 1998). Apparently males cannot distinguish the sex or even the species of other individuals visually. Mate acquisition is a trial-and-error process, with little evidence that males discriminate among females of different sizes (Hettyey, Török, and Hévizi 2005). Indeed, males often attempt to clasp almost any moving object, including, on occasion, members of other anuran species (Marco et al. 1998; Marco and Lizana

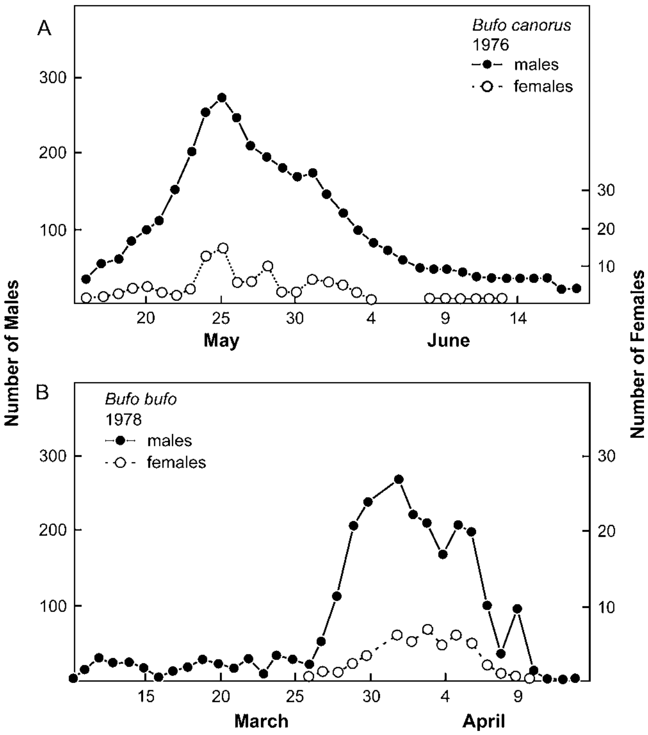

Fig. 8.5. Temporal pattern of male and female arrival at breeding ponds in explosive-breeding toads. (A) *Bufo canorus* from Yosemite National Park, California. (B) *Bufo bufo* from Great Britain. Females generally arrive later than males and in fewer numbers. (A) after Kagarise Sherman (1980). (B) after N. Davies and Halliday (1979).

2002; Hettyey and Pearman 2003; Ficetola and De Bernardi 2005). Other males are frequently clasped, but are released after giving release calls or vibrations (see chapter 7).

Males in explosive mating aggregations often struggle for possession of individual females (fig. 8.6). Unpaired males try to displace those already in amplexus, sometimes resulting in large mating balls in which a half dozen or more males clasp a female simultaneously. Contests among males sometimes are fatal to females. One often finds female wood frogs (*Rana sylvatica*) crushed or drowned after they were clasped by groups of struggling males (R. D. Howard 1980), and dead females have been found in mating balls of *Bufo bufo* as well (Verrell and McCabe 1986). Mating balls are common in many ranids and bufonids (Verrell and McCabe 1986; Forester and Thompson 1998), but occur in other families as well. For example, as many as 16 males have been observed clasping a single female *Hyla pseudopuma* during an explosive breeding event (Crump and Townsend 1990). Scramble competition and multiple males clasping females also have been observed in another hylid, *Triprion petasatus* (fig. 8.6 C), a highly explosive breeder (J. Lee and Crump 1981).

In most species, males compete by pushing and kicking one another, but in some, males use specialized weapons that can injure other males. For example, male African bullfrogs (*Pyxicephalus adspersus*) engage in prolonged wrestling bouts and bite one another with tooth-like projections on the lower jaw (B. Balinsky and Balinsky 1954; T. Hayes and Licht 1992; Channing, du Preez, and Passmore 1994). In some leptodactylid frogs, such as *Leptodactylus pentadactylus,* males are equipped with sharp spines on their front feet that are used to jab their opponents (Rivero and Esteves 1969; Shine 1979).

Competition among Males and Mating Success

In explosive breeding aggregations where male densities are high, unpaired males frequently attack mated pairs and attempt to displace males already in amplexus. Generally paired males have an advantage in such contests, so rates of displacement are low for most species, often less than 5% (Wells 1979; Gatz 1981a; Kagarise Sherman 1980; R. D. Howard 1988b; Tejedo 1988; Forester and Thompson 1998). Displacement rates of 10–39% have been reported in dense populations of *Bufo bufo* (N. Davies and Halliday 1979; Loman and Madsen 1986; Reading 2001). Usually large males displace smaller males (N. Davies and Halliday 1977, 1978, 1979; Wells 1979; Gittins et al. 1980; Kagarise Sherman 1980; Berven 1981; Lamb 1984a; R. D. Howard and Kluge 1985), but there are exceptions (e.g., Loman and Madsen 1986; Höglund and Robertson 1987).

The intense direct competition among males for possession of females generally results in large males being more successful in acquiring mates than small males (fig. 8.7; N. Davies and Halliday 1977, 1979; Wells 1979; Gittins, Parker, and Slater 1980; R. D. Howard 1980; Kagarise Sherman 1980; Berven 1981; Gatz 1981a; Reading and Clarke 1983; R. D. Howard and Kluge 1985; Loman and Madsen 1986; Olson, Blaustein, and O'Hara 1986; R. D. Howard and Young 1998). Some studies have revealed no such size advantage, however (Kruse 1981a; Arak 1983a; B. K. Sullivan 1983a, 1985b; B. K. Sullivan and Sullivan 1985; Olson, Blaustein, and O'Hara 1986; Elmberg 1987; Höglund and Robertson 1987; Ryser 1989a), or have found only a small difference between successful and unsuccessful males (R. D. Howard 1988b). One study of explosive-breeding hylid frogs in Australia (*Litoria chloris* and *L. xanthomera*) unexpectedly showed that small males were more likely to acquire mates than were large males, but this was related more to differences in chorus tenure than to competitive ability (Morrison, Hero, and Smith 2001). Size-related mating patterns are by no means fixed for a particular species. Large males enjoy a mating advantage in some populations but not in others, or the advantage varies among years in the same population (B. K. Sullivan 1985b; Olson, Blaustein,

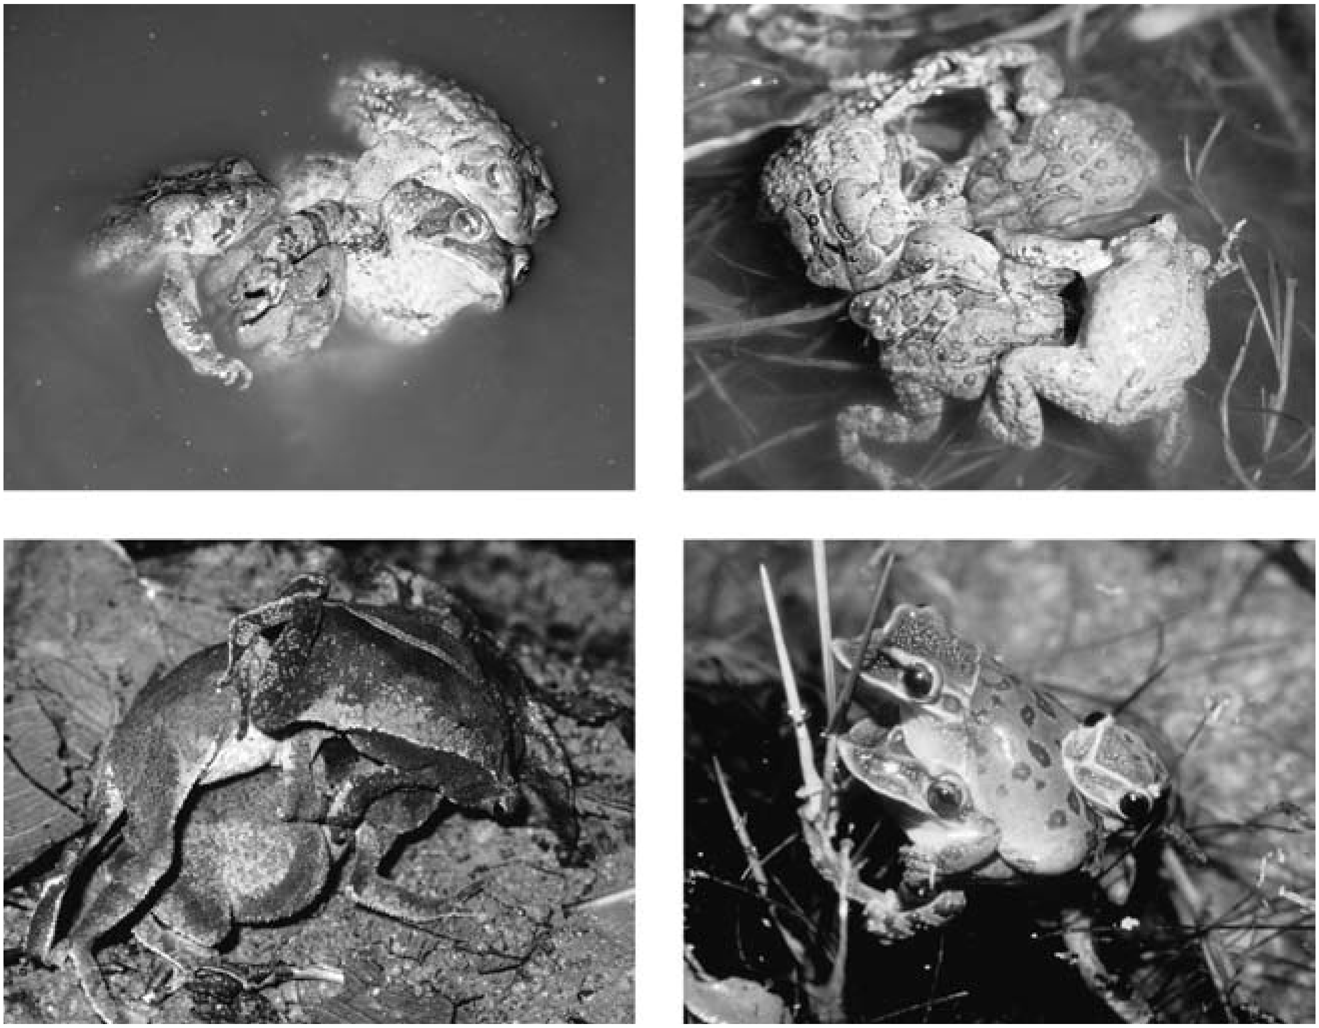

Fig. 8.6. Scramble competition among males of explosive breeding anurans. (A, B) Several male American toads (*Bufo americanus*) competing for a large female. (C) Two males of the Panamanian toad *Bufo alatus* struggling for possession of a female (D) Two males of the Central American treefrog *Triprion petasatus* in amplexus with a female. Photos by Kentwood D. Wells (A–C) and Julian Lee (D).

and O'Hara 1986; R. D. Howard 1988b; Tejedo 1992c; Halliday and Tejedo 1995). In some species, an advantage of large size is apparent at high densities but not at low densities (Arak 1983a).

There is relatively little evidence for size-assortative mating for most explosive breeding anurans (Wells 1979; Gittins Parker, and Slater 1980; Kagarise Sherman 1980; Berven 1981; Gatz 1981a; Kruse 1981a; Woodward 1982c; Arak 1983a; Hemelaar 1983; Reading and Clarke 1983; B. K. Sullivan 1983a; R. D. Howard and Kluge 1985; Loman and Madsen 1986; Olson, Blaustein, and O'Hara 1986; Elmberg 1987; Höglund and Robertson 1987; R. D. Howard 1988b; Ryser 1989a; Wogel Abrunhosa, and Pombal 2005). The occurrence of assortative mating sometime varies among years or among populations (Olson, Blaustein, and O'Hara 1986). Licht (1976) and N. Davies and Halliday (1977) proposed an adaptive explanation for assortative mating in toads, arguing that a close match in sizes of males and females in amplexus would increase the probability of eggs being successfully fertilized. Subsequent work with several explosive breeders has shown that fertilization rates in the field almost always are very high and generally are not related to relative sizes of males and females in mated pairs (Kruse 1981a; Halliday and Verrell 1984; R. D. Howard and Kluge 1985; Höglund and Robertson 1987; Krupa 1988).

The variable occurrence of assortative mating in different populations probably results from differences in male-male competition at different densities and does not require an explanation based on adaptive advantages to females. Small males clasping large females are likely to be displaced, whereas large males on large females are not (fig. 8.8). This

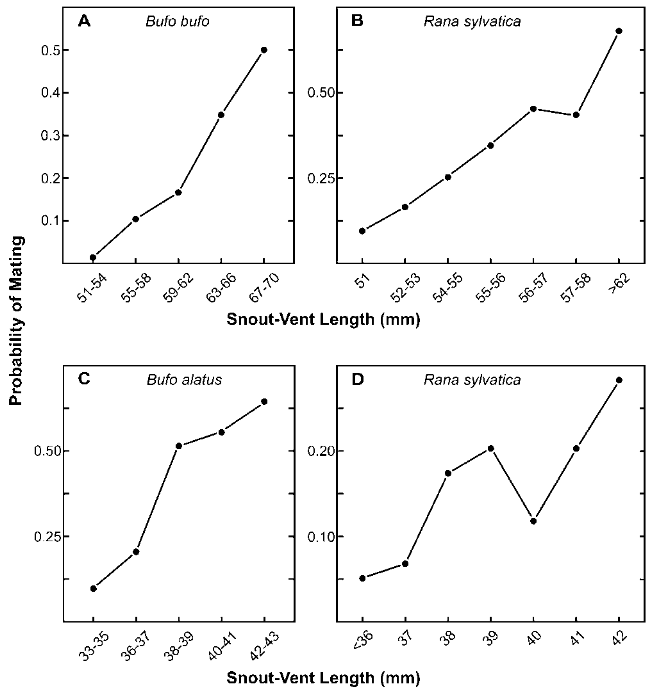

Fig. 8.7. Effect of male size on the probability of mating for several explosive-breeding anurans. (A) Common toads (*Bufo bufo*) from Great Britain. (B) Wood frogs (*Rana sylvatica*) from three ponds in Maryland and Virginia. (C) Toads, *Bufo alatus,* from Panama. (D) Wood frogs (*Rana sylvatica*) from Michigan. Plotted from data in (A) N. Davies and Halliday (1977), (B) Berven (1981), (C) Wells (1979), (D) R. D. Howard (1980).

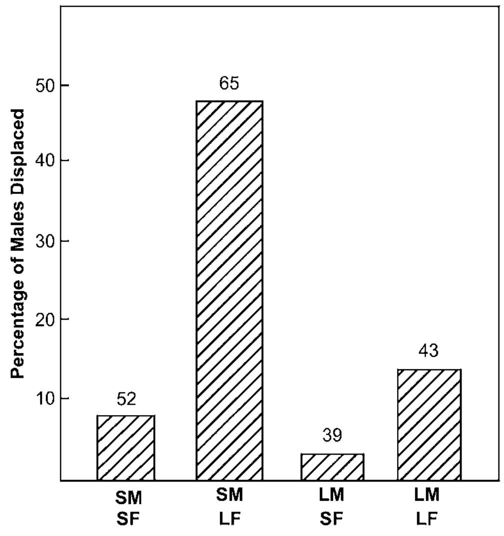

Fig. 8.8. Effect of relative size of paired males and females on the probability of a male being displaced from amplexus in wood frogs (*Rana sylvatica*). LF = large female; SF = small female; LM = large male; SM = small male. Small males have difficulty holding on to large females and therefore are more likely to be displaced than are small males on small females or large males on either larger or smaller females. Plotted from data in R. D. Howard and Kluge (1985).

would produce a positive correlation between male and female sizes in mated pairs. At very high densities, male-male competition often is so intense that small males are displaced even from small females. In those cases, large males will enjoy a mating advantage, but assortative mating will not be apparent (Gittins, Parker, and Slater 1980; Arak 1983a).

Chorus Tenure and Mating Success

In many explosive breeders, the arrival of males at the breeding site is so synchronized that variations in length of attendance are hard to detect (e.g., Wells 1979; Berven 1981). In species that have a series of relatively explosive breeding events in a single season, the total number of nights present at breeding sites probably is a major determinant of male mating success (Wogel Abrunhosa, and Pombal 2005). Even in species with a single short breeding period, slight differences in time of arrival can have a major impact on male mating success, particularly if many females arrive on the first few nights of breeding activity. This in turn can select for early arrival by males. In some early spring breeders, males can be seen making their way to breeding ponds over snow and ice, while females show up a few days later. Gatz (1981a) found that successful *Bufo americanus* males arrived slightly earlier and stayed slightly longer than did unsuccessful males; many of the early arrivals were relatively large. Kagarise Sherman (1980) reported similar results for *B. canorus.* Large males arrived earlier than small males in two of three years, and males that eventually mated arrived at ponds about 2.5 days earlier than unsuccessful males. More important, in each year, 30 to 60% more females were available during the tenure of successful males than during the tenure of unsuccessful males. In other words, mating success in this species was determined in part by males being in the right place at the right time.

In a population of *Rana dalmatina* in France, males arrived in breeding ponds earlier than females and stayed longer, and the largest males were the first to arrive. There was no information on individual mating success in this study, although there was evidence for some multiple paternity of egg clutches (Lodé, Holveck, and Lesbarrères 2005). In one study of *Rana sylvatica,* there was a slight tendency for large males to arrive earlier, and large males were more likely to obtain mates (R. D. Howard and Kluge 1985). Large males also tended to arrive earlier than small males in a population of *Bufo bufo* studied by Loman and Madsen (1986), but mating success appeared to be more related to size than to time of arrival. In another study over a 20-year period, large males with previous breeding experience consistently arrived earlier in the breeding period than did smaller, inexperienced breeders (Reading 2001). In contrast to these results, Morrison, Hero, and Smith (2001) reported that small males had longer chorus tenure than did large males in *Litoria xanthomera,* and this probably was the reason for greater mating success of small males. These authors attributed the longer chorus tenure of small males to lower energetic investment in calling.

The advantage of arriving early at a breeding site seems clear for species in which the breeding season is short and female arrival is relatively synchronous. Because many females are mating at the same time, males that arrive late risk missing the peak of female availability. The reason why large males often arrive earlier than small males is less obvious. There are several possible and nonexclusive explanations for this pattern. On a proximate level, it may be that large males, which often are older as well, are more familiar with the breeding site than are first-year breeders and therefore arrive first (Reading 2001). It also is possible that large males are more likely to move in the fall from summer home ranges to overwintering sites relatively close to breeding ponds, and therefore have less distance to cover in the spring. Autumn movements to overwintering sites close to ponds has been reported in a number of species (see chapter 6), but the influence of body size has not been examined.

Another possibility is that large males save energy by securing the available females early before small males arrive. In anurans with scramble competition mating systems, it almost certainly is more difficult to displace another male from amplexus than to clasp an unmated female, even when the initial clasping male is smaller. Indeed, as mentioned previously, mated males of most species are rarely displaced from amplexus (< 5% of mated pairs), although takeover rates as high as 30% have been reported in some populations of toads. A model developed for mate-guarding crustaceans with internal fertilization, in which males guard females until they are ready to molt, predicted that when takeovers are difficult, large males should begin guarding females early to ensure that they monopolize the available females. In cases where takeovers are easy, large males are expected to simply usurp smaller males guarding females, and prolonged mate guarding is less likely (Härdling, Kokko, and Elwood 2004; see also Candolin and Voigt 2003). Because takeovers appear to be difficult in most anurans, the usurpation tactic is not likely to be a viable one except for extremely large males, especially when there is relatively little delay between males entering amplexus and females beginning to lay eggs (a feature that differs from that of crustaceans, where males may have to wait for some time for females to become receptive).

Male Mobility and Mating Success

Because males in explosive breeding aggregations often obtain mates by active searching, one might expect male mating success to be related to mobility or activity at the breeding site. Males that move more frequently and attempt to clasp many other individuals should be those most likely to obtain mates (Wells 1977b). Unfortunately, detailed data on movements of individual males are scarce, and unless all males in a population can be monitored simultaneously, it can be difficult to relate movement patterns to mating success because many of the animals under observation do not mate (e.g., Wells and Taigen 1984).

Gatz (1981a) reported that successful male *B. americanus* did not move more often than unsuccessful males, but he considered only large-scale movements between different parts of the pond. Kagarise Sherman (1980) quantified movements of *B. canorus* and *B. exsul* males through focal-animal observations, but she was not able to relate movements to mating success. In a low-density population of *Rana sylvatica,* Woolbright, Greene, and Rapp (1990) found that males that moved were more likely to clasp females than were those that remained stationary, but they did not relate clasping success to quantitative measures of movement. Furthermore, final mating success was not greater for the more mobile individuals because several males were displaced by other males before they could fertilize a clutch of eggs. R. D. Howard (1988b) made the most concerted effort to date to measure individual variation in searching behavior. He found that male *Bufo americanus* differed in rates of movement and number of clasping attempts, but there was no relationship between these variables and mating success. The whole question of individual variation in mate searching behavior and its relationship to mating success in explosive breeders is one that needs to be addressed in more detail.

Multiple Matings and Sperm Competition

In most aquatic-breeding frogs, a single male usually succeeds in defending a female against other males and eventually fertilizes her eggs without interference, even in species that form large "mating balls." Nevertheless, this type of scramble competition provides an opportunity for multiple males to release sperm simultaneously, leading to direct sperm competition among males (Halliday 1998). In many cases, the male with his vent in closest proximity to that of the female is likely to fertilize most of her eggs, because sperm typically is released as soon as the eggs emerge from the female's vent. In some species, however, fertilization by multiple males has been documented. Genetic data from *Rana temporaria* tadpoles that hatched from single egg clutches have shown that more than one male can fertilize the eggs of a single female (Laurila and Seppa 1998). More recent work has shown that unpaired males of this species often engage in clutch piracy, clasping and fertilizing egg masses after they have been laid (Vieites et al. 2004). This is similar to behavior reported for some hynobiid salamanders (see chapter 9).

There also is evidence of multiple paternity in a mixed population of *Rana esculenta* and *R. lessonae* (Berger and Rybacki 1992), but these frogs were studied only in the laboratory. The behavioral mechanism that resulted in multiple paternity is not known. These species often lay eggs communally, so it is possible that sperm being released by several males in amplexus simultaneously become mixed and fertilize more than one batch of eggs. Other possibilities are that more than one male remains in amplexus with a single female, or unpaired males release sperm in mating aggregations. A relatively low frequency of multiple paternity has been reported in *Rana dalmatina,* a species in which males sometimes are territorial, but may engage in scramble competition when males greatly outnumber females (Lodé and Lesbarrères 2004; Hettyey, Török, and Hévizi 2005; Lodé, Holveck, and Lesbarrères 2005).

Two forms of multiple paternity have been reported in explosive-breeding species of *Leptodactylus* from Brazil (Prado and Haddad 2003). In *L. chaquensis,* up to seven satellite males placed themselves in foam nests being constructed by pairs in amplexus. The paired males tried to evict the satellite males with aggressive attacks, but often without success. Satellite males beat the foam in synchrony with the mated pairs and presumably released sperm as well. In *L. podicipinus,* a small male was seen to insert himself between a larger male and a female, with both males beating their legs to construct the foam nest and presumably releasing sperm. An analysis of testis size showed that these two species have larger testes relative to body size than do other *Leptodactylus* or other foam-nesting leptodactylids.

Multiple paternity has been investigated in some detail in *Crinia georgiana,* a small myobatrachid frog from Australia. Although this species has a relatively prolonged breeding season, breeding tends to be episodic, with large numbers of individuals aggregated into small temporary pools (P. Byrne 2002). Sex ratios are heavily biased in favor of males. Consequently, males often engage in scramble competition for access to females. As many as eight males have been found in amplexus with a single female, and groups of two or three males are common. Genetic analysis of egg clutches laid by multiply mated females showed that more than one male often fertilized the eggs of a single female (Roberts, Standish, Byrne, and Doughty 1999). Multiple paternity appears to result entirely from competition among males for access to females. Multiply mated females suffer a cost in reduced fertilization success, probably because of jostling by competing males (Byrne and Roberts 1999). There is no evidence of any genetic benefits to females in mating with more than one male that would compensate for the cost of reduced fertilization. This was determined by comparing the growth, development, and survivorship of tadpoles that hatched from eggs sired by single males or multiple males (Byrne and Roberts 2000).

Scramble Competition in Arboreal Frogs

Although intense scramble competition among males is commonly associated with large aggregations of males at aquatic breeding sites, this type of mating system is found in some nonaquatic egg-layers as well. Some phyllomedusine tree frogs that lay eggs in vegetation over water form explosive mating aggregations after heavy rains. Males actively search for females, and high densities of males can result in vigorous pushing and kicking among males competing for females. In some cases, males in amplexus fail to dislodge competing males, and several males participate in fertilizing the eggs, resulting in possible sperm competition (Halliday and Verrell 1984; Halliday 1998). N. Scott and Starrett (1974) observed an aggregation of several thousand *Agalychnis spurrelli* around a temporary pond in Costa Rica. Males clambered over one another while searching for females in vegetation overhanging the water, and some males were observed scraping eggs of other males off of leaves.

W. Roberts (1994) observed several dense aggregations of another Costa Rican species, *A. saltator.* Hundreds of individuals were climbing around in vines over a swamp, and eggs were deposited on moss that covered the vines and nearby tree trunks. Males kicked and pulled at other males in amplexus, attempting to dislodge them, and a few cases of multimale matings were observed. Direct competition for females and multimale matings also have been observed in *Pachymedusa dacnicolor* and *Phyllomedusa rohdei,* which sometimes forms explosive mating aggregations, and in *Agalychnis callidryas,* which has a prolonged breeding season, but sometimes occurs at high densities (Pyburn 1970; Wiewandt 1971; Wogel, Abrunhosa, and Pombal. 2005). In *A. callidryas,* multiple paternity of two egg clutches was confirmed by DNA analysis (D'Orgeix and Turner 1995), and it probably occurs in other phyllomedusines as well.

Several species of rhacophorid frogs that deposit eggs in foam nests on trees overhanging ponds or in shallow burrows at the edges of ponds form dense mating aggregations in which males attempt to displace others from amplexus. Multimale matings have been observed in several of these species (Kato, 1956; M. J. Coe 1967, 1974; Kasuya, Shigehara, and Hirota 1987; Kasuya, Hirota, and Shigehara 1996; Feng and Narins 1991; Fukuyama 1991; Jennions, Backwell, and Passmore 1992). In some cases, explosive mating aggregations formed after heavy rains (M. J. Coe 1974), but in others, the breeding season lasted for several weeks or months. In those cases, the specialized nature of the oviposition sites produces local aggregations of males around the best sites. In addition, the long period of time required to complete a foam nest (up to several hours in *Chiromantis xerampelina;* Jennions, Backwell, and Passmore 1992) allows males to intrude on mating pairs and attempt to fertilize eggs as peripheral or satellite males (see fig. 10.7 B). Males assist in the construction of the foam nest by beating mucus secretions produced by the female with their hind legs (see chapter 7). Coe (1967) originally interpreted multimale mating in *Chiromantis* as a form of cooperative behavior, suggesting that more than one male might be needed to build a satisfactory nest, an interpretation that was repeated by E. O. Wilson (1975). It now seems clear that this behavior is simply the result of competition among males for access to females.

Two lines of evidence suggest that direct sperm competition is a regular feature of the mating systems of these rhacophorid frogs. First, Jennions and Passmore (1993) enclosed the rear ends of *Chiromantis xerampelina* males with plastic bags, preventing them from fertilizing eggs. In two trials in which peripheral males were not present, none of the eggs was fertilized, whereas in one trial in which peripheral males were present, about 37% of the eggs hatched. Those eggs could only have been fertilized by a peripheral male. Unfortunately, DNA analysis of multiple paternity has yet to be performed with these frogs.

The second line of evidence for sperm competition comes from measurements of the relative size of testes in rhacophorids in which multimale mating has been reported. In a comparative study that was not controlled for phylogeny, Kusano, Toda, and Fukuyama (1991) showed that foam-nesting Asian rhacophorids, and *Rhacophorus arboreus* in particular, have larger testes in proportion to body size than do other Asian anurans, including bufonids, hylids, ranids, and microhylids. In a similar analysis that combined Asian and African foam-nesting frogs with anurans from several different families, Jennions and Passmore (1993) showed that the three foam-nesting genera in which multimale mating has been reported have relatively larger testes than other anurans (fig. 8.9). Based on somewhat meager field data, they also suggested that species in which multimale matings are common (*Chiromantis xerampelina* and *Rhacophorus arboreus*) have relatively larger testes than do foam-nesters in which multimale matings are less common (*Rhacophorus schlegelli* and *Polypedates leucomystax*). More detailed field observations on a larger number of rhacophorid species are needed to rigorously test this hypothesis.

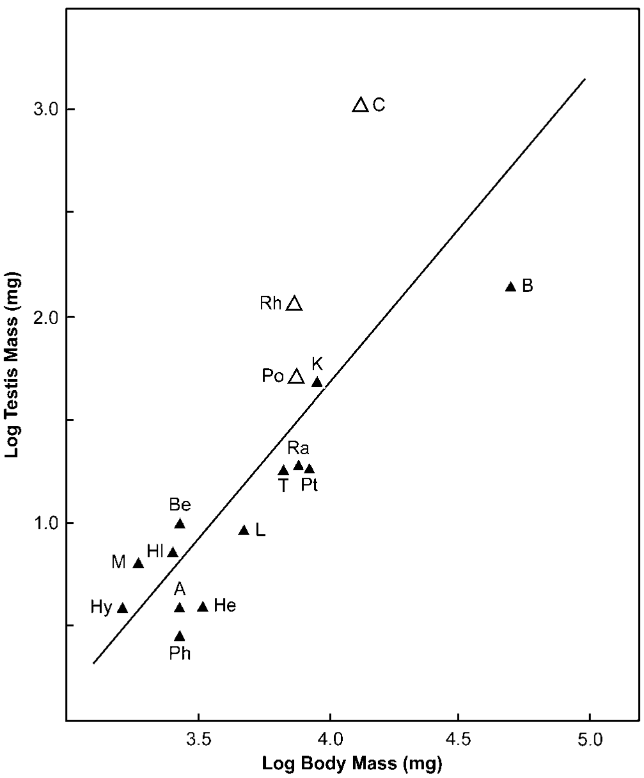

Fig. 8.9. Relative testis size in several genera of anurans. Those shown with open symbols are foam-nesting rhacophorids that exhibit multiple mating. Abbreviations: A = *Afrixalus;* B = *Bufo;* Be = *Buergeria;* C = *Chiromantis;* He = *Hemisus;* Hl = *Hyla;* Hy = *Hyperolius;* K = *Kassina;* L = *Leptopelis;* M = *Microhyla;* Ph = *Phrynomantis;* Po = *Polypedates;* Pt = *Ptychadena;* Ra = *Rana;* Rh = *Rhacophorus;* T = *Tomopterna.* This analysis is not corrected for phylogenetic relationships among these genera. After Jennions and Passmore (1993).

Male Mating Tactics in Prolonged-Breeding Anurans

In most anurans with long breeding seasons, males call from stationary locations to attract females, and do not initiate amplexus until contacted by the female (Wells 1977b). Active searching is rare, but occasionally it occurs in very dense choruses. In most prolonged breeders, however, there is little evidence of direct competition among males for possession of individual females. Instead, competition takes the form of elaborate vocal interactions (chapter 7), defense of calling sites or resource-based territories, or elaborate courtship of females. In this section, I describe the variety of mating systems of prolonged-breeding anurans in some detail. Certain groups of terrestrial-breeding frogs are treated separately, including dendrobatid frogs, members of the widespread tropical genus *Eleutherodactylus,* and the midwife toads (*Alytes*). Aspects of the breeding biology of these frogs, including nonaquatic oviposition and elaborate forms of parental care, make it difficult to fit their mating systems into categories applied to anurans that lay their eggs in or near water.

Choruses and Leks in Aquatic and Arboreal Frogs

Probably the most common mating system for aquatic-breeding frogs is for males to gather in choruses around suitable breeding sites. Males call from the shores of ponds and streams, from elevated perches on vegetation, rocks, or other prominent sites, from the surface of the water, or, in a few species, from underwater (fig. 8.10 E, F, G). Usually, males maintain some minimum distance between themselves and their neighbors, often defending calling sites with aggressive calls and physical attacks (Wells 1977b; B. K. Sullivan, Ryan, and Verrell 1995). Fidelity of individuals to specific calling sites varies among species. In some species, males defend the same calling sites for days or weeks at a time (Paillette 1970b; M. Rosen and Lemon 1974; Mac Nally 1979, 1984a; Forester and Daniel 1986; Robertson 1986b). In others, males occupy different sites on successive nights and sometimes move between calling sites on a single night (Whitney and Krebs 1975b; J. S. Garton and Brandon 1975; Fellers 1979a, b; K. Wells and Greer 1981; Arak 1983a, b, c, 1988a, b; B. K. Sullivan 1982b; Wells and Schwartz

Fig. 8.10. Spatial organization of choruses of pond-breeding anurans, showing a variety of possible mating systems. Closed triangles show calling males. Open triangles show satellite males. Curved arrows indicate movements of calling males. Dots indicate distribution of egg clutches. Shaded circles are territories or activity spaces of males. (A) Scramble competition typical of explosive-breeding frogs such as wood frogs (*Rana sylvatica*) that lay eggs in communal masses. (B) Scramble competition typical of explosive-breeding spadefoot toads like *Scaphiopus couchii* that lay eggs in dispersed clumps. (C) Mating system of frogs in the *Rana esculenta* complex. Males maintain a spatial organization similar to a lek, but engage in active searching for mates. Eggs are laid in communal masses. (D) Mating system of *Bombina bombina*. Males defend small territories, but engage in active searching within their territories. Eggs are dispersed. (E) Lek mating system of ranid frogs that breed in rice paddies, such as *Rana porosa brevipoda*. Males defend small territories that are used as mating stations, but eggs are dispersed on the periphery of the chorus. (F) Lek mating system of natterjack toads (*Bufo calamita*). Males call from dispersed territories on the periphery of the pond and sometimes are accompanied by satellite males. Eggs are laid in communal sites in shallow water. (G) Lek mating system of *Hyla versicolor* and many other treefrogs. Males call from elevated perches on the periphery of the pond or in the water and sometimes are accompanied by satellite males. Males approach females at their calling sites, but carry them to the pond to lay eggs. (H) Resource defense mating system of green frogs (*Rana clamitans*). Male territories are located mostly in sheltered sites along the shore of the pond, where females lay their eggs. Satellite males often accompany territorial males. (I) Resource defense mating system of bullfrogs (*Rana catesbeiana*), with male territories clustered in open water, where females lay their eggs. Satellite males often accompany territorial males.

1984b; Telford 1985; Gerhardt et al. 1987; Telford and Dyson 1988; Dyson 1989; M. Morris 1989; Shimoyama 1989; Cherry 1993). This sort of shifting from one calling site to another seems to be common in species that call from the surface of the water in clustered territories, in species that breed in unstable habitats where water levels or temperatures vary from night to night, and in species that utilize abundant and largely interchangeable calling sites such as tree branches or the banks of ponds and rivers.

Females typically approach males at their calling sites, enter into amplexus, and then carry the males away to suitable oviposition sites. This type of mating system resembles the leks of birds and mammals in that male territories are used for mating, but not for oviposition (Höglund and Alatalo 1995). Nevertheless, the evolutionary origins of leklike mating systems probably differ in these groups. In anurans, the locations of aggregations are determined at least in part by the distribution of suitable aquatic breeding sites, whereas in birds and mammals, the location of leks appears to be largely independent of nesting or birthing areas used by females. Some authors have referred to anuran choruses as resource-based leks. This is a somewhat confusing term, because lek mating systems usually are contrasted with resource defense mating systems. There is evidence for some groups of birds and mammals, such as grouse and ungulates, that lek mating systems are most likely to evolve when females occupy very large home ranges that make defense of resource-based territories or groups of females difficult. There is no evidence of any such relationship in anurans. Nevertheless, it does appear that many of the processes of mate choice and sexual selection described for bird and mammal leks also apply to anuran choruses.

Höglund and Alatalo (1995) suggested that lek mating systems are less common in anurans than is defense of resource-based territories. I believe just the opposite is true. Leklike choruses appear to be the predominant mating systems of aquatic-breeding anurans with prolonged breeding seasons in the families Bombinatoridae, Bufonidae, Discoglossidae, Hylidae, Hyperoliidae, Leptodactylidae, Mantellidae, Microhylidae, Myobatrachidae, Pelobatidae, Pelodytidae, Pipidae, Pseudidae, Ranidae, and Rhacophoridae (table 8.1). Many investigators have characterized the choruses of prolonged-breeding anurans as leks (Emlen 1976; Klöckner 1982; Shimoyama 1982; B. K. Sullivan, 1982b 1983b; Robertson 1986a, b; Arak 1988b, c; Márquez-M. de Orense and Tejedo-Madueno 1990; B. K. Sullivan and Hinshaw 1992; Cherry 1993; Giacoma, Kozar, and Pavignano 1993; C. Murphy 1994a, b; Bastos and Haddad 1996, 2002; Grafe 1997a; Friedl and Klump 2002), despite some quibbling over what criteria should be used to define a lek mating system (e.g., Bourne 1992). Many other anurans essentially have the same type of mating system, but were not originally described as lek species (e.g., Godwin and Roble 1983; M. Ryan 1983b, 1985b; Mac Nally, 1984a; Schwartz and Wells 1984b, 1985; Wells and Schwartz 1984a, b; Akef and Schneider 1985, 1990; B. Balinsky 1985; J. Schwartz 1986; Telford 1985; M. Morris 1989, 1991; Perrill and Shepherd 1989; Wagner 1989a, b, c; Runkle et al. 1994; Barreto and Andrade 1995; B. K. Sullivan, Ryan, and Verrell 1995; Grafe, Steffan, and Stoll 2000; Narins, Lewis, and McClelland 2000).

Lek mating systems are characteristic of anurans that use oviposition sites that cannot be easily monopolized by individual males. Many primitive anurans have inguinal amplexus, including bombinatorids, discoglossids, pelobatids, pelodytids, myobatrachids, and pipids. A common mode of egg deposition in these families is for females to attach eggs individually to plants or other substrates, or to scatter them individually or in small packets on the bottoms of breeding pools (see chapter 10). This mode of oviposition would make it difficult for males to monopolize suitable oviposition sites, so defense of resource-based territories is unlikely. Foam-nesting myobatrachids are an exception, because they often lay their eggs in single masses at sites that can be defended by individual males (see the following). Some derived frogs with axillary amplexus, including some species of *Pseudacris* and *Hyla,* also tend to scatter individual eggs or packets of eggs in different locations (see chapter 7), so they are expected to have lek mating systems as well.

Many species of ranid frogs in Asia breed mostly in rice fields, where males form dense aggregations and vigorously defend small territories against other males. This type of mating system has been described in *Rana brevipoda* (= *R. porosa brevipoda*), *R. porosa porosa, R. nigromaculata, Fejervarya limnocharis,* and *F. syhadrensis.* In these species, mated females apparently leave the cluster of male territories in deeper parts of ponds and lay their eggs in vegetation at the water's edge (Dubois 1977b; Inoue 1979; Shimoyama 1982, 1989, 1993, 1996, 1999; Mallick 1986; Kanamadi, Hiremath, and Schneider 1995). Consequently, their mating systems more closely resemble leks than resource defense (fig. 8.10 E). Mixed species choruses have been observed in rice fields inhabited by both *Rana nigromaculata* and *R. brevipoda,* and in such choruses, males of both species defend their territories against both conspecific and heterospecific males (Shimoyama 1999). Fights usually are won by *R. nigromaculata,* the larger species. The similarity of the vocalizations of these two species facilitates their use in interspecific encounters.

The ranid frogs described previously have clumped male territories and dispersed oviposition sites. Some anurans with leklike mating systems exhibit the opposite pattern, with clumped oviposition sites and more dispersed calling sites (fig. 8.10 F). Most toads (*Bufo*) lay eggs in long strings,

Notes: Data on aggressive behavior of dendrobatid frogs are given in table 11.3 along with information on parental care. Duration of study: 1 = scattered observations; 2 = < 1 month; 3 = > 1 month; 4 = > 1 season. Mark = animals marked (yes, no). Site = location of site defended (B = burrow; G = ground; N = nest; R = rocks; TH = tree hole; V = vegetation; W = water). Type = type of site defended (CS = short term calling site; CL = long term calling site; CO = calling and oviposition site; DS = daytime shelter). Classification of type of site defense represents best estimates based on available data. Behavior: AC = aggressive calling; CH = chasing; FI = fighting; SM = satellite males (+ behavior present, – behavior absent, blank cell = behavior not investigated or unknown).

with many clutches clustered together in shallow water. Some ranid frogs, even those with long breeding seasons, tend to cluster their eggs in areas with dense vegetation, or in sunny areas where warm water ensures rapid embryonic development (Blankenhorn 1977; Radwan and Schneider 1988; Sjögren, Elmberg, and Berglind 1988; Doody and Young 1995). Other species, such as the tropical foam-nesting frogs in the genus *Physalaemus,* prefer to attach their eggs to those of other females, creating huge communal masses that reduce the chances of eggs drying out (M. Ryan 1985b; Barreto and Andrade 1995). This sort of spatial clumping of oviposition sites would make it impossible for males to defend resource-based territories, but defense of small mating territories is common.

In many anurans with lek mating systems, suitable calling sites are spatially separated from oviposition sites, making defense of oviposition sites impossible. These include species in which males call on land and are later carried to water by females, such as *Uperoleia laevigata* (J. Robertson 1986a, b). Males of the Asian rhacophorid *Buergeria buergeri* sit on rocks in mountain streams and defend calling sites against other males (Fukuyama and Kusano 1989, 1992). Females approach males at their calling sites and then carry them up to 50 meters before laying eggs under rocks (Fukuyama, Kusano, and Nakane 1988). Many treefrogs call from elevated perches, ranging from emergent aquatic vegetation only a few centimeters above the water to the branches of bushes and trees (Gerhardt and Rheinlaender 1982; Passmore et al. 1984; S. Mitchell and Miller 1991). The principal advantage of such sites is that propagation of calls over long distances is enhanced by reducing excess attenuation due to ground absorption or passage of signals through dense vegetation (Forrest 1994; Gerhardt and Huber 2002). If eggs are laid in water, then the use of elevated calling sites precludes the defense of oviposition sites by territorial males (fig. 8.10 G). Hence most treefrogs are expected to have lek mating systems unless they use specialized oviposition sites, such as nests constructed by males.

Resource Defense in Aquatic and Arboreal Frogs

Resource defense mating systems are expected to evolve when males can monopolize resources that are needed by females for successful reproduction. In frogs, such resources almost always are oviposition sites. The first observation of frogs defending oviposition sites as territories was by Albert Hazen Wright, a pioneer student of anuran behavior. He reported that male bullfrogs (*Rana catesbeiana*) establish calling stations near fallen logs or stumps "in which they keep a proprietary interest" (Wright 1914). He also observed certain places along the shore of a pond that were consistently occupied by male green frogs (*R. clamitans*). He frequently found eggs in the same locations. Subsequent work on these two species demonstrated that males do indeed defend territories that are occupied for long periods of time (fig. 8.11). Females usually lay their eggs within the territories of their mates, and mate choice is influenced by the quality of male territories (Martof 1953b; Emlen 1968, 1976; Wells 1977a, 1978a; R. D. Howard 1978a,b; M. Ryan 1980a). These remain the two best-documented examples of resource-defense mating systems in anurans (fig. 8.10 H, I). B. K. Sullivan, Ryan, and Verrell (1995) listed only a few examples of resource-defense polygyny in anurans, but similar mating systems can be expected in almost any species that makes use of oviposition sites that are easily monopolized by males (table 8.1).

Territorial defense of oviposition sites is particularly common in pond-breeding ranid frogs with prolonged breeding seasons. Male carpenter frogs (*Rana virgatipes*) defend long-term territories along the shores of ponds, particularly around clumps of submerged vegetation used by females as oviposition sites (Given 1988b). Male pickerel frogs (*Rana palustris*) call underwater from clumps of vegetation and from the bases of submerged bushes, and they respond to advertisement calls of other males with distinct aggressive calls (Given 2005). Egg clumps are laid in similar locations, suggesting that males defend oviposition sites. In other North American ranids, including *R. grylio* and *R. capito,* females apparently lay eggs at male calling sites, and males probably are territorial (Wells 1977b; Lamb 1984b), although the latter species also has been reported to form explosive mating aggregations after heavy rains (Semlitsch, Gibbons, and Turberville 1995). In Europe, *Rana ridibunda* and several related species breed during the summer in large ponds and lakes. Males are widely spaced in choruses and aggressive toward one another. They probably have a territorial mating system similar to that of North American green frogs and bullfrogs, but there is little information on where females lay eggs (M. Smith 1969; Frazer 1983; Kuhn and Schneider 1984; Schneider and Joermann 1988; Kyriakopoulou-Sklavounou and Kattoulas 1990).

Some stream-breeding ranids also have resource-defense mating systems. The southern European frog *Rana graeca* breeds in rivers and streams during the spring. Males call at the surface or under water in cavities under rooks or tree roots, and eggs are laid in these cavities. Males have calls that are used in aggressive interactions, but whether they are territorial is not known (Asimakopoulos, Sofianidou, and Schneider 1990). In Asian stream-breeding ranids such as *Rana holsti* and *Paa* (= *Rana*) *boulengeri,* males exhibit strong fidelity to isolated pools that are used for oviposition and probably are territorial (C. Liu 1950). Another Asian stream-breeding frog, *Vibrissaphora ailaonica* (Megophryidae), also appears to be territorial. Males build nests be-

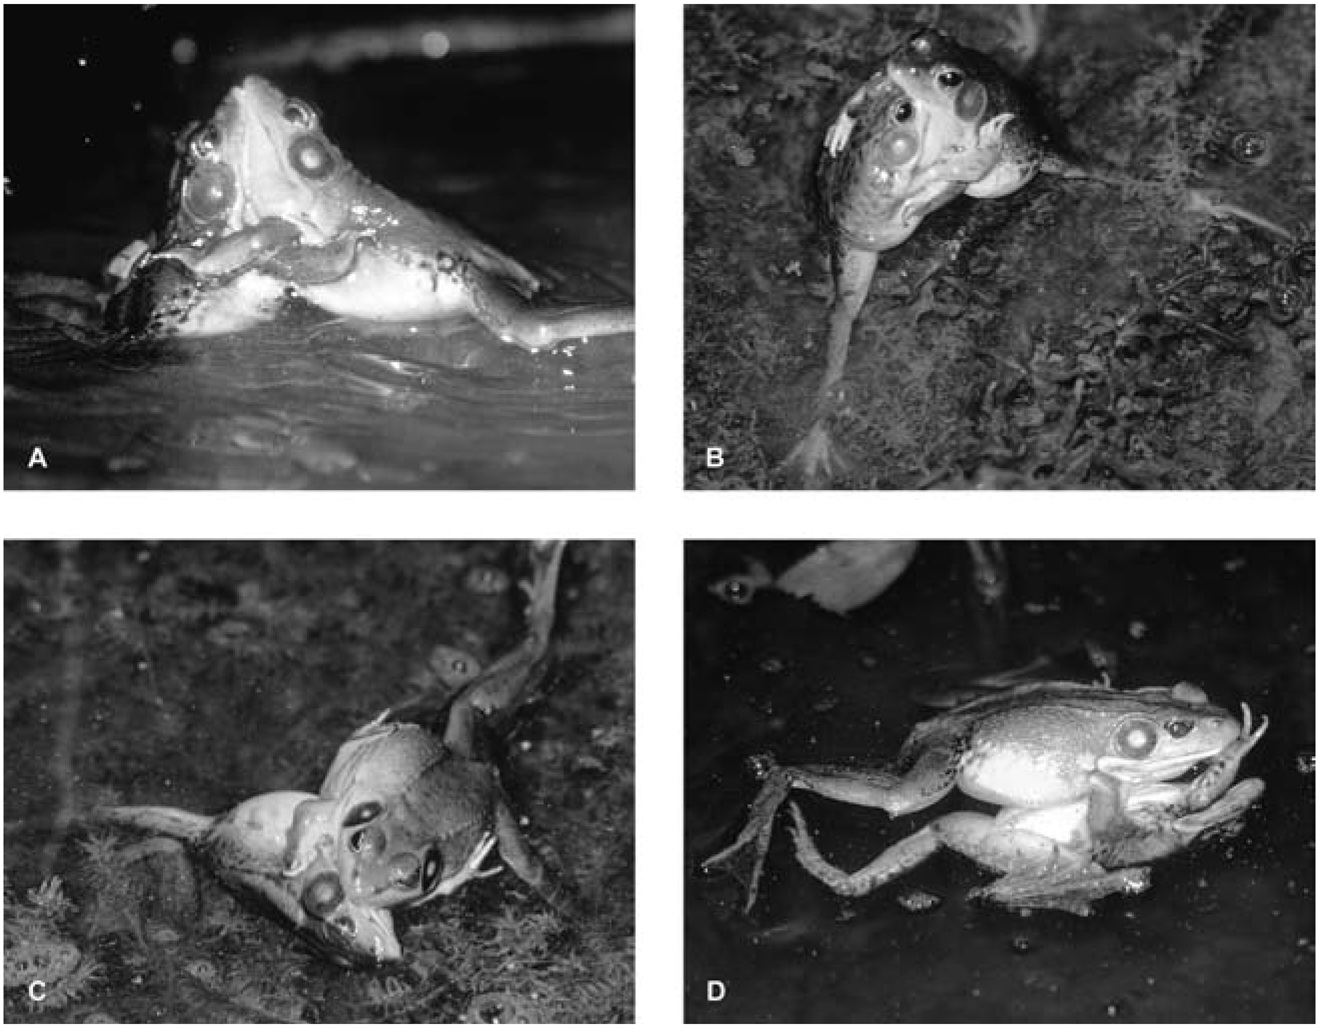

Fig. 8.11. Territorial behavior of male green frogs (*Rana clamitans*). (A) Two males wrestling while floating in the water. (B, C) Two males wrestling while standing on the pond bottom. (D) A large male holding a smaller male under water. Photos by Kentwood D. Wells.

neath rocks and call to attract females. As many as 17 egg masses have been found under one rock, but it is not entirely clear whether this represented the nest of a single male or those of several males. The males of this species remain with the eggs and guard them (Ho et al. 1999).

The fanged ranid frogs of Southeast Asia also breed in streams, and in at least some species, males build nests and defend them against other males. The species that has been studied in most detail is *Limnonectes leporinus* (formerly *L. blythii*) from Borneo, which builds nests along the edges of streams. Females visit the nests to lay their eggs, which are later guarded by the males (Emerson 1992). Males are larger than females and have hypertrophied jaw muscles and fangs on the lower jaw that are used as weapons (Emerson and Voris 1992; see "Sexual Dimorphism"). Males of this species appear not to have advertisement calls, but are territorial (Emerson and Inger 1992). Males of other fanged frogs, including species currently designated as *Limnnonectes blythii* from Vietnam and *L. kuhlii* from Taiwan, have been observed fighting over territories and biting one another with their fangs. Males of the latter species do not always build nests, but defend oviposition sites in shallow pools along streams. Males of both of these species produce advertisement calls, as do related frogs from penisular Malaysia (Matsui 1995), and some have distinct aggressive calls as well (Orlov 1997; Tsuji and Matsui 2002; Tsuji 2004). Both of these species probably will be given different names in the future, because both appear to be members of geographically separated multispecies complexes (Emerson, Inger, and Iskandar 2000.

Nest-building frogs in other families have resource-defense mating systems as well. The nest-building gladiator frogs (*Hyla boans, H. faber, H. pardalis, H. rosenbergi,* and *H. wavrini*) of South and Central America are the best known (fig. 8.12 A). These species have sharp spines on the front feet that are used in territorial battles among males (fig. 8.12 B). Defense of nests has been reported in several of these species, and in others, males often have scratches and wounds that are consistent with territorial fighting (Breder 1946; Lutz 1960b, 1973; Kluge 1981; Martins and Haddad 1988; Hoogmoed 1990b; Martins and Moreira 1991; Martins 1993a, b; Martins, Pombal, and Haddad 1998).

Many other frogs lay aquatic eggs in secluded spots that can be defended by territorial males. For example, males of the Chinese frog *Rana caldwelli* (formerly *R. adenopleura*) call from shallow water or from flooded burrows, where eggs are subsequently laid by females (C. Liu 1950), and it seems likely that males would defend their burrows. Defense of similar burrows used for oviposition has been reported in a species of *Adenomera* (Leptodactylidae) from Brazil (Kokubum and Giaretta 2005). Males of the Australian myobatrachid frog *Limnodynastes peronii* are territorial and defend sites in submerged vegetation where foam nests are subsequently placed (Clyne 1967, 1969). Males of the South American leptodactylid *Thoropa petropolitana* defend territories around oviposition sites on wet rock faces (Heyer and Crombie 1979). In another leptodactylid, *Crossodactylus gaudichaudii,* males aggressively defend calling sites along streams. They appear to select and excavate nearby nest sites under rocks and then close up the site with stones after the female has laid her eggs (Weygoldt and Carvalho e Silva 1992).

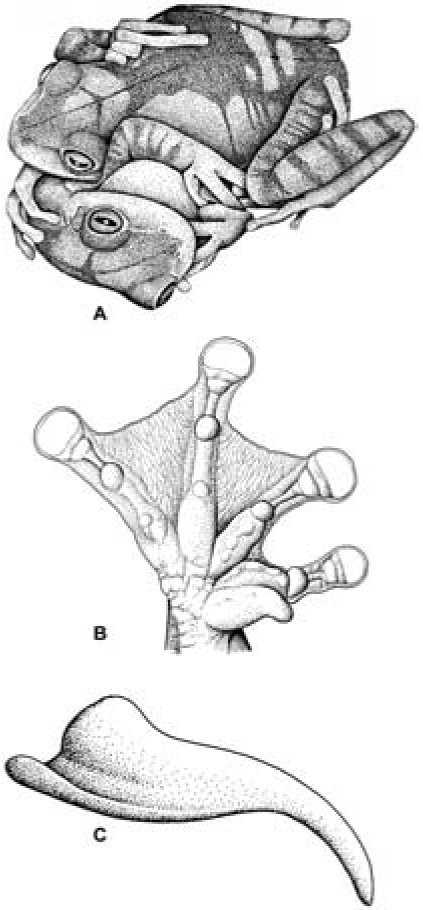

Fig. 8.12. (A) Two males of a Neotropical gladiator frog (*Hyla faber*) fighting over a territory. (B) Front foot and (C) prepollical spine of a closely related species, *Hyla boans,* used in fights between males. (A) After Martins, Pombal, and Haddad (1998); (B) after drawings by David M. Dennis in Duellman (1970).

Tree frogs in several families lay eggs in or above small bodies of water in treeholes, water-filled bromeliads, hollow bamboo stems, and other enclosed sites (see chapter 7). When males call from such sites, it is very likely that they defend them against other males, and that females assess the quality of oviposition sites when choosing mates. Males of one bromeliad breeder, *Phyllodytes luteolus,* have been observed fighting for control of suitable oviposition sites (Weygoldt 1981a), although males in one population where bromeliads were abundant were not territorial (Eterovick 1999). In other hylids that breed in treeholes and bromeliads, males often exhibit strong attachment to specific calling sites and sometimes respond to playbacks of calls with distinct, aggressive calls (Hödl 1991b; Jungfer 1996). Aggressive defense of an oviposition site in bamboo has been observed in captivity in a microhylid frog from Madagascar, *Platypelis grandis,* and males in the field have been observed calling from treeholes and water-filled leaf axils (Blommers-Schlösser, 1975b). Apparently not all treehole breeders are territorial, however. In one microhylid frog from India, *Ramanella montana,* up to four males were observed calling from the same water-filled treehole, with no evidence of aggressive interactions (Krishna, Krishna, and Vijayalaxmi 2004).

Males of many centrolenid frogs are territorial and defend calling sites on leaves overhanging streams that are subsequently used for oviposition by females (McDiarmid and Adler 1974; Duellman and Savitsky 1976; McDiarmid 1978; Greer and Wells 1980; M. Clark 1981; Jacobson 1985; M. Hayes 1991; Bolívar-G., Grant, and Osorio 1999). In many cases, the male provides parental care to the eggs and sometimes accumulates several clutches at the same site (see chapter 11). In other centrolenids, such as *Centrolene geckoideum,* eggs are laid on rocks where they are splashed by waterfalls. Aggressive behavior has not been reported, but males have been observed calling while sitting on egg clutches (J. Lynch, Ruiz, and Rueda 1983).

In contrast to the behavior of centrolenids, African hyperoliid frogs in the genus *Afrixalus,* which also place their eggs on vegetation over water, do not appear to defend oviposition sites. Males call on leaves similar to those used as oviposition sites, but mated females often explore several potential sites before laying eggs. Males do not guard eggs and do not exhibit strong site fidelity (Backwell 1991a). Hence, the mating system of these frogs appears to be more like a lek than resource defense. In most tropical hylids that lay eggs on vegetation over water, there is not a close association between male calling sites and oviposition sites, so these frogs apparently have lek mating systems as well. These include the phyllomedusines (*Agalychnis, Phyllomedusa, Pachymedusa*) and species such as *Hyla ebraccata* (personal observations), *H. brevifrons,* and *H. sarayacuensis* (Hödl 1991a). Males have been observed fighting over calling sites in some phyllomedusine frogs, including *Phyllomedusa sauvagii,* but it is not clear whether males defend oviposition sites or only calling sites (Halloy and Espinoza 1999–2000).

Mating Systems of Terrestrial Egg-Layers

The mating systems of anurans that lay their eggs on land can be difficult to classify, because males are not always aggregated at well-defined breeding areas. Explosive breeding and intense scramble competition have not been reported for terrestrial breeders, although Pombal, Sazima, and Haddad (1994) did observe attempts by males of a small terrestrial brachycephalid toad, *Brachycephalus ephippium,* to displace other males from amplexus. Most terrestrial breeders appear to have lek or resource-defense mating systems, but these two mating systems are not always easily distinguished because of a lack of information on female oviposition behavior for many species. Furthermore, many terrestrial egg-layers have some form of parental care (see chapter 11), which complicates the classification of mating systems. Traditional definitions of lek mating systems exclude cases in which males provide parental care (Höglund and Alatalo 1995). Some frogs with paternal care have mating systems with leklike characteristics, while others clearly appear to be resource defense mating systems. Rather than debating the correct classification of these mating systems, it will be more informative to simply describe them in some detail.

Defense of Subterranean and Terrestrial Nest Sites

The most obvious cases of resource defense are in species that lay eggs in burrows excavated by the male. Such burrows require a considerable investment in time and energy and therefore are likely to be aggressively defended against intruders. Several species of Australian myobatrachids in the genus *Pseudophryne* lay eggs in burrows that are later flooded. Males defend these sites with aggressive vocalizations and physical attacks (Pengilley 1971a; Woodruff 1976a). Many species of *Leptodactylus* build foam nests in underground burrows. In *L. albilabris* and *L. syphax,* males call from the burrows and respond to the calls of other males with aggressive signals (Narins 1990; Cardoso and Heyer 1995; E. Lewis et al. 2001). In *L. fuscus* males call on the ground near the entrances to burrows and lead females to them. They also respond aggressively to the calls of other males (M. Martins 1988). I have observed similar behavior in a related species, *L. fragilis* (= *L. labialis*), in Panama (unpublished observations). In one instance, a male was observed calling to a female and leading her for several meters to an underground burrow. Bernal and Ron (2004) described similar courtship behavior in this species. A male and female were seen exchanging calls and touching each other while moving toward a hidden burrow. Males of a Brazilian species, *L. troglodytes,* also lead females to burrows that they construct (Arzabe and de Almeida 1997). There is evidence of males defending burrows used for oviposition in the African microhylid *Breviceps adspersus* (Poynton and Pritchard 1976). Males of *Cophixalus parkeri,* a microhylid from New Guinea, defend terrestrial oviposition sites and guard eggs (Simon 1983), and territorial behavior has been observed in *C. ornatus* as well (Zweifel 1985). Aggressive defense of territories that include oviposition sites also has been observed in *Brachycephalus ephippium* (Pombal, Sazima, and Haddad 1994).

Hartmann, Hartmann, and Haddad (2004) described some extraordinarily complex courtship behavior in an unnamed hylid treefrog from Brazil, possibly related to *Hyla ehrhardti.* The behavior of this species resembles that of some species of *Leptodactylus* that breed in burrows. Males called from ground bromeliads and other elavated positions, but led females to previously constructed burrows in mud banks near temporary ponds on the forest floor. The frogs lay unpigmented eggs in these burrows, and tadpoles develop in nearby ponds after the burrows are flooded. Courtship behavior included use of soft courtship calls and a variety of visual and tactile displays, culminating in the male entering the burrow, followed by the female. In one instance, a female inspected a burrow, but did not mate with the owner, which continued to call inside the burrow. This species clearly seems to have a resource-based mating system, but it is not known whether males actively defend burrows against other males. In other species in the *Hyla albosignata* and *H. albofrenata* complexes, which probably are closely related to this frog, males call from subterranean burrows and presumably would defend them against intruding males (Cruz and Peixoto 1984; Gomes and Peixoto 1997).

Mating Systems of *Eleutherodactylus*

Many terrestrial breeders with direct development have oviposition sites that are some distance from calling sites. This is particularly true of species that lay eggs underground or in leaf litter, but call from elevated perches on logs, low vegetation, bushes, or tree trunks. In some species, females approach males at their calling sites and then carry them in amplexus to a suitable oviposition site. In others, males have elaborate courtship behavior and lead females to oviposition sites before going into amplexus. When males defend calling sites as territories, but females control the selection of oviposition sites, the mating system resembles a lek. If the male leads the female to an oviposition site a short distance from his calling site, it can be located within a defended territory, and the mating system can be considered resource defense. In most cases, we simply do not know enough about the biology of these frogs to clearly describe the mating system. For example, I observed fighting between males of *Eleutherodactylus urichi* from Trinidad (fig. 8.13 A), and males showed strong fidelity to their territories (Wells 1981b). Unfortunately, mating and oviposition were not observed, so it was impossible to determine whether eggs were laid within the areas defended by the males.

The behavior of *Eleutherodactylus johnstonei* from Barbados includes features of both lek and resource-defense mating systems. Males exhibit strong site fidelity and defend small calling territories near the ground against other males (Ovaska and Hunte 1992; Bourne 1997). Females approach males at calling sites, and males then lead them to oviposition sites in small cavities. It is not clear that these nest sites are within the areas defended by males, however. Both Ovaska and Hunte (1992) and Bourne (1997) observed groups of males attempting to court the same female, and Bourne reported instances of unpaired males following courting pairs into nesting cavities. When Ovaska and Hunte (1992) removed a male that was leading a female toward a nesting cavity, the female then followed another male to the same cavity. Both males and females have been reported to attend eggs after they are laid (Townsend 1996), which suggests that males do not necessarily invest heavily in defense of oviposition sites.

In a number of other species of *Eleutherodactylus,* especially those found in Puerto Rico, males call from elevated perches, but lead females to oviposition sites selected by the male (Jameson 1954, 1955a, b; Townsend and Stewart 1986; Michael 1996; Ovaska and Caldbeck 1997a). After oviposition, the males often remain with the eggs until they hatch. The best-studied species is *Eleutherodactylus coqui.* Males prefer open, elevated calling sites, probably because they enhance the transmission of calls (Narins and Hurley 1982; Townsend 1989a). Most oviposition sites are on the ground in sheltered locations, but elevated sites, such as dead *Cecropia* leaves hanging in branches, are actually used more often than expected if males were selecting oviposition sites at random (Townsend 1989a). Males lead females to oviposition sites while giving distinctive courtship calls (Townsend and Stewart 1986; Michael 1996). Males that use elevated oviposition sites tend to call closer to nest sites than those using sites on the ground, thus reducing the time required for courtship. These males also were more likely to acquire

(B) Two males of the dendrobatid frog *Allobates femoralis* from French Guiana fighting in the leaf litter. (C) Two males of the dendrobatid frog *Colostethus panamensis* from Panama fighting over a territory in a rocky stream. The top male is pressing the bottom male onto the rock. Photos by Kentwood D. Wells (A, C) and Walter Hödl (B).

multiple mates at the same site, and had higher hatching success (Townsend 1989a). Males seldom fight over calling sites, but do give aggressive calls in response to calls of nearby males (Stewart and Bishop 1994; O'Brien 2002). They are much more aggressive in defending retreat sites, especially those being used as nest sites (Stewart and Rand 1991, 1992; O'Brien 2002). The mating system of *E. coqui* can be considered a resource-defense mating system, since the quality of nest sites controlled by males probably influences mate choice by females (Townsend and Stewart, 1994).

Other species of *Eleutherodactylus* with male parental care probably have resource-defense mating systems as well. In some species, males call from oviposition sites and aggressively defend them against other males, so resource defense is clear. For example, *E. hedricki* is a tree-hole breeder and exhibits both male parental care (Townsend 1996) and territoriality (Drewry 1970). *Eleutherodactylus cooki* breeds in small caves and rock crevices. Males are aggressive, and often continue to call while attending eggs, sometimes enabling them to obtain additional matings (Joglar, Burrowes, and Rios 1996). Other species, such as *E. antillensis* and *E. cochranae,* resemble *E. coqui* in using courtship calls to lead females from calling sites to oviposition sites (Michael 1996; Ovaska and Caldbeck 1997a). Male parental care is likely in these species, but parental behavior has not been observed in detail (Townsend 1996).

Mating Systems of Dendrobatid Frogs

Many dendrobatid frogs also lay their eggs on land and exhibit elaborate parental care (see chapter 11). Some species may have resource-defense mating systems, but leklike behavior has been observed as well. The territorial behavior of males differs among species, depending in part on habitat structure and population density (Pröhl 2005b). Members of the genus *Colostethus* often are associated with rocky streams, and some form of territorial behavior probably occurs in most species, especially at high population densities. The best-studied example is the Panamanian species *C. panamensis* (formerly *C. inguinalis;* Wells 1980a). Males occur at high densities on boulders along streams and defend relatively large territories during the rainy season. They call throughout the day and are aggressive toward individuals of both sexes (fig. 8.13 C). Some territories are occupied for up to six months, and appear to contain areas suitable for feeding, shelter, courtship, and oviposition. During the dry season, males abandon their territories and congregate around sources of moisture in streambeds. Here, some males defend small territories, while others simply sit quietly in pools. During the dry season, females also defend territories centered near moist retreat sites or choice feeding sites—but they abandon their territories during the rainy season, when most of the breeding takes place. Females seem to defend small territories only when they need to secure a suitable retreat site during dry weather, whereas the large territories of males during the rainy season are related to competition for mates.

In other species, including *C. pratti, C. talamancae, C. flotator,* and *C. nubicola,* males remain at the same sites for days or weeks and are aggressive toward other males, but their behavior has not been studied in detail (Wells 1977a, 1980a, unpublished observations; K. Summers 2000). These species live on the forest floor and generally occur at lower densities than do the streamside species, so competition for territories probably is not as intense. There are brief reports of territorial behavior for other species of *Colostethus,* and males in captivity often are aggressive toward other males. Species exhibiting some form of aggressive behavior include *C. abditaurantius, C. awa, C. caeruleodactylus, C. degranvillei, C. fraterdanieli, C. marchesianus, C. nexipus, C. sauli,* and *C. subpunctatus* (Lescure 1975a; Heselhaus 1984; Coloma 1995; Fandiño, Lüddecke, and Amézquita 1997; T. Grant and Castro 1998; Lima, Caldwell, and Biavati 2002; Lüddecke 2002a; Pröhl 2005b). Unfortunately, too little is known about these species to characterize their mating systems. One species, *C. beebei,* is unusual in that breeding takes place in water-filled bromeliads, a habit usually associated with other genera of dendrobatid frogs. Males are territorial, aggressively defending their bromeliads against other males (Bourne et al. 2001). Presumably a shortage of suitable oviposition sites has led to the evolution of resource defense in this species. In *C. stepheni,* from Amazonian Brazil, males are territorial and guard oviposition sites on the forest floor (Junca, Altig, and Gascon 1994; Junca 1996, 1998). In contrast to most dendrobatids, tadpoles are not carried to water, but remain in the nest and are guarded by the male until metamorphosis (see chapter 11). Consequently, suitable nest sites might be harder to find than in species that move tadpoles to water.

In several species of *Colostethus* and *Mannophryne,* males are aggressive toward other males, but do not appear to defend long-term territories. Their spatial organization is more similar to a lek than to resource defense, but they do not fit the traditional definition of lekking behavior (Höglund and Alatalo 1995) because males also care for eggs and tadpoles. The best known is *Mannophryne trinitatis,* which has been studied in both Trinidad and Venezuela (Test 1954; Sexton 1960; van Meeuwen 1977; Wells 1980c; Praderio and Robinson 1990; Cummins and Swan 1995). Females are highly territorial and defend suitable feeding and retreat sites along rocky streams. They respond to intruding males and females by pulsating their bright yellow throats and physically attacking other frogs (fig. 8.14 A, B). Males, on the other hand, move frequently between calling sites and do not maintain permanent territories. When males are not calling or defending calling sites, they assume a cryptic brown coloration (fig.

Fig. 8.14. Aggressive behavior and communication in a dendrobatid frog from Trinidad, *Mannophryne trinitatis.* (A) Territorial female displaying her conspicuous yellow throat set off by a black band. The female pulsates her throat at intruding frogs of both sexes. (B) Two females fighting over a territory. (C) Male with light brown coloration typical of noncalling males. (D) Calling male with black coloration. Photos by Kentwood D. Wells.

8.14 C). When calling, males turn black and attack other black males calling nearby (fig. 8.14 D). They display from rocks and other prominent sites and often jump up and down while calling, making themselves very conspicuous to females. Females leave their territories and follow males to oviposition sites in leaves some distance from the males' calling sites. They attend the eggs and later carry the tadpoles to water. Two other species, *Mannophryne collaris* and *Colostethus palmatus,* exhibit a similar type of social organization, including female territoriality, darkening of coloration in displaying males, and conspicuous jumping displays by calling males (Dole and Durant 1974a; Durant and Dole 1975; Lüddecke 1974, 1976, 1999). Territorial behavior by females also has been observed in *C. abditaurantius* (Grant and Castro 1998), but nothing is known about the mating system of this species.

Most species of *Dendrobates, Epipedobates,* and *Allobates* are not closely associated with streams, but are either terrestrial or arboreal. Aggressive behavior between males has been observed in many species (fig. 8.13 B), both in the field and in captivity (Duellman 1966; Goodman 1971; Crump 1972; P. Bunnell 1973; Silverstone 1973; Wells 1978a; McVey et al. 1981; H. Zimmermann and E. Zimmermann 1980b, 1981, 1984, 1988, 1990; E. Zimmermann and H. Zimmermann 1982; Jungfer 1985; E. Zimmermann 1990; Forester, Cover, and Wisnieski 1993; Baugh and Forester 1994; Hermans, Pinxten, and Eens 2002; Narins, Hödl, and Grabul 2003). A number of recent field studies with marked individuals have confirmed that males often defend all-purpose territories that usually include both foraging areas and oviposition sites (Summers 1989, 1990, 1992; Roithmair 1992, 1994; van Wijngaarden and van Gool 1994;

Pröhl 1997b; Summers and Amos 1997; Pröhl and Hödl 1999). These species might have resource-defense mating systems, but exactly what resources are being defended is not always clear (Pröhl 2005b).

Most species of *Dendrobates* deposit tadpoles in pools, water-filled treeholes, or bromeliads. Donnelly (1989a, b) reported that males of *Dendrobates pumilio* defend territories centered near trees with bromeliads that serve as tadpole deposition sites. When bromeliads were added to experimental plots, the density of resident males increased, but addition of leaf litter that might serve as oviposition sites did not. This led Donnelly to conclude that bromeliads are the main resources being defended by territorial males. In contrast, other investigators working with the same species have found that tadpole deposition sites often are not located within territories of males, although oviposition sites sometimes are (Pröhl 1997b; Pröhl and Hödl 1999). In fact, territories of males are considerably smaller than home ranges of females and tend to be located where densities of females are highest. Female home ranges are more closely associated with tadpole rearing sites than are territories of males (Pröhl and Berke 2001).

Both males and females of *D. pumilio* were observed to mate with multiple partners, but the degree of polygamy was greater for males than for females, as was variance in mating success. Female densities were higher in a secondary forest, which had many more tadpole rearing sites, than in a primary forest, and average male mating success was consequently higher in secondary forest (Pröhl 2002). Realized reproductive success of males and females depends not only on the number of matings obtained, but also on survival of egg clutches. Loss of egg clutches was a frequent occurrence, and when clutch losses were high, mating frequencies of males were higher, because females were not occupied with caring for tadpoles and therefore could produce new clutches of eggs more quickly. On the other hand, realized reproductive success of males was actually lower when clutch loss was high (Pröhl 2005a).

Overall, the mating system of *D. pumilio* appears to be closer to a lek than to resource defense, with competition among males for calling sites and male calling performance being the main determinants of mating success (Pröhl 2003). Nevertheless, the mating system of this species defies simple classification because of the heavy investment in parental care by both males and females. Although males do not defend tadpole rearing sites, such sites can be limiting for female reproductive success, and females sometimes aggressively defend such sites against other females (Haase and Pröhl 2002). It is not entirely clear whether females are defending rearing sites as resources for future use, or are protecting tadpoles already deposited in these sites against competition or cannibalism.

In species that use treeholes and other large pools as tadpole deposition sites, such as *D. auratus,* such sites often are not located within a male's territory and often are used by more than one male (K. Summers, 1990). Presumably these relatively large pools are scarce, but also difficult for one male to defend against intruders. In contrast, males of *D. ventrimaculatus* and *D. vanzolinii* are territorial and defend water-filled leaf axils or treehole cavities that serve both as oviposition sites and tadpole deposition sites (Caldwell 1997; Summers and Amos 1997; Caldwell and Oliveira 1999). Eggs are laid above pools of water, where they are attended by both parents. Some tadpoles fall into pools without being carried, but others are picked up and carried to other pools. Males carry tadpoles, but they periodically call females to the pools to deposit unfertilized eggs to feed the tadpoles (see chapter 11). In *D. ventrimaculatus,* more than one male sometimes deposited tadpoles in the same axil, and genetic analysis using microsatellite markers revealed that tadpoles inhabiting the same pool often were unrelated. This indicates that the territorial behavior of males is not always successful in preventing other males from using their pools. This can be costly, because if an intruding male deposits large tadpoles in a pool containing small tadpoles from a resident male's clutch, then the larger tadpoles often eat the smaller ones (Summers and Amos 1997).

There is some evidence that territories tend to be somewhat larger in dendrobatids in which males provide parental care than in those with female parental care. For example, territory size is relatively large in *Dendrobates auratus, D. leucomelas, Allobates femoralis,* and *Epipedobates trivittatus,* all of which have male parental care (Summers 1989, 1992; Roithmair 1992, 1994). Territories of males often are quite small in *D. pumilio, D. granuliferus,* and *D. histrionicus,* species in which females assume the primary parental role (Donnelly 1989b; Summers 1992; van Wijngaarden and van Gool 1994; Pröhl 1997b; Pröhl and Hödl 1999; Pröhl and Berke 2001). This difference could simply reflect differences in body size (the species with male parental care are considerably larger) or differences in population density. It also is possible that males of the former group maintain large territories so that egg clutches of different females can be widely separated to prevent egg cannibalism by females (Wells 1978a; Summers 1992). Roithmair (1992, 1994) found that male mating success was positively correlated with territory size in *Allobates femoralis* and *Epipedobates trivittatus,* and suggested that females use territory size as an indicator of male quality. Territory size also was positively correlated with mating success in a population of *Dendrobates pumilio,* but this variable was much less important than the calling activity of the male and the height of his calling perch (Pröhl and Hödl 1999; Pröhl 2003).

Like some other frogs that lay eggs on land at oviposition sites separated from calling sites, dendrobatid frogs often have elaborate courtship behavior that can last for an hour or more. Usually a female initiates courtship by approaching a calling male (Crump 1972; Polder 1974b, c; Wells 1978a, 1980a; H. Zimmermann 1974, 1978, 1982; Limerick 1980; Weygoldt 1980a, b, c, 1982, 1983; H. Zimmermann and E. Zimmermann 1980a, b, 1981, 1984, 1985; Schülte 1981a, b; E. Zimmermann and H. Zimmermann 1982, 1985; E. Zimmermann 1983; Heselhaus 1984; Jungfer 1985; Lüddecke 1999; Pröhl and Hödl 1999; Bourne et al. 2001). When females are territorial, as in *Mannophryne trinitatis* and *M. collaris,* males initiate courtship at a distance, by using elaborate jumping displays and conspicuous color changes (Dole and Durant 1974a; Wells 1980c). Once a female is nearby, the male leads her to a concealed oviposition site in dead leaves, a rock crevice, or a bromeliad. Sometimes the male and female pause and engage in elaborate tactile interactions. In *Dendrobates histrionicus, D. lehmanni,* and related species, the male follows the female and actively strokes her with his feet (Silverstone 1973; H. Zimmermann and E. Zimmermann 1980b, 1981; E. Zimmermann and H. Zimmermann 1982). In *D. auratus, D. azureus, D. leucomelas, D. tinctorius, Phyllobates terribilis, P. vittatus,* and *Allobates femoralis,* the female takes the more active role (Polder 1974b; Wells 1978a; H. Zimmermann 1974; 1982; H. Zimmermann and E. Zimmermann 1980a, 1981, 1985; Weygoldt 1983; Summers 1989, 1990, 1992). This partial reversal of the usual sex roles in courtship seems to reflect competition among females for preferred males, or attempts by females to prevent tadpoles of other females from being deposited in pools with their own tadpoles, where they suffer cannibalism (Summers 1990, 1992).

When the male and female have found a suitable oviposition site, they often engage in additional tactile interactions, displays, and preparations for mating. These usually include cleaning or wiping motions on the substrate. The details of oviposition and fertilization vary considerably. In some species of *Colostethus, Phyllobates,* and *Dendrobates,* the male clasps the female in cephalic amplexus (see fig. 10.1 D). The male holds the female with the upper surfaces of the front feet pressed against her throat (Myers et al. 1978; Wells 1980a; H. Zimmermann 1982, 1983; E. Zimmermann 1983; Weygoldt 1983; Heselhaus 1984; H. Zimmermann and E. Zimmermann 1985; Bourne et al. 2001). In other species, the male lies loosely across the back of the female during oviposition and fertilizes eggs (Lüddecke 1974, 1999; Silverstone 1976; Schülte 1981b).

In several species in the *Dendrobates auratus* group, males are reported to sit on the eggs and fertilize them after they are laid (Senfft 1936; Polder 1974b, 1976a, b; H. Zimmermann 1974, 1978; H. Zimmermann and E. Zimmermann 1980a; E. Zimmermann 1983). Similar behavior has been reported in *D. histrionicus* and some of its close relatives (H. Zimmermann and E. Zimmermann 1980b, 1981). In *Colostethus beebei,* males were observed to initially clasp females in cephalic amplexus during courtship, but fertilization apparently occurred when males sat on the eggs after they were laid (Bourne et al. 2001). Males of *C. caeruleodactylus* were not observed in amplexus, but did move around on eggs after they were deposited (Lima, Caldwell, and Biavati 2002). In some derived species of *Dendrobates,* such as *D. pumilio, D. speciosus,* and *D. ventrimaculatus,* males apparently deposit sperm on the substrate before eggs are laid (Limerick 1980; Weygoldt 1980a, b; Lescure and Bechter 1982; Jungfer 1985). However, in *D. granuliferus,* the male and female are reported to place their vents in contact, and the male fertilizes the eggs as they are laid (Crump 1972).

There are several possible reasons for the evolution of elaborate courtship in dendrobatids (Wells 1977a, 1980a). First, females could benefit from remaining "coy" until a suitable oviposition site is located. Summers (1989) reported that *Dendrobates auratus* females prefer certain males based on the quality of their territories. They vigorously pursue males and try to prevent other females from mating with them. Males, on the other hand, should persist in courtship only if they receive clear signals that a female is receptive. This could lead to the evolution of a complex exchange of signals between males and females. Second, dendrobatids generally remain in the same habitat throughout the year. Consequently, males must frequently encounter both receptive and nonreceptive females; complex courtship allows males to assess the reproductive condition and receptivity of females that enter their territories. This would be especially important if males and females compete for similar territory sites (Wells 1980a). A male should attempt to determine whether an intruding female is a potential competitor or a potential mate and adjust his behavior accordingly. It also is possible that females require prolonged stimulation to initiate ovulation (Bourne et al. 2001), although it is not clear why this should be more important for dendrobatids than for other frogs.

The Mating Systems of Midwife Toads

One group of anurans, the midwife toads (genus *Alytes*), has a mating system that does not fit conveniently into the categories described for other anurans. Male midwife toads call on land, either from open ground or from crevices or other retreat sites. Calling sites usually are within 50 meters of pools where tadpoles eventually develop, but are not necessarily immediately adjacent to bodies of water. The breeding period can be prolonged (up to two months) or explosive (less than one week), depending on local weather, but prolonged breeding seasons tend to be broken into a series of short episodes of reproductive activity. Males advertise themselves to females by calling. They are not territorial, although males sometimes maintain a minimum distance between themselves and other individuals. In some cases, however, more than one male calls from the same retreat site (Bush 1997). Compared to other frogs, males exhibit little aggressive competition for calling sites or mates, although occasional struggles over individual females have been reported. Males also will increase their calling rate in response to the calls of other males, a behavior indicative of some level of competition for the attention of females (Bosch and Márquez 1996). Females approach calling males and often answer their calls with their own vocalizations, an unusual occurrence in anurans (see chapter 7). Sometimes a male and female will alternate calls with one another for several minutes before going into amplexus.

The eggs are laid in strings, which the male wraps around his hind legs. He then carries them for several weeks before depositing hatching tadpoles in a pond (Heinzmann 1970; Crespo 1982; Reading and Clarke 1988; Raxworthy 1990; Márquez and Verrell 1991; Márquez 1992, 1993, 1995, 1996; Verrell and Brown 1993; Bush 1996; Bush, Dyson, and Halliday 1996). In *Alytes obstetricans* and *A. cisternasii,* males often mate several times and care for more than one clutch of eggs simultaneously, and large individuals are most likely to obtain multiple matings (Reading and Clarke 1988; Raxworthy 1990; Márquez 1993, 1995; Böll and Linsenmair 1998). Multiple clutches are less common in *A. muletensis* (Bush 1996).

Three features of the mating systems of midwife toads set them apart from most other anurans. First, males and females often gather in mixed-sex groups during the breeding season, and groups of males have been reported to call to the same female. Second, both males and females call. In most cases, the females call in response to males, which stimulates the males to call more quickly (Heinzmann 1970; Márquez and Verrell 1991; Bush 1997; Bosch 2001, 2002). This provides the female with better directional information about the location of the male. In the Majorican midwife toad (*Alytes muletensis*), females were observed advertising for males by calling and even searched for males in rock crevices, but this occurred only when females needed to lay their eggs immediately. Third, females have been observed fighting over males (fig. 8.15; Verrell and Brown 1993; Bush 1997; Bush and Bell 1997). This behavior is predicted to occur in species with a high level of male parental investment, where the availability of males to care for eggs limits the reproductive rate of females (Trivers 1972). Competition among females also is expected when there is a shortage of receptive males for some other reason, or substantial variation in the quality of males available as mates (Jennions and Petrie 1997). In some species, there appears to be variation among males in their readiness to mate, and this could lead to a shortage of mates for females in the population (Lea, Halliday, and Dyson 2003).

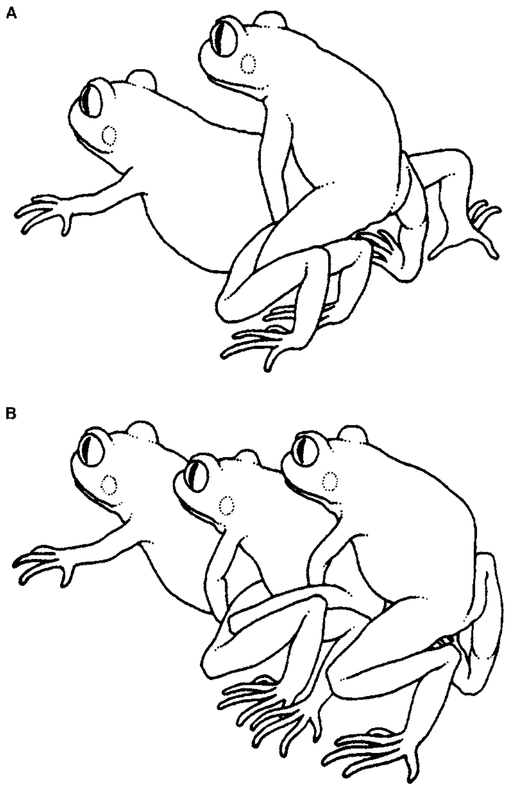

Fig. 8.15. Competition between females for access to a male in the Majorcan midwife toad (*Alytes muletensis*). (A) Normal amplexus position, with male on the back of the female. (B) A second female clasping the male from behind, interfering with his mating attempt. After Bush and Bell (1997).

There is some evidence for active choice of mates by both female and male midwife toads. In two species, *A. obstetricans* and *A. cisternasii,* large males obtained more egg clutches than small males. The lack of extensive male-male competition suggests that female choice probably accounts for this variation in male mating success, although the evidence comes mostly from correlational studies of male traits and reproductive success rather than experimental studies (Márquez 1993; Böll and Linsenmai, 1998; Lodé and Le Jacque, 2003). Females did exhibit a preference for low-frequency calls, like those produced by large males, in playback experiments (Márquez 1995), but the preference was not very strong (Bosch and Márquez 2005). Females of *A. cisternasii* showed a stronger preference for high calling rates. In *A. muletensis,* a species in which receptive females appear to outnumber available males, females did not prefer low-frequency calls or long calls, both of which are characteristic of large males (Dyson et al. 1998). Males oriented toward the calls of females and showed a stronger response to loud calls than to less intense calls. They did not, however, prefer low-frequency calls of large females to high-frequency calls of small females (Bush, Dyson, and Halliday 1996). This result was contrary to predictions that males should prefer larger females because they produce larger clutches or larger eggs. The fact that males exhibit any selectivity toward females is unusual among male anurans, which tend to be relatively indiscriminant in their choice of mates (Krupa 1995). Males are expected to be selective only when excess females are available, or individual females differ substantially in the number or quality of eggs they produce.

Aggressive Displays, Fighting, and Territory Defense

In anurans that defend either calling sites or oviposition sites, displays and aggressive behavior tend to be much more elaborate than in species that engage in scramble competition over females (table 8.1). Presumably the evolution of elaborate displays and aggressive behavior are driven by sexual selection, especially when variance in male mating success is high. In general, aggressive interactions among males appear to be more frequent and more intense in species that defend a valuable resource, such as an oviposition site, than in those that defend only space around their calling sites, although this has not been rigorously quantified.

Visual Signals

Typically, aggressive encounters are preceded by exchanges of aggressive calls, which usually are structurally distinct from the advertisement call (see chapter 7). Although acoustic signals tend to predominate, many species also use visual displays in close-range encounters. For example, in some species, males display to other males by adopting an inflated or elevated posture (Test 1954; Sexton 1960; Duellman 1966; Emlen 1968; Wiewandt 1969; Goodman 1971; Crump 1972; Durant and Dole 1975; Wells 1977b, 1978b, 1980a, c, 1981b; Howard 1978a; M. Ryan 1980b). In others, males engage in push-up or rocking displays (Brattstrom and Yarnell 1968; McDiarmid and Adler 1974; Greer and Wells 1980) or wave the front feet (Crump 1988; Lindquist and Hetherington 1996, 1998).

In several unrelated species of frogs that call near noisy streams, vocal advertisement is supplemented or has been replaced by foot-flagging displays that involve extension of the hind feet (fig. 8.16). Often, males have light blue or other reflective colors on the webbing of the hind feet that enhances the display (Haddad and Giaretta 1999; Hödl and Amézquita 2001). These displays are directed at other males or potential mates, or both. In *Hyla pardalis,* foot-flagging displays elicited similar displays from other males, suggesting they function mainly in territory advertisement (Amézquita and Hödl 2004). Such displays may be advantageous in an environment characterized not only by high acoustic noise levels, but considerable visual clutter as well. Hindleg waving displays also have been observed during aggressive encounters in *Phyllomedusa sauvagii,* but this species does not call near noisy streams (Halloy and Espinoza 1999–2000). Males of a recently described dendrobatid frog from Amazonian Brazil, *Colostethus caeruleodactylus,* develop bright blue toes during the breeding season, but obvious displays of these markings during aggression and courtship have not been reported (Lima and Caldwell 2001; Lima, Caldwell, and Biavati 2002).

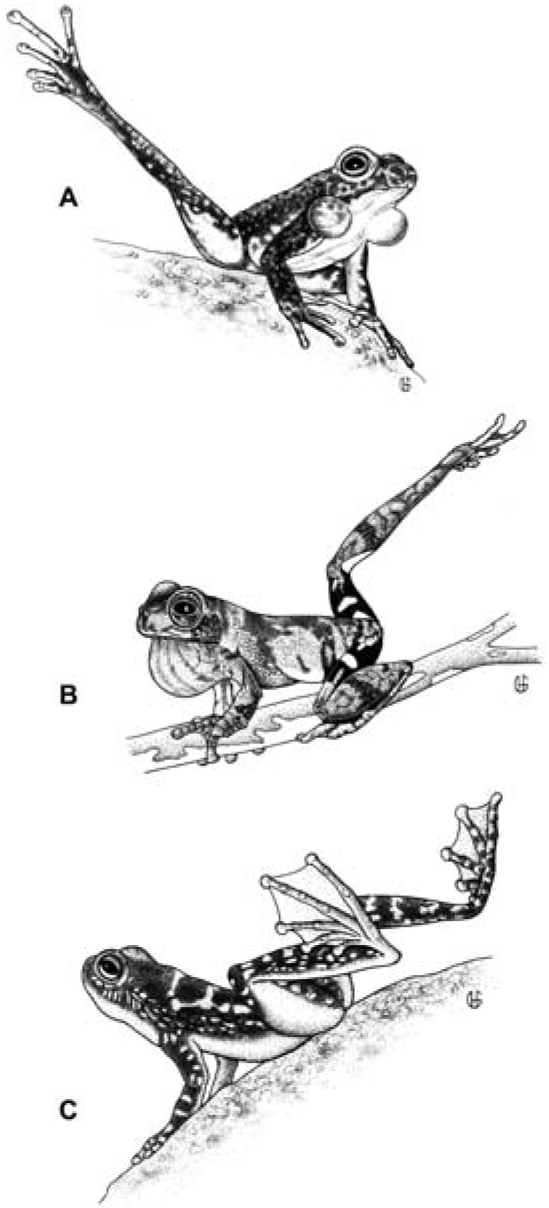

Fig. 8.16. Convergent evolution of foot-flagging displays in three species of stream-breeding frogs. (A) *Hylodes asper,* a Brazilian frog that breeds in torrential streams. (B) *Hyla parviceps,* a stream-breeding frog from Venezuela. (C) *Staurois latopalmatus,* a ranid frog that calls from boulders in streams in Borneo. After Hödl and Amézquita (2001); original drawings by H. C. Grillitsch.

Many species of frogs display brightly colored patches on the throat during territorial encounters (Test 1954; Sexton 1960; Emlen 1968; Wiewandt 1969; Durant and Dole 1975; Wells 1978b, 1980a; M. Ryan 1980b). In *Allobates femoralis,* pulsations of the vocal sac are an important component of aggressive displays. Models that were manipulated to pulsate the vocal sac during call playbacks elicited more aggressive responses from territorial males than did acoustic playbacks alone or silent throat movements (Narins, Hödl, and Grabul 2003; Narins et al. 2005). Even in species without distinctly colored vocal sacs, movements of the vocal sac may serve as a visual signal to other males or to females searching for mates (Rosenthal, Rand, and Ryan 2004). In at least two species of dendrobatid frogs, *Colostethus palmatus* and *Mannoprhyne trinitatis,* calling males turn completely black and are aggressive mainly toward other black males (fig. 8.14 D). Males signal submission by turning brown (Lüddecke 1974, 1976, 1999; Wells 1980c).

Seidel (1999) described an unusual form of territorial display in *Bombina variegata.* In the population that he studied in Austria, choruses have a leklike spatial organization, but males employ a variety of tactics to acquire mates. Large males defended small territories in open water, which they advertised by calling and by producing waves on the surface of the water. They produced the waves by rhythmically striking the surface of the water with their hind legs, sending a series of concentric waves radiating outward. These appeared to demarcate territories that were largely avoided by other males. Smaller males usually did not defend such territories, but engaged in scramble competition for females.

Fighting Behavior

When vocalizations and displays are ineffective in repelling intruders into territories, male anurans often resort to overt aggression. Physical encounters take a variety of forms, including jumping on opponents, attempting to push opponents off of elevated perches, grappling with the forelimbs, or wrestling with the forelimbs interlocked (fig. 8.12–8.14; Tunner 1976; Wells 1977b, 1978b, b, 1980a, c, 1981b; R. D. Howard 1978a; Fellers 1979a; M. Ryan 1980b; Cardoso 1981b; Weygoldt 1981a; H. Zimmermann and E. Zimmermann 1981, 1984, 1988, 1990; B. K. Sullivan 1982a; Telford 1985; Arak 1983b; Cardoso and Haddad 1984; Akef and Schneider 1985; Robertson 1986b; Crump 1988; Given 1988b; Dyson 1989; Summers 1989, 1990, 1992; Roithmair 1992, 1994; Forester, Cover, and Wisnieski 1993; Baugh and Forester 1994; Halliday and Tejedo 1995; Rödel 1996; Orlov 1997; Summers and Amos 1997; Bolívar-G., Grant, and Osorio 1999; Halloy and Espinoza 1999–2000; Rodrigues, de Souza, and Filho 2003; Wogel, Abrunhosa, and Pombal 2004). In *Atelopus varius,* most fights include a peculiar squashing behavior in which one frog jumps on an opponent's back and presses him to the ground (Crump 1988). This resembles the wrestling behavior of several dendrobatid species, including *Colostethus panamensis* (fig. 8.13 C; Wells 1980a).

Fig. 8.17. Skull of a male fanged frog of the genus *Limnonectes* from Borneo, showing sharp fangs used in fighting with other males. Photo by Kerry Matz, courtesy of Sharon Emerson.

More violent aggression occurs as well, including biting (Rabb and Rabb 1963b; Brattstrom and Yarnell 1968; Weygoldt 1981a; Giddings 1984; Townsend, Stewart, and Pough 1984; Katsikaros and Shine 1997). Some frogs have fangs or tusks on their jaws that are used in intraspecific combat (Fabrezi and Emerson 2003). These include the Australian myobatrachid frog *Atelotus brevis* (Katsikaros and Shine 1997) and a group of fanged frogs in the genus *Limnonectes* (fig. 8.17) from Southeast Asia (Emerson 1994, 1996; Emerson and Voris 1992; Emerson and Inger 1992).

Some frogs have spines on the chest or forelimbs that are used to stab or slash opponents in fights. The latter has been studied most thoroughly in the nest-building gladiator frogs, including *Hyla faber, H. pardalis,* and *H. rosenbergi* (Lutz 1960b, 1973; Kluge 1981; Martins and Haddad 1988; Martins, Pombal, and Haddad 1998). In these species, males have a curved, sharp prepollical spine on each front foot, which is used to slash opponents during prolonged wrestling bouts (fig. 8.12 C). Males are frequently injured in fights, sometimes fatally (Kluge 1981). Similar spines are found on the forelimbs of males in several species of *Leptodactylus* and in several other families of anurans (Shine 1979), often associated with other sexually dimorphic characters such as enlarged forelimbs (see "Sexual Dimorphism," following). Probably such structures are used in fighting, but the social behavior of most species is unknown. Males of centrolenid frogs in the genus *Centrolene* have humeral spines on their forelimbs that often are very sharp. In at least one species, *C. buckleyi,* males suffered injuries after grappling with other males, and injuries that could have been inflicted by these spines have been observed in other species as well (Bolívar-G., Grant, and Osorio 1999).

Male Behavior and Mating Success in Prolonged-Breeding Anurans

Competition between Males

Most of the literature on aggressive interactions of anurans is still relatively descriptive. Only a few investigators have attempted to measure the factors that determine the winners of contests. In territorial species, encounters usually are won by larger individuals or by residents of territories, a pattern found in most territorial animals (R. D. Howard 1978a; Wells 1978b; 1980a; Kluge 1981; Robertson 1986b; Given 1987, 1988b; Crump 1988; Dyson 1989; Pröhl and Hödl 1999; Seidel 1999; Shimoyama 1999; Pröhl and Berke 2001; Toledo and Haddad 2005). In *Rana clamitans,* an intruder had virtually no chance of evicting a resident unless the intruder was considerably larger (Wells 1978b). Contests were more likely to be escalated when intruders were at least as large as resident males. Otherwise intruders were chased away after a few seconds. In *R. virgatipes,* residents won most interactions. Body size was more important in determining the winner when contests were escalated to physical fights rather than being settled by exchanges of aggressive calls (Given 1988b). Again, escalated fights were more likely to occur when males were relatively evenly matched in size, a trend also reported in *Uperoleia laevigata* by Robertson (1986b). In that species, large males won most contests settled either by vocal interactions or escalated fights. Large males also won more fights in *Bufo woodhousii* (B. K. Sullivan 1982b) and *B. calamita* (Arak 1983b), both of which defend calling sites, but not oviposition sites. In a territorial dendrobatid frog, *Dendrobates pumilio,* there often is little variation in body size among males in a population. Levels of aggression and the outcome of fights in this species are affected by prior residence in a territory, by the length of time a male has been in his territory, and by relative territory quality (Forester, Cover, and Wisnieski 993; Baugh and Forester 1994; Prohl and Hödl 1999). All of these are variables that commonly influence the outcome of fights in other territorial animals.

It seems likely that most aggressive interactions among male frogs are settled by exchanges of vocal signals (chapter 7). This is particularly true of lek-breeding species that do not defend oviposition sites. In many such species, escalated contests are rare compared to those seen in frogs such as *Rana clamitans* and *R. catesbeiana.* In species such as *Hyla versicolor,* for example, males give aggressive calls in response to other males calling nearby, but only occasionally attack another male (Fellers 1979a; Wells, personal observations). Physical aggression seems to be somewhat more frequent in hylids that form very dense choruses, such as *Hyla ebraccata* and *H. microcephala,* but even in these species, most contests are settled with aggressive calling (Wells and Schwartz 1984b; Schwartz and Wells 1985). There is evidence for several species that males can use the pitch of the advertisement call to assess the body size of opponents (N. Davies and Halliday 1978; Arak 1983b; Ramer, Jenssen, and Hurst 1983; Robertson 1986b; Given 1987; Bee and Perrill 1996; Bee, Perrill, and Owen 1999, 2000). Presumably they could do so from aggressive calls as well, and this could have a major effect on the outcome of aggressive encounters (see chapter 7 for a more detailed discussion of aggressive calling).

Despite the fact that large males are likely to win most fights over territories, the largest males in a population do not necessarily achieve the highest mating success. In *Rana clamitans* and *R. catesbeiana,* for example, large males generally were more successful than small males in defending high-quality territories and in obtaining mates, but the correlation between male size and mating success in different years varied from weak to very strong (Wells 1977c; R. D. Howard 1978a, 1981a, 1983). Mating success was more a function of territory quality than male size per se (see the following discussion of female choice). Nevertheless, if females choose good territories, and the largest males occupy the best territories, then this will result in indirect selection for large body size in males.

Large body size probably provides an advantage to males in many other species that defend resource-based territories, even if only indirectly, through female choice based on territory quality. This was true for *Rana virgatipes* (Given 1988b), *Atelotus brevis* (Katsikaros and Shine 1997), and *Limnonectes kuhlii* from Taiwan (Tsuji 2004). On the other hand, large males did not enjoy a mating advantage in the nest-building frog *Hyla rosenbergi* (Kluge 1981). The range of body sizes of males actively defending nests was relatively small for such a large frog, and Kluge (1981) suggested that the lack of effect of body size on mating success might have been due to an inability of females to clearly distinguish between large and small males. Mating success also was not related to body size in two species of centrolenids that defend oviposition sites, *Hyalinobatrachium fleischmanni* (Greer and Wells 1980; Jacobson 1985), and *Centrolene prosoblepon* (Jacobson 1985), or in *Dendrobates pumilio* (Pröhl and Hödl 1999; Pröhl 2003). In all of these species, the range of body sizes of males in the population was relatively small. A large-male mating advantage has been reported in a number of other species, including *Physalaemus* *pustulosus* (M. Ryan 1980a, 1983b), *Bufo calamita* (Arak 1983b), some populations of *Bufo woodhousii* (Woodward 1982b, c), *Hyla arborea* (Márquez-M. de Orense and Tejedo-Madueno 1990), and *Hyla elegans* (Bastos and Haddad 1996). These species have lek mating systems, but do not defend resource-based territories.

In many lek-breeding anurans, large males do not consistently have a mating advantage over small males. This was the case for *Hyla cinerea* (Gerhardt 1982; Gerhardt et al. 1987), *H. versicolor* (Fellers 1979b), *H. chrysoscelis* (Godwin and Roble 1983), *H. gratiosa* (C. Murphy 1994b), *H. ebraccata* (except for one year; M. Morris 1991), *H. labialis* (Lüddecke 2001; Gutiérrez and Lüddecke 2002), *Pseudacris regilla* (Perrill 1984), some populations of *Bufo woodhousii* (B. K. Sullivan 1982b, 1983b, 1987), *Bufo rangeri* (Cherry 1993), *Bufo verrucossisimus* (Tarkhnishvili 1994), *Bombina variegata* (Barandun 1990), *Hyperolius marmoratus* (Passmore and Telford 1983; Telford and Dyson 1988; Dyson et al. 1992; Dyson, Bush, and Halliday 1998), *Chiromantis xerampelina* (Jennions, Backwell, and Passmore 1992), and *Polypedates leucomystax* (Arak 1988b). In some cases, this was simply due to a very narrow range of body sizes in the male population, but in others, body size had little effect on mating success, despite significant size variation among males.

There is only limited evidence for size assortative mating in anurans with prolonged breeding seasons. R. D. Howard (1981a, 1983, 1988a) found a weak positive correlation between sizes of males and females in mated bullfrog (*Rana catesbeiana*) pairs in two of three years, and Katsikaros and Shine (1997) reported a similar relationship for *Atelotus brevis*. Positive assortative mating also was reported for a population of *Hyla arborea* (Márquez-M. de Orense and Tejedo-Madueno 1990) and on some nights for *H. labialis* (Lüddecke 2001; Gutiérrez and Lüddecke 2002). Robertson (1986a) reported a positive correlation between the mass of male and female *Uperoleia laevigata* in amplexus, even though body lengths were not correlated. In general, the body mass of paired males was about 70% of the body mass of their mates. Robertson originally speculated that females might use body mass as an indicator of male physical condition, but he later showed that females with mates about 70% of their own body mass had the highest rate of fertilization of eggs (Robertson 1990). He suggested that larger males hampered the females in their oviposition behavior, whereas smaller males might have had insufficient sperm reserves. The relative sizes of males and females are reported to affect fertilization success in several other species as well, including *Scinax rubra* (Bourne 1993), *Hyla elegans* (Bastos and Haddad 1996), and *H. labialis* (Gutiérrez and Lüddecke 2002). Two studies of *Hyperolius marmoratus,* on the other hand, showed no evidence of assortative mating or any effect of relative male and female size on fertilization success (Dyson et al. 1992; Grafe 1997a), and there is little evidence for assortative mating in most other frogs. Another possibility is that larger females prefer larger males because the frequency to which their ears are tuned decreases as they grow, so large males with low-frequency calls are likely to be heard better by large females (Márquez-M. de Orense and Tejedo-Madueno 1990).

Chorus Tenure

In anurans with prolonged breeding seasons, receptive females often arrive asynchronously over a period of several weeks or months. Consequently, males present on many nights are more likely to encounter females than are those that are present on only a few nights (Halliday and Tejedo 1995). A positive correlation between duration of male attendance and mating success has been reported for many species, including *Bufo calamita* (Arak 1983b, 1988b; Denton and Beebee 1993a), *Bufo fowleri* (Given 2002), *B. gutteralis* (Telford and van Sickle 1989), *B. rangeri* (Cherry 1993), *B. woodhousii* (Woodward 1982b), *Hyalinobatrachium fleischmanni* (Greer and Wells 1980; Clark 1981; Jacobson 1985), *Centrolene prosoblepon* (Jacobson 1985), *Physalaemus pustulosus* (M. Ryan 1980a, 1983b, 1985b), *Eleutherodactylus coqui* (Townsend and Stewart 1994), *Hyla rosenbergi* (Kluge 1981), *H. chrysoscelis* (Godwin and Roble 1983; Ritke and Semlitsch 1991), *H. cinerea* (Gerhardt et al. 1987), *Hyla faber* (Martins 1993a), *H. gratiosa* (C. Murphy 1994a, b), *H. versicolor* (B. K. Sullivan and Hinshaw, 1992; Bertram, Berrill, and Nol 1996), *Epipedobates trivittatus* (Roithmair 1994), *Hyperolius marmoratus* (Dyson et al. 1992), *Chiromantis xerampelina* (Jennions, Backwell, and Passmore 1992), *Buergeria buergeri* (Fukuyama and Kusano 1989), *Rana catesbeiana* (R. D. Howard 1978a) *R. clamitans* (Wells 1977c), *R. virgatipes* (Given 1988a, b), and *Limnonectes kuhlii* (Tsuji 2004). In a few studies, male chorus tenure was not correlated with mating success, or was positively correlated with mating success in only some years of the study (Fellers 1979b; B. K. Sullivan 1987; M. Morris 1989).

Male chorus tenure often explains a large fraction of the total variation in male mating success. This reduces the amount of variation to be explained by mechanisms of male-male competition and female choice, and makes identification of other determinants of mating success difficult without large sample sizes. The causes of individual differences in chorus tenure are not fully understood. Two factors that seem most important are depletion of energy reserves (Wells 1978b; Mac Nally 1981; Godwin and Roble 1983; A. Green 1990; C. Murphy 1994a, b; Dyson et al. 1998; Eggert and Guyétant 2003; see also chapter 5) and death due to predation (R. D. Howard 1978a; M. Ryan, Tuttle, and Rand

1982; M. Ryan 1985b, 1988b; Pough et al. 1992). In some studies, large males had longer chorus tenure than small males, perhaps because they have lower mass-specific metabolic rates and larger energy reserves, and this can lead to a positive correlation between body size and mating success, independent of competitive interactions among males (Tejedo 1992c; Tsuji 2004). In other studies, there was not a correlation between body size and chorus tenure (Halliday and Tejedo 1995). In *Pelobates fuscus,* younger males remained in the chorus longer than did older males (Eggert and Guyétant 2003). This could be a result of older males obtaining mates more quickly and then leaving the chorus, or younger males employing mating tactics that require less expenditure of energy.

C. Murphy (1994a, b) found a strong correlation between chorus attendance and male mating success in *Hyla gratiosa* over several years (fig. 8.18). Variation in chorus attendance appeared to be in part to variation in energy reserves of males in the chorus. Males suffered reductions in body mass throughout their time in a chorus, but those that remained longer in the chorus were in better condition and lost mass more slowly than those that were present for only a few nights (see chapter 5 for a more detailed discussion of this work).

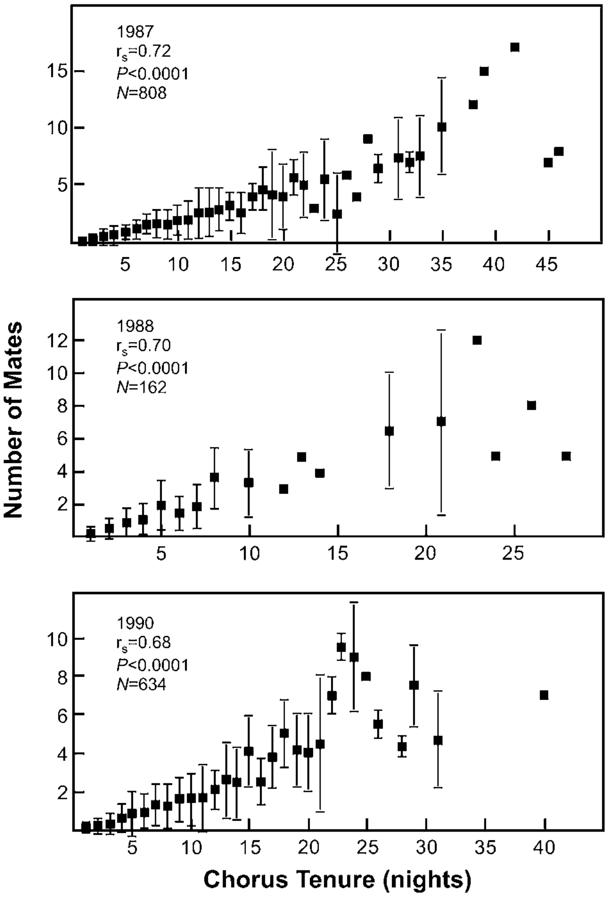

Fig. 8.18. Relationship of chorus attendance by male *Hyla gratiosa* to male mating success in three breeding seasons. In all three years, chorus tenure accounted for a substantial proportion of variation in male mating success. After C. Murphy (1994b).

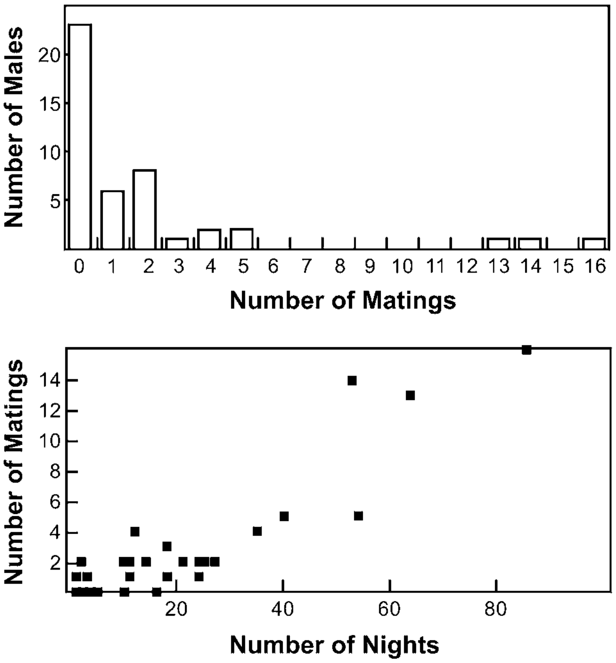

Fig. 8.19. Mating success and chorus attendance in an African frog, *Hyperolius marmoratus.* (Top) Variation in number of matings in a chorus of 45 males during a breeding season lasting 167 nights. (Bottom) Relationship of male mating success to male chorus attendance. Successful males spent more time in the chorus than did unsuccessful males, and this was especially true for three males with very high mating success. After Dyson, Henzi, Halliday, and Barrett (1998).

Dyson, Bush, and Halliday (1998) monitored the chorus attendance of a small population (45 males) of *Hyperolius marmoratus* for 167 days at a natural pond in South Africa. Chorus tenure of individual males was extremely variable (1–86 nights), but the median was low (five nights). Eighty-six females mated in the chorus, but mating success of males was unevenly distributed. More than half the males did not mate at all, but some mated as many as 16 times (fig. 8.19 top). Male mating success was strongly correlated with number of nights that males were present in the chorus (fig. 8.19 bottom). Furthermore, a male that mated on one night was twice as likely to mate on the next night as a male that had not mated previously. In this species, most matings occur within the first 1.5 hours of a chorus. Males that acquire mates typically call for much shorter periods and produce about a third the number of calls produced by males that do not mate (Passmore, Bishop, and Caithness 1992). Because the cost of calling in this species is very high (Grafe 1996b), this reduction in total calling effort could result in substantial energy savings, thereby prolonging a male's stay in a chorus and increasing his chances of acquiring additional mates.

It seems unlikely that this explanation can account for the very long chorus attendance (50–86 nights) of the few males that mated many times (13–16 mates; fig. 8.19). The disproportionate success of these few males could have been related to other factors, such as superior foraging ability or behavioral attributes such as calling rate that were not measured in the study.

Plasticity in Anuran Mating Systems

The discussion of mating systems so far has focused on relatively discrete categories of mating systems, including scramble competition, leks, and resource defense. In fact, it has become clear that mating systems of anurans often are quite variable, both within and between populations. Within breeding aggregations, males sometimes shift between calling and searching tactics as a function of chorus density. They also shift the location of searching activity as a function of body size, or alternate between calling and satellite behavior. In addition, some species of anurans have mating systems that combine elements of active searching and territorial behavior. The result is a tendency for scramble competition in high-density choruses to grade into leklike behavior at lower densities, with leklike mating systems in turn grading into resource defense as densities decrease even further. Similar density-dependent shifts from scramble competition to lek behavior to resource defense have been reported in other vertebrates (Langbein and Thirgood 1989; Balmford et al. 1993; Thirgood, Langbein, and Putnam 1999). In addition, some reptiles, birds, and mammals have mixed mating systems within a single population, with some males visiting leks while others defend isolated territories (Gosling 1986; Gosling and Petrie 1990; Wikelski, Carbone, and Trillmich 1996; Lanctot and Weatherhead 1997). Satellite behavior and other alternative mating tactics are common in other vertebrates as well (Andersson 1994).

Density-Dependent Shifts between Searching and Calling

The tactics used by males to acquire mates in explosive mating aggregations often vary with male density (Wells 1977b; Arak 1983a; Olson, Blaustein, and O'Hara 1986; R. D. Howard 1988b; B. K. Sullivan 1989a, 1992; Wagner and Sullivan 1992). In very dense choruses, males devote more of their time to active searching and attempting to displace other males from amplexus than they do to calling. They move over relatively large areas in search of females, but searching sometimes becomes concentrated around a communal oviposition site (fig. 8.10 A) as the breeding period progresses (Blankenhorn 1974; N. Davies and Halliday 1979; R. D. Howard 1980; Ryser 1989a). At low densities, males often abandon searching altogether and switch to stationary calling. This reduces the amount of direct competition among males for individual females and provides more opportunities for females to select their mates (Wells 1977b). Density-dependent shifts in male behavior are apparent in comparisons between species, between populations of the same species, or between years in the same population.

Kagarise Sherman (1980) studied the effects of male density on the behavior of *Bufo canorus* by making observations of focal animals. Within years, male density was negatively correlated with individual calling rate and the proportion of time that individuals spent calling. Frequency of movement and frequency of clasping attempts were positively correlated with male density, and males also tended to move farther in a given period of time as density increased. Hence, males clearly shifted from active searching to stationary calling as density decreased. Similar differences were apparent in comparisons between years. A comparison of choruses of *B. canorus* and *B. exsul* revealed that the latter always had higher density aggregations and showed a greater tendency to locate mates by active searching.

A density-dependent shift from searching to calling also has been observed in *Bufo bufo*. This species lacks a vocal sac, and in dense choruses, males seldom call (Heusser 1969a). In a low-density chorus, however, some males remained stationary and called to attract females (Höglund and Robertson 1988). The proportion of males calling increased as density decreased. Other toads that exhibit density-dependent changes in mate-locating tactics include *Bufo americanus* (B. K. Sullivan 1992), *B. woodhousii* (B. K. Sullivan 1986b), *B. cognatus* (L. E. Brown and Pierce 1967; B. K. Sullivan 1982a, 1983a; Krupa 1989, 1994), and *B. valliceps* (Wagner and Sullivan 1992). Similar changes in behavior were reported for wood frogs (*Rana sylvatica*) by Woolbright, Greene, and Rapp (1990). This species normally breeds in dense choruses with very active searching by males (R. D. Howard 1980; Berven 1981; R. D. Howard and Kluge 1985). In the low-density chorus studied by Woolbright et al., males spent less time searching and more time calling than in more typical wood frog choruses. Experimental reduction of male density resulted in even less searching and more calling.

Density-dependent shifts between calling and searching are less common in species with longer breeding periods, probably because densities seldom reach levels seen in explosive mating aggregations. Nevertheless, I have seen males of *Hyla versicolor* swimming about on the surface of a pond searching for mates when densities were very high, even though they normally call from fixed locations. A shift to active searching at high densities has been reported for several toads with relatively long breeding periods, including *Bufo calamita* (Arak 1988c) and *Bufo valliceps*

(Wagner and Sullivan 1992). In *Rana porosa,* an inhabitant of rice fields that has a long summer breeding season, males shift from defense of individual territories at low densities to active searching and attempts to displace males from amplexus at high densities (Shimoyama 1989). The European agile frog (*Rana dalmatina*) also shows some plasticity in behavior. This species has a relatively short, early spring breeding season, with elements of both scramble competition and lek behavior. At low densities, most males call and sometimes defend calling sites as territories, but as a densities increase, many males stop calling and apparently shift to satellite behavior. It is during these periods of highest male density that multiple paternity of egg clutches is most likely to occur, although it is not clear how fertilization by multiple males is achieved (Lodé, Holveck, and Lesbarrères 2005).

Size-Dependent Variation in Searching Behavior

Males also vary in where they choose to search for mates. This was first studied in *Bufo bufo* by N. Davies and Halliday (1979), who found that males searched either at the spawning site or around the periphery of the breeding area, distributing themselves so that the probability of mating was approximately equal. Males on the periphery were able to intercept females early and suffered less competition from other males. However, when the pairs moved to the spawning site, small males suffered an increased probability of being displaced by males searching there. Large males are more likely than small males to do well in areas where competition for females is intense (Arak 1983a; Loman and Madsen 1986). In *Rana temporaria,* small males tended to search for mates around the edges of a pond or on land, whereas larger individuals were more likely to search at the spawning site (Arak 1983a; Ryser 1989a). In a population of *Bufo americanus* with a somewhat longer breeding period, small males tended to search for females on land around the breeding pond, and they intercepted 70% of the females approaching the pond (Forester and Thompson 1998). Nearly two-thirds of these males remained paired with females after an hour, even though larger males often tried to displace them once they reached the pond, indicating the advantage of being the first male to clasp a female. These mating tactics are by no means fixed; both large and small males were observed to switch mate-locating tactics in all of these studies.

Gradation between Scramble Competition and Lek Behavior

In some anurans with relatively short breeding seasons, males engage in active searching behavior, but restrict their searching to a relatively small area, resulting in some degree of spatial organization within an aggregation (e.g., *Rana aurora:* Calef 1973b; *R. esculenta:* Wahl 1969; *R. temporaria:* Elmberg 1986; *Bufo boreas:* Black and Brunson 1971; *B. regularis:* Tandy and Keith 1972; *Pelobates fuscus:* Eibl-Eibesfeldt 1956; *Discoglossus pictus:* Knoeppffler 1962; Weber 1974; *Bombina bombina* and *B. variegata:* Heusser 1961; Lörcher 1969; *Bombina orientalis:* Akef and Schneider 1985; *Pyxicephalus adspersus:* Channing, du Preez, and Passmore 1994). Males sometimes defend a small area around themselves, but they usually do not defend permanent territories. Such aggregations have a spatial organization similar to that of a lek (fig. 8.10 D, E), but females often are intercepted by searching males, or have their initial mates displaced by larger males. This leaves females with few opportunities to mate with males of their own choosing (Wahl 1969; Blankenhorn 1974, 1977; Tunner 1976; Kagarise Sherman 1980; Klöckner 1982; B. K. Sullivan 1982b; Radwan and Schneider 1988; Channing, du Preez, and Passmore 1994; Bergen, Semlitsch, and Reyer 1997).

The tendency for scramble competition to grade into lek-like behavior is illustrated by the behavior of the Neotropical hylid frog *Scinax rubra.* Bourne (1992) studied this species in Guyana and characterized its mating system as a lek, but in contrast to the relatively continuous breeding patterns of most lekking anurans, this species breeds in a series of explosive mating aggregations after especially heavy rains (Bourne 1992; Bevier 1997a). Males call for many hours on peak nights of breeding and defend small areas around their calling sites with aggressive vocalizations. Yet males also tend to move frequently while calling, especially small individuals (Bourne 1992; Wells, personal observations). Females move through the chorus and attempt to choose mates, but sometimes are intercepted by noncalling satellite males. More than two-thirds of the matings observed by Bourne (1992) resulted from large males displacing other individuals from amplexus. Hence, any possible advantage to females in choosing particular males as mates often is thwarted by direct competition among males for possession of females (Bourne 1993). While the spatial organization of choruses in this species resembles a lek mating system, the mating tactics used by males are similar to those of many other explosive-breeding frogs.

The African bullfrog (*Pyxicephalus adspersus*), another species that breeds only after heavy rains, has a somewhat similar mating system, but males are much more aggressive toward one another than are males of *Scinax rubra.* Males defend small territories around themselves in a densely packed chorus by attacking and even biting other males (B. Balinsky and Balinsky 1954; Grobler 1972; Picker 1983). The mating system has been described as a lek (Channing, du Preez, and Passmore 1994), but females arriving in the chorus often are chased by several males until one achieves amplexus, so females probably have few opportunities to choose their mates.

Another mating system that combines characteristics of both scramble competition and lek behavior is that of the water frogs of Europe (fig. 8.10 C). The edible frog, *Rana esculenta,* is a hybrid originally produced by matings between *R. lessonae* and *R. ridibunda* (Berger 1977; Graf and Polls Pelaz 1989; Hellriegel and Reyer 2000; see also chapter 7). Matings between male and female *R. esculenta* produce nonviable or sterile offspring with the *R. ridibunda* phenotype. Hybrids therefore must mate with individuals of one of the parent species to reproduce. Most populations of *R. esculenta* are maintained by this hybridogenetic mode of reproduction. Most commonly hybrids are found in mixed populations with *R. lessonae.* The latter predominates in the ancestral breeding areas for this species, such as pools in marshes and forests, whereas *R. esculenta* tends to be more common in disturbed areas such as gravel pits. These frogs can be active at breeding sites for a month or more, but peaks of mating activity often last only a few days. Males gather on display arenas, sometimes at densities up to 25 males per square meter. They establish small territories and constantly jockey for position in the chorus, using both aggressive calls and physical attacks (Wahl 1969; Blankenhorn 1974, 1977; Klöckner 1982; Radwan and Schneider 1988).

Females swim among the calling males, but often are clasped by searching males. Males sometimes attempt to displace other individuals from amplexus. Females of both phenotypes are expected to prefer to mate with *R. lessonae* males. *Rana lessonae* females should do so because they are conspecifics, whereas *R. esculenta* females should do so because only matings with *R. lessonae* males can produce viable offspring. Females apparently are not able to assess the relative densities of the two male phenotypes from long-distance acoustic cues emanating from choruses, but both *R. lessonae* and *R. esculenta* females are attracted to the calls of individual *R. lessonae* males (Roesli and Reyer 2000). When *R. esculenta* females were given a choice of male phenotypes in situations where male-male competition was prevented, they preferred *R. lessonae* males (Abt and Reyer 1993). In a competitive situation with different numbers of the two types of males, however, females mated with them in proportion to their occurrence, suggesting that male-male competition nullifies any preference for *R. lessonae* males (Bergen, Semlitsch, and Reyer 1997). Nevertheless, there is evidence of "cryptic female choice" in this system, because females that were seized by *R. esculenta* males released fewer eggs than did those seized by *R. lessonae* males (Reyer, Frei, and Som 1999). Some females subsequently laid the remainder of their egg clutches later in the same season, but most females apparently resorbed unlaid eggs, thereby improving their body condition and increasing reproductive success the following year. Males are indiscriminant in their choice of mates when presented with parental and hybrid females, at least in laboratory experiments, so *R. lessonae* males often end up mating with hybridogenetic females, even though they do not derive any genetic benefit from such matings (Engeler and Reyer 2001).

Several workers who have studied this system have reported that *R. esculenta* males are more aggressive toward other males than are the *R. lessonae* males. The latter mostly engage in searching behavior and attempts to clasp other frogs (Blankenhorn 1974, 1977; Klöckner 1982; Radwan and Schneider 1988; Abt and Reyer 1993; Bergen, Semlitsch, and Reyer 1997). Blankenhorn (1977) reported that the largest *R. esculenta* males were so aggressive that they did relatively poorly in acquiring mates, even though they outnumbered the *R. lessonae* males, but Bergen, Semlitsch, and Reyer (1997) concluded that the more aggressive males actually enjoyed a mating advantage in mixed populations. A possible explanation for the greater aggressiveness of *R. esculenta* males is the hybrid origin of this phenotype. These frogs are intermediate between the two parental species in morphology (Berger 1977; Schneider and Brzoska 1981; Brzoska 1982; Schneider and Joermann 1988). Patterns of aggressive and sexual behavior are likely to have a genetic basis and to be intermediate between that of the two parental species. *Rana lessonae* males appear to have a typical scramble competition mating system, with little aggression among males and much searching for females. *Rana ridibunda,* on the other hand, is a prolonged breeder, and appears to have a lek or resource-defense mating system (M. Smith 1969; Heym 1974; Frazer 1983; Kuhn and Schneider, 1984; Schneider and Joermann 1988; Kyriakopoulou-Sklavounou and Kattoulas 1990). Males are aggressively territorial and have a variety of aggressive calls. The peculiarly aggressive behavior of *R. esculenta* males could result from their behavior combining elements of two parental species that have different mating tactics.

Gradation between Lek Behavior and Resource Defense

There is some evidence that pond-breeding ranids that normally defend resource-based territories shift to lek behavior when choruses are unusually dense. This could be the reason for the leklike spatial organization of choruses of Asian frogs that breed in rice fields, where frogs tend to be very abundant. Emlen (1976) originally described the mating system of a dense population of bullfrogs (*Rana catesbeiana*) in Michigan as a lek. Males defended closely packed territories in well-defined choruses that changed position throughout the summer. Emlen observed three females in amplexus that left the chorus before laying eggs, and five of six egg masses that he found were outside the chorus area.

Subsequent work by R. D. Howard (1978a) on the same population in years when population densities were somewhat lower revealed that most egg masses were deposited in the territories of males, and he concluded that these frogs have a resource-defense mating system. However, it is possible that the conflicting results of these studies reflect a density-dependent shift in mating tactics.

In my study of green frogs (*Rana clamitans*), some males abandoned territories along the shore of a pond during dry weather and formed a chorus with males much closer together near the center of the pond, suggesting a shift to leklike behavior (Wells 1977c). The chorus broke up after heavy rain raised water levels in the pond, so I was not able to observe any mating behavior. Some European ranids seem to shift from defense of individual territories to lek behavior or even active searching at high densities, and some also exhibit seasonal shifts in spatial organization (Radwan and Schneider 1988; Kyriakopoulou-Sklavounou and Kattoulas 1990). This sort of intraspecific variation in mating systems needs to be investigated more thoroughly in anurans.

Satellite Behavior

In addition to population-level shifts in the structure of the mating system, individual males also adopt alternative mating tactics within a chorus. Often this involves some males adopting a satellite role and parasitizing the calling efforts of other males. Such behavior is common in many other vertebrates and invertebrates, and there is a large theoretical and empirical literature on alternative mating tactics (Dawkins 1980; Rubenstein 1980; Waltz 1982; Austad 1984; Dominey 1984; Waltz and Wolf 1984). Alternative mating tactics can be expressions of a conditional strategy in which disadvantaged males adopt less preferred mating tactics. They also can represent mixed evolutionarily stable strategies, in which different males adopt different tactics that yield roughly equal payoffs in mating success (Arak 1983a; Gardner, Morris, and Nelson 1987; Lucas and Howard 1995; Lucas, Howard, and Palmer 1996; McCauley et al. 2000).

Explosive Breeders

Satellite behavior in explosive-breeding anurans is somewhat similar to the shift between calling and searching discussed earlier, except that satellite males tend to focus their search for mates around particular calling males instead of particular parts of the breeding site (Leary et al. 2004). Again, this appears to be largely a density-dependent phenomenon, occurring mostly at intermediate densities as males shift between calling and searching tactics. Although satellite males sometimes are smaller than callers, this is not always true (Kagarise Sherman 1980; Krupa 1989), and switching between calling and satellite roles probably is common. In *Bufo cognatus,* satellite males tend to be smaller than calling males, although not necessarily younger (Krupa 1989; Leary et al. 2005), and they were most likely to gather around large males that had long calls. In this species, the satellite tactic was clearly inferior to calling, with more than 90% of all matings going to calling males. Satellite males also were smaller, but not younger, in explosive-breeding populations of *Bufo woodhousii* in Oklahoma (Leary et al. 2005). In both of these species, individuals that experience slow growth early in life appear to be more likely to adopt a satellite tactic than do faster-growing males.

Prolonged Breeders

Satellite behavior is much more common in prolonged breeders with leklike or resource-defense mating systems than in explosive-breeding anurans. Such behavior represents either a mixed evolutionarily stable strategy or a conditional strategy adopted by smaller, younger, or weaker males excluded from choice calling sites (Gardner, Morris, and Nelson 1987; Halliday and Tejedo 1995). Large size differences between territorial and satellite males appear to be most common in anurans with resource defense mating systems. In *Rana clamitans* and *R. catesbeiana,* for example, satellite males often are considerably smaller and younger than territorial residents (fig. 8.20; Wells 1977c, 1978b; R. D. Howard 1978a, 1981a, 1984). In bullfrogs, satellite males sometimes intercept females approaching territorial males, but the mating success of satellite males is relatively low, probably accounting for less than 20% of all matings in the population (R. D. Howard 1978a, 1981a). Satellite males probably also intercept females occasionally in *R. clamitans,* although it has not yet been observed (Wells 1977c, 1978a). In both species males are opportunistic, and readily abandon the satellite role and occupy territories deserted by other males. Young male bullfrogs also attempt to set up territories in areas not occupied by larger males, but quickly abandon them if challenged (R. D. Howard 1981a 1984). Similarly, in *R. virgatipes,* smaller males sometimes assume satellite roles and sometimes are territorial, but quickly retreat when challenged by a larger male or when they are presented with recordings of large male calls. Large males in turn give more aggressive responses when presented with the calls of small males (Given 1987). Small males also adopted satellite tactics in the Asian fanged frog *Limnonectes kuhlii,* and a few succeeded in acquiring mates (Tsuji 2004).

Satellite males have been observed in several species of prolonged-breeding toads (Wells 1977b; Arak 1988c). In most cases, satellites are somewhat smaller than calling males, but quantitative data are scarce. In *Bufo calamita,* three or four individuals often sit near one another in a group, with the largest male calling most of the time and the

Fig. 8.20. Satellite behavior in frogs with resource defense mating systems. (A) A green frog (*Rana clamitans*) satellite male in low posture next to a territorial resident in inflated high posture. (B) A large male bullfrog (*Rana catesbeiana*) accompanied by a much smaller satellite male. This male sometimes had as many as three satellites around him at the same time. Photos by Kentwood D. Wells.

others acting as satellites. When large calling males were removed, the smaller satellite males generally dispersed. Removal of satellite males had no effect on the behavior of other males in the group. When calls were played through a speaker, small males often adopted satellite roles around the speaker, but large males were more likely to move away from the speaker. Satellite males in this species sometimes intercept females, but their mating success is lower than that of calling males, even though the latter do not defend resource-based territories (Arak 1983a; 1988a).

Satellite males are common in hylids (table 8.1) and probably other tree frogs (e.g., rhacophorids, Arak 1983c). Satellite males sometimes are slightly smaller than calling males (Garton and Brandon 1975; Arak 1983c; Forester and Lykens 1986; Backwell and Passmore 1991; Haddad 1991), but often there is little or no difference in body size (Perrill, Gerhardt, and Daniel 1978, 1982; Fellers 1979a; Roble 1985; Perrill and Magier 1988; Lance and Wells 1993). Consequently, several authors have suggested that these species exhibit a mixed evolutionarily stable strategy, with calling and satellite strategies yielding equal payoffs (Arak 1983a; Gardner, Morris, and Nelson 1987). Satellite males have been observed intercepting females as they approach calling males (Miyamoto and Cane 1980; Roble 1985; Perrill and Magier 1988; Haddad 1991). Nevertheless, mating success of satellite males often appears to be much lower than that of calling males, and in some studies, satellite males have not been observed to mate at all (Backwell and Passmore, 1991). Perrill et al. (1978) released *Hyla cinerea* females near pairs of calling and satellite males. In 43% of the tests ($N = 30$), the satellite male clasped the female. These data do not necessarily show that the overall payoff of calling and satellite behavior is nearly equal. To determine this, one would require data on the proportion of all matings during the breeding season obtained by calling and satellite males.

In many tree frogs, males readily switch between calling and satellite roles, although some individuals tend to spend more time calling and others more time as satellites. When calling males are removed from caller-satellite associations, satellite males often begin calling, or they reorient toward other calling males (Perrill, Gerhardt, and Daniel 1982; Haddad 1991). In one series of experiments with *Hyla cinerea,* calling males were removed from associations and replaced with a speaker playing recorded calls; all satellite males became satellites on the speaker. Synthetic advertisement calls were effective in eliciting satellite behavior, but synthetic aggressive calls were not (Perrill, Gerhardt, and Daniel 1982). In similar experiments with *Acris crepitans,* some calling males switched to a satellite role when presented with a loud recorded call, but switching was less common than in *H. cinerea* (Perrill and Magier 1988).

These experiments demonstrate the flexibility of mating behavior in these species, but the factors determining which role a particular male will adopt on any given night are unknown. Several theoretical models have predicted that a male's tendency to adopt a satellite role will depend on several factors, including his age, body size, and energy reserves (Lucas and Howard 1995; Lucas, Howard, and Palmer 1996; McCauley et al. 2000). For example, the model by McCauley et al. (2000) predicted that males with low energy reserves should switch to satellite behavior to save energy. This prediction is not yet supported by empirical data from natural populations, but very few studies have compared body condition or energy reserves of callers and satellites in the same population. Lance and Wells (1993) did not find any difference in body condition of callers and satellites in spring peepers (*Pseudacris crucifer*), but satellite males were present only early in the breeding season, when energy reserves of males are expected to be high. On the other hand, calling males collected late in the season did have lower body mass for any given length than did those collected early in the season, probably because of depletion of lipid reserves (McKay 1989; Ressel 1993; see chapter 5).

Emerson (2001b) proposed that switches from calling to satellite behavior are mediated by decreasing energy reserves leading to increased production of the stress hormone corticosterone. This in turn was expected to reduce circulating levels of testosterone, perhaps resulting in males switching to satellite behavior. Leary et al. (2004) tested the model with two species of toads, *Bufo woodhousii* and *B. cognatus*. They found that calling males had higher levels of corticosterone than did satellite males, but there was not a negative relationship between corticosterone and testosterone. In both species, satellite males were significantly smaller than calling males, and in *B. woodhousii,* satellite males also were in poorer condition. Their results suggest that differences in both body size and body condition play a role in determining behavioral tactics, but there is not a simple hormonal control mechanism mediating behavior. Leary et al. (2004) suggested that switches between calling satellite behavior are mediated not by testosterone, but by interactions between corticosterone and arginine vasotocin (AVT), which is known to mediate calling behavior in anurans (Marler, Chu, and Wilczynski 1995; Ten Eyck 2005)

Mating Tactics of Female Anurans

So far, the discussion of anuran mating systems has focused almost entirely on the behavioral tactics used by males to acquire mates, and we tend to classify mating systems based largely on the behavior of males. Yet as Darwin clearly recognized, females often play an active role in choosing their mates, by assessing variation in quality of the males themselves or the resources they control. Much of the recent work on anuran mating systems has focused on the tactics used by females to assess mate quality and the effect of female choice on the evolution of male traits. B. K. Sullivan, Ryan, and Verrell (1995) and Gerhardt and Huber (2002) provide detailed reviews of recent literature on female choice in anurans.

Females could derive either direct or indirect benefits from choosing particular males as mates. Direct benefits include anything that increases the female's production of offspring, whereas indirect benefits refer to anything that enhances the genetic quality of those offspring (Kirkpatrick and Ryan 1981; Kirkpatrick 1982; Andersson 1994). The most obvious direct benefit that females might derive from mate choice would be access to resources controlled by males, such as high-quality oviposition sites, because this is likely to directly affect the survivorship of her offspring. Similarly, if males provide parental care, then choice of males with superior parental abilities would yield immediate fitness benefits to the female. Even when males do not provide the female with resources or parental care, as in lekking species, females could benefit by selecting the most fertile males. If a male's size relative to that of the female affects his ability to fertilize her eggs, then selection of males of the appropriate size would yield direct benefits as well. Females also might benefit from avoiding males infected with parasites or diseases that could be transmitted to her (K. Pfennig and Tinsley 2002). Finally, if searching for a mate is costly because of energetic constraints or the risk of predation, then females will benefit by choosing males that produce especially conspicuous signals that can be easily located (Grafe 1997a; Jennions and Petrie 1997). In some cases, males might evolve signals that exploit some preexisting sensory bias in females, thereby making their signals more easily detected by females (M. Ryan 1990; M. Ryan and Rand 1990, 1993b; see also chapter 7).

Indirect benefits of mate choice depend on genetic benefits provided by males. One form of indirect sexual selection is the so-called runaway sexual selection process first proposed by R. A. Fisher (1930). He proposed that an initial preference for a certain male trait might exist because of some benefit it provides to the female. Once the preference becomes established in the population, the preference and the trait become genetically correlated, so that selection for more exaggerated traits leads to increased preference for the trait, leading to runaway sexual selection. This process has been difficult to demonstrate in nature, and there is no clear evidence that any trait in male anurans evolved by runaway sexual selection. Consequently, nearly all discussion of indirect benefits of mate choice has focused on good genes models of sexual selection. These models postulate that females select mates on the basis of traits that are indicators of overall genetic quality, or traits that reveal the presence of genes that enhance particular aspects of fitness, such as resistance to parasites, high growth rate, or a high physiological capacity for activity (Andersson 1994). For example, suppose females prefer males with high calling rates. If a high calling rate provides reliable information about some fitness-related trait, then a genetic correlation between the trait and the preference cause both the frequency of the correlated trait and the strength of the female preference to increase in the population (B.K. Sullivan, Ryan, and Verrell 1995).

Parker (1983) argued that many apparent examples of active female choice actually could be the result of passive attraction to male displays. Variation among individual males in display behavior might or might not be correlated with genetic differences that would affect female fitness. This is particularly relevant to anurans, because females often must locate a chorus, and individual males within a chorus, before choosing a mate. If females simply go to a male producing the most conspicuous signal, it does not necessarily imply that females actively compare the qualities of different individuals or derive a fitness benefit from choosing one male over another (Arak 1988a; Dyson and Passmore 1988). In practice it often is difficult to distinguish between active choice and passive attraction. B. K. Sullivan (1989b) argued that the distinction is not very useful because it confuses questions about the mechanisms by which females select mates and the ultimate fitness benefits of mate choice (see also Ryan 1990; Forrest and Raspet 1994; B. K. Sullivan, Ryan, and Verrell 1995; Grafe 1997a; Jennions and Petrie 1997). There is considerable evidence that female anurans approach calling males by following a gradient of call intensity, and are more likely to approach louder or closer calls than softer or more distant calls (Beckers and Schul 2004; Castellano, Rosso, and Giacoma 2004). It is less clear whether females are simply reacting to the intensity of stimulation of the auditory system or are discriminating among males on the basis of cues related to male quality.

Most work on female choice in anurans has focused on the proximate cues used by females to select their mates. There is convincing evidence for females selecting mates on the basis of resources controlled by males, as well as phenotypic traits such as body size or calling activity. It has been much more difficult to demonstrate the fitness benefits to females making such choices, especially indirect genetic benefits (B. K. Sullivan, Ryan, and Verrell 1995; Grafe, 1997a; Doty and Welch, 2001; Welch, 2003). A largely neglected area of research is the cost of mate choice by females and variation in the nature and strength of female preferences (Wagner 1998). There is some evidence for anurans that choices made by females are repeatable (Jennions, Backwell, and Passmore 1995; Gerhardt, Dyson, and Tanner 1996; Gerhardt and Huber, 2002), but there also is evidence that the criteria used by females to choose mates sometimes vary within and among individuals and among populations of the same species, even when the general direction of preference is similar for all females (Jennions and Petrie 1997; R. D. Howard and Young 1998; Schwartz and Gerhardt 1998; C. Murphy and Gerhardt 2000; Gerhardt and Huber 2002). The effect of such individual variation in female preference for certain male traits is to weaken potential selection on those traits. Hence, to fully understand how sexual selection acts on male traits, we need replicated studies of mate choice both within and between populations.

Female Choice in Explosive-Breeding Anurans

Many authors have speculated about criteria that might be used by females to select mates in explosive-breeding aggregations (Licht 1976; N. Davies and Halliday 1977; Wilbur, Rubenstein, and Fairchild 1978; Gatz 1981a; J. Lee and Crump 1981). Nevertheless, there is relatively little convincing evidence that female choice is a major determinant of male mating success in most species that form very dense breeding choruses and engage in scramble competition (Arak 1983a; Halliday 1983a; Halliday and Tejedo 1995; B. K. Sullivan, Ryan, and Verrell 1995). Upon entering a chorus, females usually are mobbed by searching males. Nevertheless, in low-density choruses, some females can approach individual calling males and initiate amplexus without being intercepted by other individuals. For example, Kagarise Sherman (1980) found that approximately half of all matings observed in a population of *Bufo canorus* were initiated when females contacted calling males. B. K. Sullivan (1982a) reported that *B. cognatus* females sometimes approached and contacted calling males and attempted to shake off satellite males that intercepted them. Studies of several other explosive-breeding toads at low densities also have revealed some opportunities for female choice (R. D. Howard 1988b; B. K. Sullivan 1992; Tejedo 1992c).

The criteria used by females to select mates in explosive-breeding species are largely unknown. These species do not defend resources, so any mate choice would have to be based on phenotypic or behavioral characteristics of males. B. K. Sullivan (1983a) found that successful *Bufo cognatus* males called more frequently than did unsuccessful males, and he suggested that females might choose mates on the basis of differences in calling rates. However, he measured only the percentage of observation periods in which males were calling, not hourly calling rates, so these data do not necessarily demonstrate a preference for high calling rates.

B. K. Sullivan (1992) showed that females of *Bufo americanus* preferred a higher calling effort (calling rate × call duration) in controlled playback experiments, but he did not find any evidence that females discriminated between calls of high and low frequency. He was not able to correlate mating success in the field with any aspect of calling behavior, but his sample of matings was very small. R. D. Howard and Palmer (1995) tested females of the same species with high- and low-frequency calls presented in alternation or overlapped with one another (the more common situation in the field). Females preferred calls of low frequency if the calls were alternated or if the low-frequency call preceded the high-frequency call in an overlapped pair, but they showed no preference when the high-frequency call was presented first. Although large males of this species often have a mating advantage (R. D. Howard 1988b), it is not known whether females can assess differences in male body size from the relatively small differences in call frequency usually present in natural choruses (R. D. Howard and Palmer 1995).

Later work on the same population revealed repeatable differences between males in call characteristics (R. D. Howard and Young 1998). Call-dominant frequency was negatively correlated with male body size, and females initially tended to pair with larger than average males. Howard and Young removed some females from amplexus and allowed them to pair repeatedly with different males, and these individuals showed little consistency in their tendency to pair with males of a particular size. Both calling rate and call duration were highly variable, both within and between males, but these traits were not related to body size. Howard and Young did not investigate the effect of these variables on mate choice by females in natural choruses, however. In this population, only about half of the males called actively in the chorus; the remainder mainly engaged in active searching for females. This pattern is typical for this species (Forester and Thompson 1998). Overall, the results of these studies indicate that female American toads sometimes have an opportunity to select individual males in a chorus, but female preferences often are negated by the activities of searching males that seize females as soon as they are encountered.

Female Choice in Prolonged-Breeding Anurans

Most of the work on female choice in anurans has focused on species with relatively long breeding seasons, in which males form leklike choruses or defend resource-based territories. Females typically have ample opportunities to move among calling males and compare the quality of potential mates or their territories. Unfortunately, we know relatively little about the sampling tactics used by females to assess males in large choruses. In laboratory experiments, females often choose between alternative acoustic stimuli in less than a minute, but they often spend much more time sitting and listening to calling males in the field before beginning their approach. J. Schwartz, Huth, and Hutchin (2004) designed a field experiment to determine how much time is required for females of *Hyla versicolor* to assess differences in number of pulses in calls, a criterion known to be important in mate choice. They found that females probably need only about two minutes to assess subtle differences between calls, even though they appear to take much longer to approach males in the field. This experiment presented females with a somewhat simplified task, however, because they only were required to choose between two sound sources in a relatively quiet environment, whereas females in the field often are confronted with multiple sound sources and high levels of background noise.

One of the few studies in which the behavior of individual females was monitored in detail was that of M. Morris (1989) on *Hyla chrysoscelis*. She found that females typically visited a relatively small subset of calling males in a chorus before choosing a mate. Presumably the potential costs of wider searching, including exposure to predation, outweigh the benefit of sampling a larger number of males. Females of *H. gratiosa* exhibit even more restricted mate sampling (Murphy and Gerhardt 2002). Most individuals mated with the first male encountered upon entering the chorus, suggesting that females evaluate males from a distance before approaching them. The specific criteria used by females to choose mates vary with the type of mating system. Some evaluation of territory quality almost certainly is important for any species in which males defend oviposition sites, because the quality of the oviposition site can have an immediate effect on a female's reproductive success. When males do not defend resources, however, it becomes more difficult to determine how females assess the quality of potential mates.

Female Choice and Resource Quality

The easiest form of female choice to understand is choice based on resource quality. If males defend territories centered on oviposition sites and these sites vary in quality, then females are expected to choose mates on this basis. There is good evidence for female choice based on territory quality in *Rana clamitans* and *R. catesbeiana* (Wells 1977c; R. D. Howard 1978a). In both species, physical features of territories were correlated with mating success of territory owners. Although large males tended to acquire the best territories, small males with good territories were more likely to mate than large males with poor territories. R. D. Howard (1978b) demonstrated that bullfrog oviposition sites varied in temperature, resulting in variable hatching success of eggs (fig. 8.21). In one year, hatching success was strongly correlated with male size (R. D. Howard 1978a, b), but in two other years it was not (R. D. Howard 1983). Apparently this was due to a reduction in the number of males competing for territories, leading to greater availability of high-quality sites.

Males of other species, such as *Hyla rosenbergi* and several centrolenid frogs, also defend oviposition sites, but it is not clear whether females choose mates on the basis of territory quality. Kluge (1981) did not find consistent differences between nests defended by successful and unsuccessful *H. rosenbergi* males; he suggested that female choice was more likely to be based on some aspect of male behavior, especially aggressiveness. Greer and Wells (1980) found no differences in survivorship of *Hyalinobatrachium fleischmanni* eggs at sites used frequently for oviposition and those used infrequently, so it was not clear that female choice of mates at particular sites enhanced female fitness.

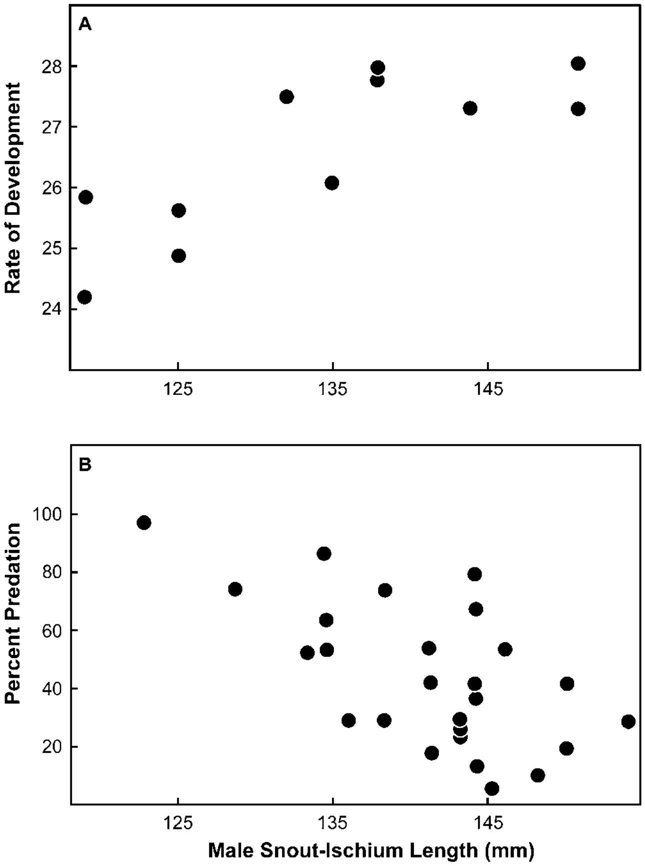

Fig. 8.21. Two measures of territory quality as a function of male body size in bullfrogs (*Rana catesbeiana*) from Michigan. (A) Relationship between body size and rate of embryonic development for eggs deposited in male territories. Rate of development is an index of the time required for eggs to reach the hatching stage. (B) Relationship between body size and rate of predation on eggs by leeches. Larger males defended better-quality territories, where embryos developed more quickly than in poor-quality territories, thereby escaping predation by leeches. After R. D. Howard (1978b).

Nevertheless, there could have been differences in post-hatching survival of tadpoles related to placement of oviposition sites. Some egg clutches, for example, were laid on leaves that were not directly over water, increasing the risk that tadpoles would fall onto dry land when they dropped out of the egg mass. It is not known, however, if females can accurately assess whether oviposition sites are properly positioned over water.

Female Choice and Male Parental Ability

Male parental ability is frequently cited as a possible criterion for female choice in a variety of animals (Clutton-Brock 1991; Andersson 1994; Jennions and Petrie 1997), but there are relatively few convincing demonstrations that females can accurately assess the parental abilities of potential mates. Summers (1989) observed females of *Dendrobates auratus* competing among themselves for access to males. There always were plenty of males advertising for mates, so he interpreted this as competition for particularly high-quality males, or males controlling high-quality territories. He did not, however, have any direct evidence that females assess differences in parental abilities of males. Felton et al. (2006) reported that females of a small microhylid frog in Australia, *Cophixalus ornatus,* preferred nest cavities constructed by older males (some up to 14 years old), but the amount of time males spent attending their eggs after oviposition was not significantly correlated with male age, body size, or condition. These results suggest that females probably have few cues available to accurately predict male parental ability.

Márquez (1993) studied parental care and female choice in two species of midwife toads, *Alytes obstetricans* and *A. cisternasii.* Males often carry more than one clutch at a time, and large males were more likely to obtain multiple clutches than smaller males. Hatching success of the eggs, however, was not correlated with either male body size or the number of clutches a male carried. An earlier study by Reading and Clarke (1988) produced similar results. This suggests that females do not assess the parental ability of males. In these studies, hatching success was measured only once for each male, so it was not possible to measure the repeatability of male parental ability to determine whether there are consistent differences among males that would affect female fitness. It still is possible that females prefer to mate with males already carrying eggs, if this is an indicator of male parental ability. Females of *A. obstetricans* actually appear to suffer some cost if they choose males already carrying eggs. Males with large egg complements retain the eggs longer and release the tadpoles into pools later than do males with small egg complements, thereby exposing the eggs to possible desiccation, or the tadpoles to low water levels late in the summer (Márquez 1996). In an experimental study of another species, *A. muletensis,* Bush (1996) reported that females did not exhibit a significant preference for either brooding or nonbrooding males. Her field studies agreed with those of Márquez in finding no relationship between the number of clutches carried by males and hatching success.

Female Choice and Call-Dominant Frequency

Many authors have suggested that female anurans might choose mates on the basis of call features that reflect differences in male body size, especially the dominant frequency of male calls (see Gerhardt and Huber 2002, for a review). Unfortunately, there was confusion in some of the early literature about which features of a frog's call are correlated with male body size (Licht 1976; Wilbur, Rubenstein, and Fairchild 1978; Fairchild 1981), despite a clear discussion of the subject by Zweifel (1968b; see also B. K. Sullivan 1982c; Sullivan and Sullivan 1985). In general, interspecific comparisons of closely related species reveal a clear negative correlation between male body size and the dominant frequency of the call. A negative correlation between size and dominant frequency often is found within species as well, but can be more difficult to detect because of the narrower range of body sizes. Even when body size and call frequency are negatively correlated, the correlation sometimes is relatively weak (Oldham and Gerhardt 1975; M. Ryan 1980a, 1983a; Kagarise Sherman 1980; B. K. Sullivan 1982b, 1992; Arak 1983b; B. K. Sullivan and Sullivan 1985; Krupa 1990; B. K. Sullivan and Hinshaw 1992; Cherry 1993; Wagner and Sullivan 1995; Burmeister et al. 2002; Esteban et al. 2002). This means that even if females are capable of fine-scale frequency discrimination, there is a high probability of error in estimating body sizes of males (Gerhardt 1982; J. Robertson 1986a; Gerhardt and Huber 2002). Furthermore, body size sometimes is a relatively poor predictor of age (Lykens and Forester 1987; Halliday and Verrell 1988; R. D. Howard and Young 1998), so the common assumption that females should prefer larger males because they are older is not always valid. In one species, *Cophixlus ornatus,* call-dominant frequency not only was negatively correlated with body size, but also with male age after correcting for body size, even though size and age were not correlated with each other (Felton et al. 2006).

In a number of studies, two-choice playback experiments have been used to test the ability of females to discriminate frequencies within the range found in the population. In some early studies, females were tested mainly with calls at the high and low ends of the population frequency distribution, but high-and low-frequency calls were not tested against those of average frequency. For example, M. Ryan (1980b, 1983b, 1985b) showed that female *Physalaemus pustulosus* could discriminate between calls differing by 60 Hz in fundamental frequency; all females tested approached the speaker playing the lower-pitched call. These frequencies were near the extremes found in natural populations of this species, so the calls of most males would fall between those tested. Females also could discriminate between calls differing by 40 Hz, but not between calls differing by only 30 Hz (M. Ryan 1983b). Ryan's results show that females can make subtle distinctions between calls based on frequency alone, and that some information about male body size might be gained. The degree to which this contributes to the nonrandom mating pattern observed in this species is not clear, because male mating success also is affected by a variety of other factors (M. Ryan 1983b, 1985b). Later work on this species showed a bias toward low-frequency calls, but not a strong preference (Wilczynski, Rand, and Ryan 1995).

Forester and Czarnowsky (1985) presented female spring peepers (*Pseudacris crucifer*) with a choice of calls differing in dominant frequency by about 750 Hz; the stimuli were near the extreme values for their population. As in *Physalaemus,* females preferred the lower frequency call. Unfortunately, this experiment was marred by multiple tests of the same females and a failure to equalize playback intensities at the release point. Furthermore, Forester and Czarnowsky did not test preferences of females for average versus high- or low-frequency calls. In another study of the same species, Doherty and Gerhardt (1984b) found that females preferred calls with average dominant frequencies to those with dominant frequencies above or below the average frequency in the population. J. Schwartz and Gerhardt (1998) found that female spring peepers did not exhibit a preference for any frequency in the absence of background noise, and when noise was present, they actually preferred higher-than-average to lower-than-average frequency calls. They also found that females were not very consistent in their choice of frequencies when they were tested more than once. Furthermore, when auditory tuning curves were determined for the same females that had been tested in playback experiments, there was little or no relationship between frequency sensitivity of individual females and their behavioral responses. Schwartz and Gerhardt concluded that females of this species do not exhibit strong frequency discrimination and are unlikely to choose mates on the basis of differences in call dominant frequency. Bosch, Márquez, and Boyero (2003) reported a similar low level of consistency in choice of dominant frequency for two species of midwife toads (*Alytes*).

Studies with several species have shown either stabilizing selection on call frequency, or weak directional selection for low-frequency calls (Gerhardt and Huber 2002). For example, females preferred calls of average frequency to either high- or low-frequency calls in *Hyla cinerea* (Gerhardt 1982; Gerhardt et al. 1987), *H. gratiosa* (Gerhardt 1981b; C. Murphy and Gerhardt 2000), *H. versicolor* (Gerhardt 1991), *Bufo viridis* (Castellano and Giacoma 1998), *Hyperolius marmoratus broadleyi* (Grafe 1997a), and *Crinia georgiana* (M. J. Smith and Roberts 2003b).

Relatively weak preferences for lower than average frequency calls have been found in several other species. In *Hyla chrysoscelis,* M. Morris and Yoon (1989) found that females preferred low-frequency calls to high-frequency calls, but they did not discriminate between either high- or low-frequency calls and those of average frequency. In *Hyperolius marmoratus marmoratus,* females showed a slight preference for low- over high-frequency calls, but this preference could be altered by changing the timing of the two calls (Dyson and Passmore 1988). Females of *Physalaemus enesefae* preferred low-frequency or average-frequency to high-frequency calls, but did not discriminate between low and average frequencies. The preference for low-frequency calls was strongest when the low-frequency call preceded the high-frequency call and disappeared when calls partially overlapped (Tárano and Herrera 2003). Two species of midwife toads (*Alytes obstetricans* and *A. cisternasii*) showed small biases toward lower-than-average frequency calls as well (Márquez 1995; Márquez and Bosch 1997a), and in one population, mating success was negatively correlated with call frequency (Lodé and Le Jacques 2003). In *Cophixalus ornatus,* males that acquired mates had calls with lower dominant frequencies than did unmated males nearby, but not compared to the population as a whole (Felton et al. 2006).

A few species have shown somewhat stronger preferences for low-frequency calls. Wollerman (1998) reported that female *H. ebraccata* preferred low-frequency calls (2960 Hz) to average-frequency calls (3240 Hz), but did not discriminate between average calls and those of slightly lower frequency (3170 Hz) or higher frequency (3330, 3480 Hz). Nevertheless, four of 20 individuals responded to the average-frequency call when tested with the lowest-frequency call. A significant preference for low-frequency calls also was found in *Acris crepitans* (M. Ryan, Perrill, and Wilczynski 1992), but only in two-thirds of the preference tests. Overall, the evidence suggests that there is not strong directional selection on call-dominant frequency in many anurans, and in some cases, selection is strongly stabilizing in favor of average-frequency calls.

There is considerable evidence that frequency preferences observed in playback experiments with various species roughly correspond to average frequency tuning of the ears of females in the population (see chapter 7). In those experiments in which females preferred calls of average frequency, the preferred call was close to the average best frequency response of the ear of females in that population (Doherty and Gerhardt 1984b). In species in which females preferred lower-frequency calls, the ears of females were tuned to frequencies somewhat lower than the average frequency of calls in the population (e.g., M. Ryan et al. 1992; Sun et al. 2000). Preferences for low-frequency calls over high-frequency alternatives could simply reflect the steeper decline in sensitivity of the ear at frequencies above the best frequency (Gerhardt 1991; Schwartz and Gerhardt 1998; Gerhardt and Huber 2002). In other words, given a choice of calls 200 Hz above and below the best frequency of the female's ear, a female should hear the lower frequency better. In some species, large females show a stronger preference for low-frequency calls than do small females (M. Ryan et al. 1992; Jennions, Backwell, and Passmore 1995). This probably reflects the lower-frequency tuning of the ears of larger females, particularly frequencies detected by the basilar papilla (see chapter 7). One must be cautious, however, in extrapolating from average responses of populations of females to choices made by individual females. The work of Schwartz and Gerhardt (1998) showed considerable variation in behavioral responses both within and among females in a population that was not easily predicted from neural frequency responses.

Further evidence that preferences for low-frequency calls are related to the frequency sensitivity of the ear comes from experiments showing that a preference for low-frequency calls can be reversed by increasing either the intensity or rate of the less-preferred call (Gerhardt 1988, 1994a; Gerhardt and Huber 2002). For example, when M. Morris and Yoon (1989) increased the sound pressure level of a high-frequency call of *Hyla chrysoscelis* by 3 dB, the preference for a low-frequency alternative disappeared. When high-frequency calls were presented at twice the rate of low-frequency calls, the preferences were reversed. On the other hand, *H. versicolor* females continued to prefer calls of average frequency over higher- or lower-frequency calls even when the sound pressure level of the average-frequency calls was reduced by 6 dB (Gerhardt and Doherty 1988). Gerhardt, Dyson, and Tanner (1996) found that in natural choruses of this species, variation in dominant frequency of calls among males in the population was rarely large enough to elicit intensity-independent preferences by females.

All of these experiments. taken together. suggest that in most frogs, any selection on dominant frequency is more likely to be weakly directional or stabilizing than strongly directional (Gerhardt 1991, 1994a; Gerhardt and Huber 2002). In some anurans, however, there appears to be little frequency discrimination by females. Most experiments with toads, for example, have found little evidence of frequency selectivity by females (Arak 1983b, 1988b; B. K. Sullivan 1983b; Höglund and Robertson 1988; B. K. Sullivan 1992; Cherry 1993; Wagner and Sullivan 1995). When such selectivity was evident, it was affected by other variables, such as degree of call overlap (R. D. Howard and Palmer 1995). Lopez and Narins (1991) also failed to find evidence of frequency discrimination in *Eleutherodactylus coqui.*

Other studies have shown that any frequency discrimination evident in two-speaker playback experiments often disappears or is modified in more complex acoustic environments. This was first demonstrated by Gerhardt (1982), who found that the ability of *Hyla versicolor* females to discriminate between calls of different dominant frequency diminished considerably when they were tested in a four-speaker arena. Márquez and Bosch (1997a) used a computer to broadcast calls of different frequencies from an array of seven speakers to females of two species of midwife toads. One species, *Alytes obstetricans,* showed a weak preference for lower-than-average frequency calls. Many females chose the other alternatives, however, and responses of individual females were not consistent. In the multispeaker array, the other species, *A. cisternasii,* did not show a significant preference for low-frequency calls, and again, repeated choices by the same females were not consistent.

In *Hyperolius marmoratus,* females tested in two-speaker playback experiments exhibited a clear preference for low-frequency over high-frequency calls (Dyson and Passmore 1988; Jennions, Backwell, and Passmore 1995), but detailed field studies showed no evidence of a consistent mating advantage for large males (Telford and Dyson 1988; Dyson et al. 1992). Studies of animals in experimental enclosures revealed that large males enjoyed a mating advantage in small choruses, but male mating success was random with respect to size in larger choruses (Telford, Dyson, and Passmore 1989). Other experimental studies showed frequency discrimination by female *Hyperolius* diminished if males were very close together (Dyson and Passmore 1992a; see also Schwartz and Gerhardt 1989). Discrimination also can be affected by the temporal relationship of calls (Dyson and Passmore 1988; Dyson, Henzi, and Passmore 1994). The tendency for females to approach a speaker in playback experiments can be influenced by the presence of suitable perches near the speaker, especially on moonlit nights (Backwell and Passmore 1990). Possibly these frogs prefer not to approach males on the ground or in the water, where they are vulnerable to predators such as snakes (Grafe 1997a). Clearly, caution is required in extrapolating from simplified playback experiments to patterns of mate choice in more complex acoustic environments and situations where mate choice can be costly. Overall, the evidence that female anurans use differences in the dominant frequencies of calls to assess the body size of males when selecting mates is relatively weak. Frequency discrimination could be important in enabling females to avoid mating with males of the wrong species, but it might not contribute very much to variation in male mating success in natural choruses (Gerhardt 1994a; Schwartz and Gerhardt 1998; Gerhardt and Huber 2002).

Female Choice and Male Calling Performance

Although many investigators have examined the importance of dominant frequency as a determinant of male mating success, other aspects of male calling performance probably are more important. In a natural chorus, females must locate males in a noisy and acoustically complex environment. Therefore, males that produce the loudest, longest, or most complex calls, or those that call most frequently, probably have an advantage in attracting mates (Wells 1977a 1988; Gerhardt 1982, 1988). This advantage need not be related to any genetic benefits accruing to females, but simply reflect the ease with which females perceive and locate males in a noisy chorus (Arak 1983a, 1988b; Halliday 1983a; G. Parker 1983; Wells and Schwartz 1984a; Grafe 1997a). Nevertheless, calling at high rates, or producing loud, long, or complex calls usually increases the energetic costs of calling (see chapter 5), so females might use differences in calling performance to assess differences in the quality of males in a chorus.

Females of many anurans will move toward speakers playing the louder call in playback experiments (Fellers 1979b; Arak 1983a, b, 1988b; Forester and Czarnowsky 1985; Gerhardt 1988, 1994a; Schwartz 1993; Bishop, Jennions, and Passmore 1995; Beckers and Schul 2004; Castellano, Rosso, and Giacoma 2004; and this would be expected of most species. Perceived call intensity depends on a female's proximity to a male, as well as the acoustic properties of the male's calling site (chapter 7). Call intensity per se probably provides the females with little information about the male, although in some species, larger males produce louder calls (Gerhardt 1975; Given 1987). Fellers (1979a) suggested that *Hyla versicolor* males calling from unobstructed sites might have an advantage in attracting females, but he failed to show that successful males occupied superior sites more often than unsuccessful males. Godwin and Roble (1983) found no relationship between mating success and the physical features of calling sites in the closely related species, *H. chrysoscelis*. On the other hand, males of *Hyalinobatrachium fleischmanni* that occupied elevated, unobstructed sites obtained more mates than did those at low, densely vegetated sites (Greer and Wells 1980); the higher sites were those most likely to enhance the broadcasting of calls (Wells and Schwartz 1982). Males of the Puerto Rican frog *Eleutherodactylus coqui* also exhibit a strong preference for elevated sites. Not only do elevated sites affect the propagation of calls (Narins and Hurley 1982), but such sites also are closer to preferred nest sites than are sites closer to the ground (Townsend 1989a).

The vocal interactions among males in a chorus also can influence their ability to acquire mates (Wells and Schwartz 1984a; Wells 1988). Males often increase calling rates, lengthen their calls, or add secondary notes to their calls when they hear the calls of other individuals or detect females nearby (see chapter 7 for a detailed discussion). Female frogs almost always prefer high calling rates to low rates (Whitney and Krebs 1975a; B. K. Sullivan 1983b; J. Schwartz 1986; Gerhardt et al. 1987; Wells and Bard 1987; Arak 1988a; Gerhardt 1988; Wells 1988; Lopez and Narins 1991; Passmore, Bishop, and Caithness 1992; B. K. Sullivan 1992; B. K. Sullivan and Hinshaw 1992; Cherry 1993; Jennions et al. 1995; Polakow et al. 1995; Wagner and Sullivan 1995; Kasuya et al. 1997; Smith and Roberts 2003a, b; Tárano and Herrera 2003). Females sometimes exhibit a preference for calling rates well above the normal range of variation for their species (Gerhardt 1987, 1991), but a preference for high calling rates can be eliminated if another species with a higher calling rate is present (K. Pfennig 2000). Forester, Lykens, and Harrison (1989) tested reactions of female *Pseudacris crucifer* in the field to variation in calling rate by setting up several speakers equipped with traps that captured females. There was an almost linear increase in number of females captured as calling rate increased, indicating that males investing more energy in calling (Taigen et al. 1985; Wells, Taigen, and O'Brien 1996) are more likely to acquire mates.

This is true for other species as well, because the energetic cost of calling generally is a linear function of calling rate (Pough et al. 1992; Prestwich 1994). In a study of *Hyla microcephala* in Panama, Schwartz, Ressel, and Bevier (1995) monitored the calling of several males in a chorus simultaneously with a computer system. Females selected the males with the highest calling rates first. Because females often arrive at the breeding site relatively late at night, males must continue to call for several hours to maximize their chances of mating. Calling at a high rate rapidly depletes the frogs' reserves of glycogen in their trunk muscles, so they must pause periodically to conserve energy. Frogs that were stimulated to call at unusually high rates, which would be most attractive to females, depleted even more of their energy reserves.

In *Hyla versicolor,* males increase call duration but they reduce calling rate in response to other males' calls (Wells and Taigen 1986; Schwartz, Buchanan, and Gerhardt 2002). This does not seem to increase aerobic costs, but could decrease the amount of time a male can call by depleting some types of energy reserves more quickly (Taigen and Wells 1985; Wells and Taigen 1986; Grafe 1997b). Females of this species prefer long calls to short calls, even when total calling effort (seconds of calling per hour) is equalized (Klump and Gerhardt 1987; Gerhardt, Dyson, and Tanner 1996). Females also prefer faster calling rates if call duration is equal, and longer calls if calling rate is equal. The same is true for *H. chrysoscelis* (Gerhardt 2005). Thus, females prefer calling patterns that require increased expenditures of energy. However, the ability of females to discriminate among calls of different durations is considerably reduced in a large chorus with high levels of background noise, but they do tend to avoid males giving very short calls (Schwartz, Buchanan, and Gerhardt 2001).

Females prefer complex calls (i.e., those with distinct secondary notes) in *Physalaemus pustulosus* (Rand and Ryan 1981), *Geocrinia victoriana* (Littlejohn and Harrison 1985), *Hyla ebraccata* (Wells and Schwartz 1984a), and *H. microcephala* (Schwartz 1986). In cricket frogs (*Acris crepitans*), males do not produce distinct secondary notes, but they respond to calls of neighboring males by increasing the number of call groups and the number of pulses per call. These changes have been interpreted as aggressive responses (see chapter 7), but they also make the calls more attractive to females (Kime, Burmeister, and Ryan 2004). It is not entirely clear whether females typically prefer longer or more complex calls because these calls provide females with information about male quality (M. Ryan 1983b), or because complex calls are more easily detected in a noisy chorus. In some species, such as *H. microcephala,* the energetic cost of calling is a linear function of the number of call notes produced, so the number of call notes may provide reliable information about male quality (Wells and Taigen 1989). In other species, such as *Physalaemus pustulosus,* addition of secondary notes does not appear to increase energetic costs (Bucher, Ryan, and Bartholomew 1982), so females would not necessarily gain information about male quality, but might be able to locate calls more effectively.

In most species tested with multinote calls, or calls of different durations, the preferences for more longer or more complex calls is open ended, so that calls that are longer than normal elicit a stronger response from females than do more typical calls. One species from Taiwan, *Rhacophorus moltrechti,* did not show this pattern. This species produces calls with an introductory note with a slow pulse rate, sometimes followed by a number of secondary notes with a faster pulse rate. Females preferred multinote calls of normal duration to calls with just the introductory note alone, but addition of a larger number of secondary notes did not make calls any more attractive (T.-U. D. Chen 2002).

While playback experiments often have demonstrated preferences by females for loud calls, high calling rates, long calls, or more complex calls, it has been surprisingly difficult to correlate individual variation in these aspects of calling behavior with male mating success in the field (B. K. Sullivan, Ryan, and Verrell 1995). In some cases, this probably is because the number of males observed mating for which detailed behavioral information was available was relatively small (e.g., B. K. Sullivan 1992). In other cases, preferences for certain call characteristics, such as high calling rate, can be overridden by stronger preferences for another characteristic, such as call intensity (Schwartz 1986; Arak 1988a; Gerhardt 1988, 1991, 1994a; M. Ryan and Rand 1990). Nevertheless, several studies have demonstrated significant correlations between male mating success and variation in calling rate or total number of calls produced (B. K. Sullivan 1983b; Arak 1988a; M. Morris and Yoon 1989; B. K. Sullivan and Hinshaw 1990; Passmore et al. 1992; Cherry 1993; Grafe 1997a; Kasuya et al. 1997; Pröhl and Hödl 1999; Pröhl 2003; Smith and Roberts 2003a).

In many natural choruses, females probably select their mates from a relatively small subset of males that are calling (M. Morris 1989), so comparisons of successful and unsuccessful males are best made within these subsets of males. Because neighbors often interact with one another and have closely matched calling performance (e.g., Wells 1988; Brush and Narins 1989; Bosch and Márquez 1996; Bendix and Narins 1999; Grafe 2003), variation within local subsets of males often is less than that of the chorus as a whole. Finally, the types of call characteristics that appear to be most subject to directional sexual selection, such as calling rate, call duration, call complexity, and perhaps even call intensity, are features that often vary considerably even within a single male (that is, they are dynamic call properties). Consequently, even when a clear preference can be demonstrated in playback experiments, the potential for sexual selection on these traits is limited by intramale variability. Correlations between male mating success and calling behavior can be difficult to detect, or can vary from one year to the next. Nevertheless, most recent studies of dynamic properties of anuran calls have revealed sufficient among-male variation for females to discriminate among individuals (Gerhardt 1991, 1994a; Runkle et al. 1994; B. K. Sullivan, Ryan, and Verrell 1995; Wagner and Sullivan 1995; Gerhardt, Dyson, and Tanner 1996; Welch, Semlitsch, and Gerhardt 1998; Docherty, Bishop, and Passmore 2000; Bee et al. 2001; Tárano 2001; Friedl and Klump 2002; Given 2002).

Genetic Benefits of Female Choice

While there is abundant evidence that female anurans prefer certain male traits both in laboratory tests and under natural conditions, there is relatively little evidence establishing a clear link between such preferences and genetic benefits to their offspring. Several investigators have used laboratory experiments to determine whether choice of large males by females yields genetic benefits to their offspring, such as enhanced growth rates or higher survivorship of tadpoles fathered by large males. Although these experiments produced some evidence for paternal effects on fitness-related traits of tadpoles, there was no consistent tendency for offspring of larger males to have faster growth rates, shorter larval periods, larger size at metamorphosis, or higher survivorship. Therefore, these experiments do not provide strong evidence that indirect selection favors choice of large males by females (Woodward, Travis, and Mitchell 1988; S. Mitchell 1990; Howard, Whiteman, and Schueller 1994; Semlitsch 1994). Two studies that investigated the relationship between parasite infection, male calling performance, and male mating success found little effect on male fitness (Hausfater, Gerhardt, and Klump 1990; Tinsley 1990).

Hyla versicolor is one of the few frogs in which a preference for some aspect of calling performance has been linked to putative genetic benefits to offspring. Welch, Semlitsch, and Gerhardt (1998) reported that tadpoles fathered by males that gave long calls generally had higher growth and survivorship than did those fathered by males that gave short calls, but the performance of tadpoles varied with food availability and between years. Subsequent work showed that offspring of males with longer than average calls tended to feed more as tadpoles than did offspring of males with shorter calls (Doty and Welch 2001). The genetic mechanism that links male calling performance with tadpole performance is not known, however, and any genetic benefits accruing to offspring are likely to be heavily dependent on environmental conditions that they encounter as larvae. For example, Welch (2003) found that tadpoles fathered by males with long calls were slightly (8%) heavier than those fathered by males with short calls under low-density conditions, but this advantage disappeared at high density. Hence a consistent preference by females for long calls would not necessarily be advantageous. While females theoretically could alter their preferences for male traits if they could assess future environmental conditions for their offspring, it is not clear that female gray treefrogs can make such assessments.

Sexual Selection on Male Traits

The mating systems of anurans described previously affect the way in which sexual selection operates on male traits, because different traits are likely to be favored depending on whether males compete directly for females, defend resources attractive to females, or call in choruses or leks to attract females. Sexual selection is just one component of selection operating on traits that affect overall male reproductive success or fitness (S. Arnold and Duvall 1994). The lifetime fitness of an individual male is determined by the number of offspring produced by all of his mates (fecundity) and the male's probability of dying in any given year (mortality; fig. 8.22). The number of offspring fathered by a male depends on the fecundity of each female with which he mates (fecundity per mate) and the number of mates he acquires (mating success). Any traits that determine the number of offspring a male produces through their effect on mating success can be considered sexually selected traits.

Males can influence the fecundity of females either by providing a nuptial gift of food (a behavior unknown in amphibians), or by providing parental care for her offspring (fig. 8.22). Male parental care would normally have a positive effect on survivorship of a male's offspring, but it can have either a negative or positive effect on a male's mating success. If the time devoted to parental care reduces a male's ability to advertise or search for additional mates, then the effect is negative. On the other hand, if females actually prefer to mate with males that have demonstrated their parental abilities by caring for the offspring of other females, then the effect can be positive. Even if females do not prefer males that are already caring for offspring, males would not suffer a major cost of parental care if they can continue to attract additional mates while performing parental duties, such as guarding eggs (see chapter 11).

Male mating success is affected by the amount of time required for a male to mate with one female and then locate another (mate cycling time) and by the male's ability to per-

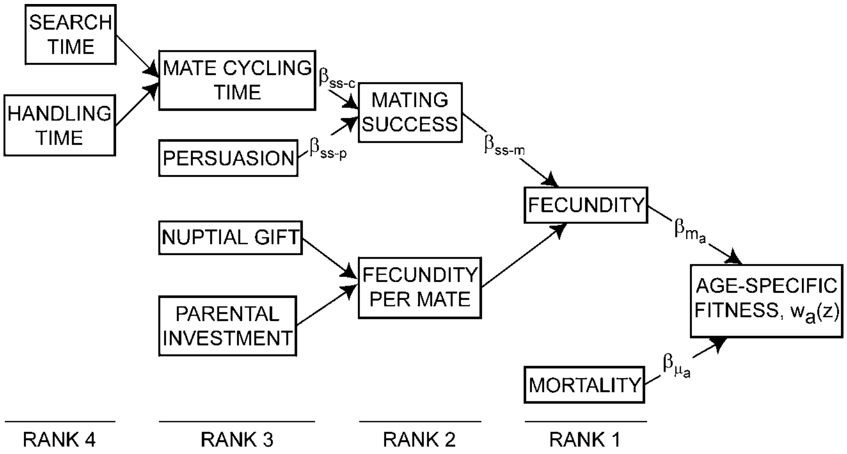

Fig. 8.22. Diagram of types of traits affected by sexual selection. Search time and handling time together constitute mate cycling time, a measure of how frequently a male can mate. Traits that influence mate cycling time and traits that influence a male's ability to attract or retain a female (persuasion) together affect mating success and are subject to sexual selection. Other traits combine to affect fecundity, or the number of eggs fertilized by a male. Fecundity and mortality together determine age-specific reproductive success. After Arnold and Duvall (1994).

suade each female to mate with him (persuasion; fig. 8.22). Mate cycling time is influenced both by the time required to locate mates (search time) and the time used for courtship and mating (handling time). Let's consider the behavior of an explosive breeding toad, *Bufo bufo,* as an example (N. Davies and Halliday 1979). Males actively search for females, and a male sometimes spends many hours or even several days searching for a mate. He will then spend several additional hours fertilizing the eggs as they are laid. The long search time and relatively long handling time imposed by the slow rate of oviposition by the female often means that a male will have few opportunities to mate again in a very short breeding season.

In a species with this type of explosive breeding behavior, any traits that reduce either search time or handling time would be favored by sexual selection. Search time might be reduced in a number of ways. One is for males to arrive early at the breeding site to intercept the first females to arrive. Males also might increase their rates of searching at the breeding pond, search a wider area to intercept females before they reach the pond, or concentrate their searching around oviposition sites or other areas where females are most likely to be found. Males also might attempt to displace males already in amplexus. Traits associated with enhanced physiological capacity for movement or calling, or those related to the size and strength of the male, would be favored. Handling time would include not only the time spent fertilizing eggs, but also any mate guarding, to prevent competitors from displacing a male from amplexus. In a species with external fertilization, a male probably has little control over how much time is devoted to fertilizing eggs, since this depends on how rapidly females lay their eggs. In contrast, traits correlated with male size and strength might reduce handling time by enhancing mate-guarding ability. For many explosive breeders, persuasion probably is of little significance in determining male mating success, because most females do not choose their mates.

Now let's consider a frog with a resource-defense mating system, such as *Rana clamitans.* In this species, search time can be considered equivalent to time spent advertising for mates, since males do not actually search for females. Any traits that reduce the amount of time needed to advertise for a mate will thus be favored by sexual selection. For example, any morphological or physiological traits that allow a male to produce louder calls or call at a higher rate would be favored. Once a female is attracted to a male's territory, handling time can be considerable if females spend time visiting several males before choosing a mate (Wells 1977c). Fertilization takes less than 15 minutes in this species (Aronson 1943b), so this adds little to handling time. Defense of an oviposition site can be considered a form of persuasion. A male with a high-quality territory is likely not only to persuade a female to mate with him relatively quickly, but he also is likely to acquire more mates than a male with a low-quality territory. In species with resource-defense mating systems, male traits associated with successful defense of territories, such as size and strength, probably are more important than traits related to calling ability. In a lek species, such as *Hyla versicolor,* persuasion is likely to take the form of enhanced calling ability, but traits associated with defense of mates or territories, such as large body size, enlarged forelimb muscles, or elaborate nuptial pads and spines, are less likely to be important. In terrestrial breeders, such as dendrobatid frogs, a male's ability to persuade a female to mate with him could depend both on his calling or courtship behavior and his ability to provide a suitable oviposition site.

Measuring Sexual Selection in Anuran Populations

Until recently, most studies of sexual selection were designed to demonstrate that males with certain phenotypic characters are more successful than others at acquiring mates (Andersson 1994), and many studies of anurans have followed this approach. Most investigators have not collected data that allow them to directly estimate the strength of sexual selection acting on particular traits, although this approach has been used more frequently in recent studies (B. K. Sullivan, Ryan, and Verrell 1995). To understand how selection operates, we need measurements of the fitness of individuals in natural populations, as well as methods for estimating the effects of selection on various components of fitness. These statistical methods will not be discussed in detail here, but a number of good summaries are available (Arnold 1983a, b; R. D. Howard 1983; Arnold and Wade 1984a, b; W. Sutherland 1985; D. Brown 1988; Clutton-Brock 1988b; Grafen 1988; Koenig, Albano, and Dickinson 1991; Arnold and Duvall 1994).

In considering how sexual selection operates in nature, it is important to distinguish between selection and the evolutionary response to selection (Wade and Arnold 1980; Arnold and Wade 1984a). The former refers to changes in the statistical distribution of phenotypic characters within a generation. For example, if the size distribution of males that acquire mates differs from that of the entire male population, then selection has occurred. However, the evolutionary effect of selection on a phenotypic character (e.g., body size) depends on the way in which that character is inherited. In some cases, as when mating success is correlated with male body size, much of the variance in body size is related to differences in age or to environmental effects, such as the amount of food acquired by each male. Knowledge of the genetic basic of most phenotypic characters, particularly those directly related to fitness, is virtually nonexistent for amphibians, so my discussion will refer mainly to the opportunity for sexual selection. It also is important to distinguish the effects of sexual selection and natural selection, since these work either in the same direction or in opposite directions. The net effect of successive episodes of sexual or natural selection acting on a phenotypic character is referred to as the *total opportunity* for selection (Arnold and Wade 1984a, b).

The key to measuring the opportunity for sexual selection acting on male traits is to collect data on variation in male mating success (Clutton-Brock 1988). Such data can be obtained either through cross-sectional or longitudinal studies (Arnold and Wade 1984b). In some studies of anuran mating systems, only cross-sectional data have been collected. The usual approach is to collect samples of mated and unmated males on a few nights of the breeding season. The samples are then compared with respect to some phenotypic character, such as body size or calling rate (Licht 1976; Wilbur, Rubenstein, and Fairchild 1978; Gittins, Parker, and Slater 1980; Fairchild 1981; Gatz 1981b; J. Lee and Crump 1981; Woodward 1982c; Hemelaar 1983; Crump and Townsend 1990, Lopez and Narins 1991). Such data are relatively easy to collect, but they provide little information about the mating system. It is not possible to estimate total variation in reproductive success from cross-sectional data alone. This type of data can be used to estimate opportunities for sexual selection only if the relative fitness of different phenotypic classes (e.g., different size classes) does not change over time and the phenotypic character being considered does not change with age (Arnold and Wade 1984b). Both assumptions seem unrealistic for most anuran populations, because large and small males often arrive at different times, and body size generally increases with age.

The most useful data on variation in reproductive success are those obtained from longitudinal studies of marked individuals throughout a breeding season. There are problems associated with this approach as well. First, many species are not very good subjects for studies of mating success because one cannot monitor the behavior of individuals with sufficient accuracy to be sure that all matings are observed. It is very difficult to correlate male mating success with other variables when the number of matings observed in a population is very small (e.g., Fellers 1979b; Lopez and Narins 1991; B. K. Sullivan 1992; Bertram, Berrill, and Nol 1996). Second, there is the problem of choosing an appropriate measure of reproductive success. For most anurans, the appropriate measure is the number of matings obtained by each male, since variation in mating success is the best measure of the intensity of sexual selection. Other measures, such as the number of eggs fertilized, number of hatchlings produced, or the number of offspring surviving to reproductive age (R. D. Howard 1979) often are not practical, and they measure variables affected by both sexual selection and other components of selection, such as fecundity selection (Arnold and Wade 1984b). In species in which direct sperm competition is a possibility, as in rhacophorid or phyllomedusine frogs with multimale matings, measuring mating success accurately is difficult without genetic analyses of parentage.

A third problem is the time over which estimates of reproductive success are made. Most studies of reproductive success in anurans and most attempts to calculate selection intensities or opportunities for sexual selection have considered only selection within breeding seasons (Kluge 1981; B. K. Sullivan 1983b, 1986b; Arnold and Wade 1984b). Opportunities for selection vary considerably from pond to pond or from year to year in the same population (B. K. Sullivan 1986b), but the intensity of sexual selection over the lifetime of an individual cannot be estimated from these data. Consequently, data on variation in lifetime reproductive success of both males and females are needed for a complete understanding of sexual selection (Wade 1979; Wade and Arnold 1980; Clutton-Brock 1983, 1988; Arnold and Wade 1984b). Unfortunately, such estimates are difficult to obtain and are available for only a few animal species (Clutton-Brock 1983, 1988). These data indicate that seasonal and lifetime estimates of reproductive success are not always tightly correlated, especially if reproductive success is strongly affected by age (Clutton-Brock 1983).

Actual data on lifetime reproductive success are not available for any anuran species, but R. D. Howard (1983, 1988a) used data on age-specific survivorship and reproductive success to estimate lifetime reproductive success for *Rana catesbeiana* and *R. sylvatica* from computer simulations. In both species, seasonal reproductive success of males was heavily skewed, with many individuals producing no offspring, and a few males producing many. The number of unsuccessful males was especially high in *R. sylvatica* because of a heavily male-biased sex ratio at the breeding pond (R. D. Howard and Kluge 1985; R. D. Howard 1988a). In *R. catesbeiana,* some males mated several times in a season while others never mated, and male reproductive success was much more variable than that of females (fig. 8.23).

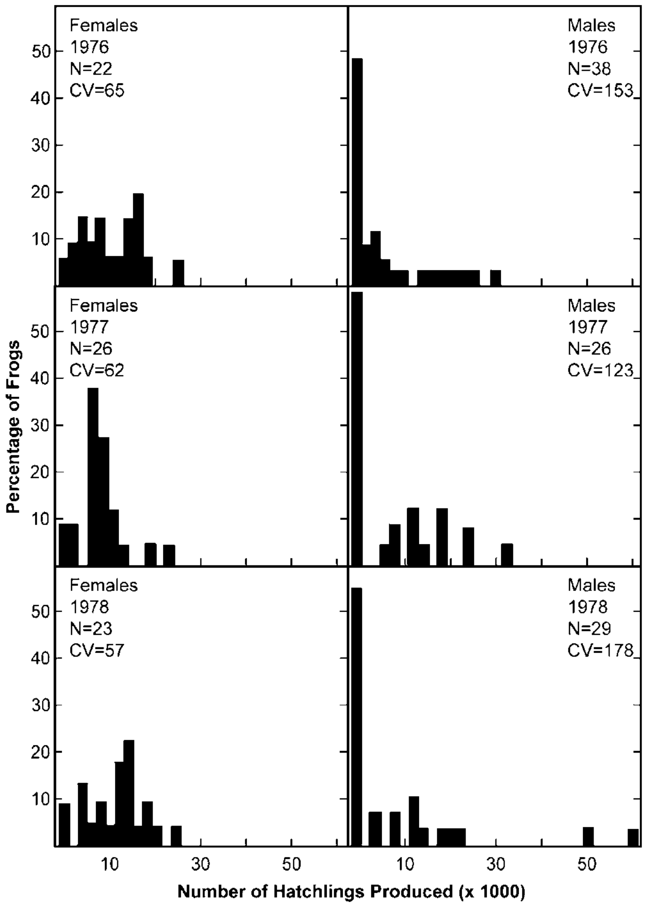

Fig. 8.23. Comparison of seasonal estimates of the number of offspring produced by male and female bullfrogs (*Rana catesbeiana*) in Michigan. The higher variance in males was due primarily to some individuals acquiring several mates in one season and only secondarily to the fecundity of their mates. After R. D. Howard (1983).

In both species, estimates of variation in lifetime reproductive success, measured as the number of zygotes produced, were much greater in both sexes than seasonal variation in reproductive success. This was due to the strong influence of survivorship on lifetime estimates. However, the difference between males and females decreased in both species when lifetime estimates were used. This does not necessarily mean that the intensity of sexual selection acting on the two sexes is similar. Since lifetime reproductive success in both species is strongly influenced by adult survivorship (a component of natural selection), variation in lifetime reproductive success alone provides a poor estimate of the opportunity for sexual selection (R. D. Howard 1988a). The importance of sexual selection over the lifetime of the animal can be estimated only if the relative effects of natural and sexual selection are partitioned in the same way as the data from a single season (Arnold and Wade 1984b; Koenig, Albano, and Dickinson 1991).

An additional problem in assessing the potential effect of sexual selection on phenotypic characters is a lack of information on how different phenotypic traits are correlated with one another. Most studies of sexual selection in anurans and other animals have tended to focus on single characters, particularly body size (Arnold and Wade 1984b; Koenig, Albano, and Dickinson 1991). Occasionally, behavioral traits such as calling rate are considered as well (e.g., B. K. Sullivan 1983b). Different phenotypic traits often are either positively or negatively correlated with one another, and selection can affect one trait indirectly by acting on a correlated character (Arnold and Wade 1984b). This makes statistical analysis of the data much more complicated, because covariance between phenotypic traits must be considered. To date, very few studies of sexual selection in anurans have adequately documented the relationship of reproductive success to morphological characters other than body size.

Arnold and Wade (1984b) used R. D. Howard's (1979) data on one season's mating success in bullfrogs (*Rana catesbeiana*) to estimate the relative contribution of sexual and natural selection to total selection on male body size. Variation in number of matings provided an estimate of the opportunity for sexual selection, whereas variation in number of eggs per mate and hatching success provided estimates of fecundity selection. Arnold and Wade concluded that sexual selection was the major force favoring large body size in male bullfrogs, accounting for 75% of the total selection differential (i.e., the change in mean body size after selection). In contrast, fecundity selection, acting through number of eggs per mate and hatching success, accounted for only 25% of the total selection differential. To estimate relative contributions to the total opportunity for selection on male body size, it also was necessary to consider covariation between the different measures of fitness (number of mates, number of eggs per mate, hatching success). Arnold and Wade found that sexual selection accounted for 59% of the total opportunity for selection on male body size. Lifetime reproductive success would be heavily influenced by size- or age-specific survivorship of males, a component of selection not considered in this single-season analysis.

Sexual Selection and Sexual Dimorphism

Darwin (1871) originally proposed his theory of sexual selection to account for the evolution of sexually dimorphic characters that he believed could not be explained by ordinary natural selection. He recognized that polygynous species (those with high variance in male reproductive success) generally exhibit greater sexual dimorphism than monogamous species. This pattern has been supported by subsequent studies of birds and mammals (Selander 1972; Clutton-Brock, Harvey, and Rudder 1977; Clutton-Brock, Albon, and Harvey 1980; Alexander et al. 1979; Clutton-Brock 1983; Payne 1984), although there are exceptions (Ralls 1976, 1977). Several investigators have discussed the relationship of sexual dimorphism to social behavior in amphibians and reptiles (Shine 1978, 1979; Wells 1978b; Berry and Shine 1980; R. D. Howard 1981b; Woolbright 1983, 1989; R. D. Howard and Kluge 1985; Halliday and Verrell 1986; J. Lee 1986; Halliday and Tejedo 1995; Monnet and Cherry 2002), but much remains to be done. Most anurans exhibit some type of sexual difference in morphology or coloration that allows males and females to be readily distinguished, but in many cases, the functional significance of these differences is not well understood. The most noticeable difference in most species is the presence of vocal sacs in males, a trait obviously related to calling behavior. Many species also are sexually dimorphic in body size or exhibit sexual differences in limb morphology, muscle structure, skin color, skin texture, and other traits (Noble 1931; Duellman and Trueb 1986). I will focus primarily on traits that seem most likely to be related to sexual selection, even when the functional significance of the traits is unclear.

Sexual Dimorphism in Body Size

Because many anurans continue to grow throughout their lives, interpreting patterns of sexual size dimorphism presents some problems. Apparent differences in body size in a population can reflect different age structures brought about by differential predation on the two sexes or delayed maturity in one sex (R. D. Howard 1981b; Márquez, Esteban, and Castanet 1997; Monnet and Cherry 2002; Gramapurohit, Shanbhag, and Saidapur 2004a). If so, then sexual size dimorphism would not be due to selection for different growth rates. For example, Monnet and Cherry (2002) presented a statistical analysis of size and age, controlled for phylogeny, in a variety of anuran species. They found a strong correlation between the average difference in age between males and females in a population and degree of sexual dimorphism. In most populations included in their analysis, females were older than males and reached larger sizes. This suggests that females often delay sexual maturity and continue to grow, or suffer lower rates of mortality. Monnet and Cherry (2002) concluded that sexual selection is of minor importance in determining patterns of sexual dimorphism in anurans. Nevertheless, early sexual maturity in males can itself be a sexually selected trait that could result in males being smaller than females. Furthermore, their sample included very few species in which males are larger than females, so a role for sexual selection in the evolution of large male body size cannot be ruled out.

In contrast to many birds and mammals, females of most anuran species are considerably larger than males (Shine 1979; Monnet and Cherry 2002). Selection probably favors large body size in females because larger females produce larger clutches of eggs (see chapter 10). In some species, however, males are as large as or larger than females. In some populations of *Bombina bombina* and *B. variegata,* males are as large as or larger than females and exhibit sexual dimorphism in other traits, such as hind leg length and head width. The functional significance of these differences is not clear, however (Radojičić et al. 2002). In temperate-zone ranids, females of explosive breeders such as *Rana sylvatica* and *Rana temporaria* are considerably larger than males (Wells 1978b; R. D. Howard 1980; Berven 1981; R. D. Howard and Kluge 1985; Ryser 1986). In contrast, males and females of territorial species such as *Rana catesbeiana* and *R. clamitans* grow at similar rates and reach similar maximum sizes (Martof 1956a; Durham and Bennett 1963; Schroeder and Baskett 1968; Wells 1978b; R. D. Howard 1981b). In these species, large males win more fights than small males, and spend more time defending territories (fig. 8.24). The same is true for *Hyla rosenbergi* and related species that engage in territorial combat, and again, males tend to be as large as or larger than females in these species (Kluge 1981; Martins and Haddad 1988). Males of the hylid genus *Plectrohyla* also tend to be as large as or slightly larger than females (Duellman and Campbell 1992). These frogs have not been observed fighting, but they have several other morphological features that suggest that male combat is common (see the following). In the African frogs *Pyxicephalus adspersus* (fig. 8.25; Stewart, 1967; T. Hayes and Licht 1992) and *Petropedetes johnstoni* (H. Parker 1936), males are much larger than females. The size differences in *Pyxicephalus* results from higher growth rates in young males than in young females (T. Hayes and Licht 1992). Males are known to fight vigorously among themselves during the breeding season (B. Balinsky and Balinsky 1954; Channing, du Preez, and Passmore 1994). In several species of *Leptodactylus,* some of which are known to exhibit male combat, males are at least as large as females (Shine 1979).

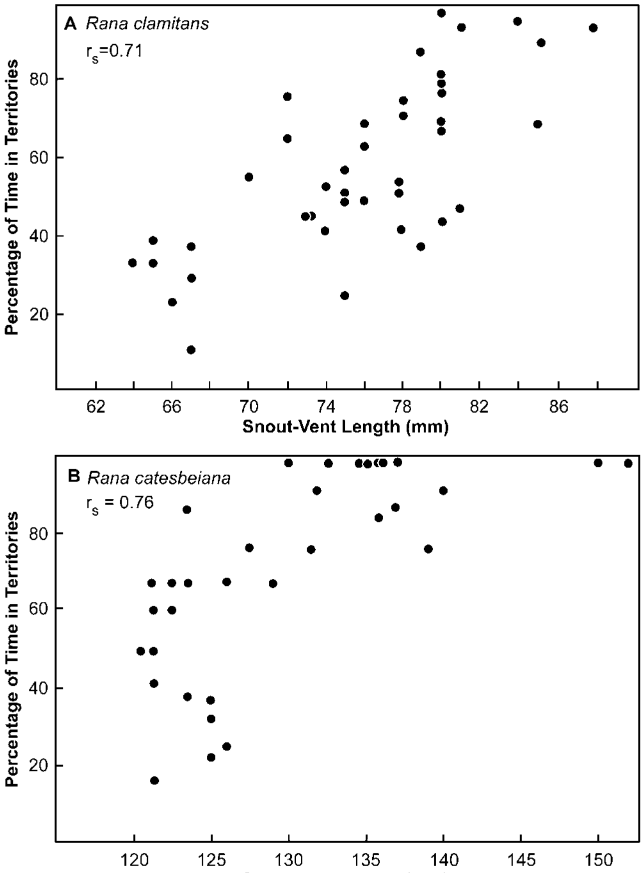

Fig. 8.24. Amount of time spent defending territories as a function of male size in two prolonged-breeding North American ranid frogs. (A) *Rana clamitans* from upstate New York. (B) *Rana catesbeiana* from Michigan. Plotted from data in (A) Wells (1976a) and (B) Emlen (1976).

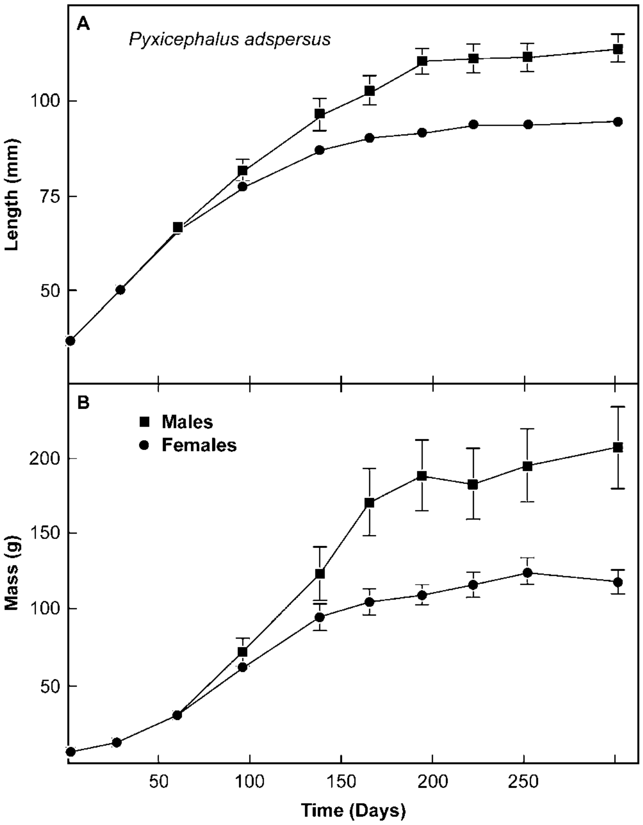

Fig. 8.25. Sexual dimorphism in the African ranid frog *Pyxicephalus adspersus.* (A) Rate of growth in length in males and females. (B) Rate of growth in mass in males and females. After about two months, males grow at much faster rates than do females and reach larger asymptotic sizes. After T. Hayes and Licht (1992).

Similar sexual dimorphism in body size is found in the fanged ranid frogs (*Limnonectes*) of Southeast Asia (the current taxonomy of this group is confusing, with numerous unnamed species currently grouped together under the same names; Emerson and Ward 1998; Emerson et al. 2000; Emerson 2001a; B. Evans et al. 2003). In most species, males are larger than females, have wider heads, and are equipped with hypertrophied jaw muscles and fangs on the lower jaw (fig. 8.26 A). Males of several species of fanged frogs have been observed biting one another in fights over territories around nest sites (Orlov 1997; Tsuji and Matsui 2002). There is variation among species, however, in the degree of sexual dimorphism. The ancestral condition for the clade appears to be male body size larger than female body size, with large fangs in males, but both smaller fangs and larger female body size have evolved multiple times in the group. Although males are larger than females in all species with large fangs, males also are larger in some species with smaller fangs (Emerson 2001a). The evolution of larger body size in males and changes in the size and shape of the head probably are related to sexual selection for fighting ability in males and not to ecological differences such as

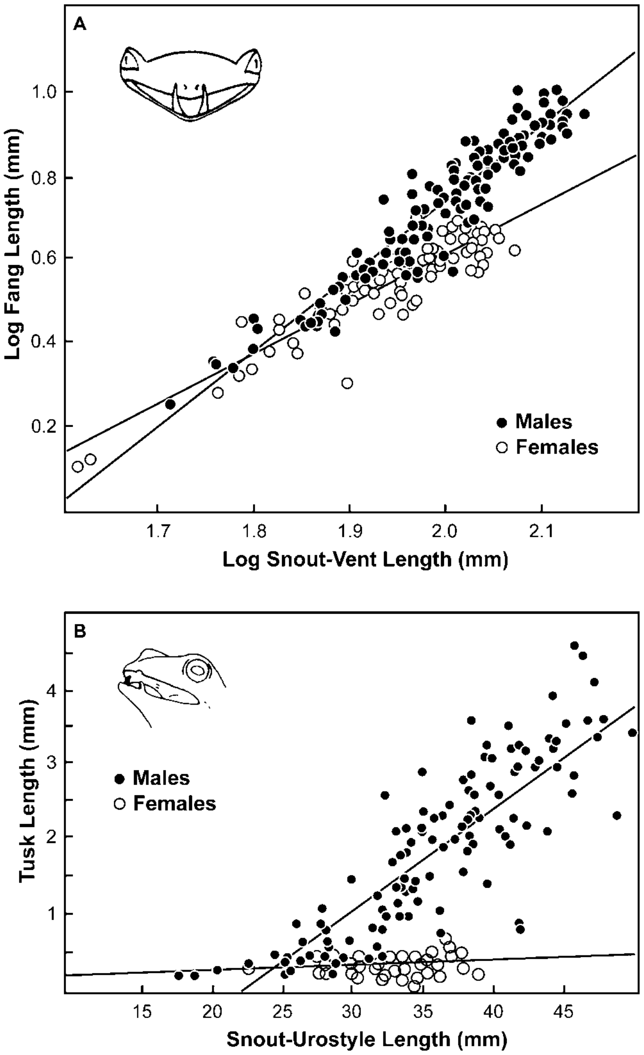

Fig. 8.26. Sexual dimorphism in weapons used for fighting by male frogs. (A) Sexual dimorphism in fang length in *Limnonectes leporinus.* After Emerson and Voris (1992). (B) Sexual dimorphism in tusk length in *Atelotus brevis.* After Katsikaros and Shine (1997).

prey selection (Emerson and Inger 1992; Emerson and Voris 1992; Emerson 1994, 1996; Emerson and Ward 1998). Conversely, the evolution of female body size larger than male body size appears to be associated with the evolution of small fangs in males, small body size, and a switch to terrestrial modes of reproduction (Emerson 2001a).

An analysis of sexual dimorphism in the Australian myobatrachid *Atelotus brevis* similarly suggested that sexual selection rather than ecological differentiation is responsible for differences between males and females (Katsikaros and Shine 1997). Males grow larger than females, have larger heads, and are equipped with tusks in the lower jaw, used for fighting (fig. 8.26 B). Males and females eat somewhat different types of prey, but this appears to reflect differences in microhabitat selection rather than differences in body morphology. Males reach larger sizes than do females in several other groups of frogs in which males probably fight with one another, but their behavior has been poorly studied. These include the Asian ranids *Paa* (= *Rana*) *boulengeri* and *P. yunnanensis* (= *Rana phrynoides;* C. Liu 1950) and some Asian stream-breeding megophryid frogs, including some species of *Scutiger* and species in the genus *Vibrissaphora* (Ho et al. 1999). Males of the latter genus are known to build nests under rocks in streams and almost certainly are territorial, but the behavior of *Scutiger* is not well known.

The relationship between male combat and large male size is not very robust when all anurans are considered. Shine (1979) suggested that males should be as large as or larger than females in species with male combat, but this certainly is not true for most small hylids. Many of these were classified as nonfighting species by Shine, but in fact, most probably exhibit aggressive defense of calling sites (table 8.1). Actual physical combat tends to be infrequent, however, with most aggressive encounters being resolved through exchange of vocalizations. Consequently, body size could have relatively little effect on a male's ability to maintain a territory, and therefore little influence on male reproductive success. Patterns of sexual dimorphism cannot be predicted from information on mating systems alone; data on the way in which phenotypic characters influence reproductive success in the two sexes are needed as well, because it is these characters that are subject to sexual selection (Clutton-Brock 1983). Furthermore, even when sexual selection favors large body size in one sex or the other, other selective pressures can favor small body size, so the evolutionary outcome is difficult to predict (Arnold 1983b; Arnold and Wade 1984b; Halliday and Verrell 1986; Halliday and Tejedo 1995).

Woolbright (1983) proposed an explanation for patterns of sexual size dimorphism in anurans based on the combined effects of sexual selection and energetic constraints on males and females. He suggested that the ratio of male to female size should be related to the proportion of the growing season used for reproductive activities, as well as the relative advantage enjoyed by large males in obtaining mates. Woolbright's model is based on several assumptions: (1) that sexual selection always favors large body size in male anurans, (2) that selection for increased clutch size always favors large body size in females, and (3) that energetic constraints on males limit growth rates and hence adult body size.

Woolbright predicted that females should be larger than males in explosive breeders from the temperate zone because the intensity of sexual selection acting on males should be relatively weak, so selection for increased body size would not be very strong. He predicted that in prolonged breeders from the temperate zone, males would be as large as or larger than females, because sexual selection for large body size would be more intense. However, Woolbright argued that in tropical species, a very long breeding season would impose severe energetic constraints on males, so growth rates would be limited and males could not reach a size comparable to females.

Woolbright (1989) demonstrated that *Eleutherodactylus coqui* males raised in the laboratory grew at rates equivalent to those of females and reached a similar size, whereas males in the field had much slower growth rates and were smaller than adult females. The energy limitation hypothesis also is consistent with a study by Given (1988a) showing a direct tradeoff between calling rates and growth rates of small *Rana virgatipes* males. Nevertheless, a number of the assumptions of Woolbright's model do not appear to be valid for all anurans, and therefore the model probably is too simplistic to provide a general explanation of sexual dimorphism for all species (B. K. Sullivan 1984).

One problem is that Woolbright failed to consider increased energetic investment in multiple egg clutches by females of prolonged breeding species, so it is not necessarily true that males of these species expend more energy relative to females than do males of explosive breeding species. Furthermore, the long breeding seasons of many tropical species do not necessarily translate into greater energetic constraints on male growth; some males simply abandon reproductive activities for extended periods to replenish energy reserves. Males of different species also exhibit a variety of calling tactics, some probably very expensive and some less so (see chapter 5). Finally, the assumption that sexual selection always favors large male body size is not necessarily valid, nor is there any clear evidence that sexual selection on male body size is stronger in tropical species with long breeding seasons. In fact, the most convincing evidence for a large-male mating advantage comes from studies of explosive breeding species from the temperate zone, just those species for which Woolbright predicted sexual selection on body size should be the weakest. Even patterns of sexual dimorphism reported in the literature are not always consistent with the model. For example, in some tropical frogs with long breeding seasons, males are smaller than females, while in others they are similar in size (Crump 1974).

Sexual Dimorphism in Limb Morphology

In addition to differences in body size, anurans exhibit many other forms of sexual dimorphism. One common type is a difference in the proportions of the forelimbs, with those of males generally being larger or more robust than those of females. In many explosive breeding ranids, including *Rana sylvatica*, *R. pipiens*, and *R. temporaria*, the male's arms completely encircle the female during amplexus, with his front toes entwined under the female's body (Banta 1914; Noble and Aronson 1942; R. Savage 1961). This enables a male to hold on firmly while repelling other males attempting to steal his mate. R. D. Howard and Kluge (1985) hypothesized that sexual selection should favor elongation of the arms in males, and measurements of *Rana sylvatica* revealed that males have longer arms relative to body length than females (fig. 8.27). In contrast, males of the territorial species *R. clamitans* do not completely encircle the female during amplexus, and there is no evidence that males have longer arms than females (fig. 8.28 bottom). Males do wrestle with each other, and arm strength probably is a major determinant of fighting success. Measurements of forelimb proportions revealed that both upper arm diameter (fig. 8.28 top) and forearm diameter are greater in males than in females (Wells, unpublished data).

Tests of Howard and Kluge's hypothesis with other species have yielded mixed results. R. D. Howard (1988b) found no evidence that forelimb length influenced male mating success in *Bufo americanus*, and there was no sexual dimorphism in limb length. J. Lee (1986) found that in two explosive breeding toads, *Bufo terrestris* and *B. marinus*, males in amplexus had relatively longer forelimbs than unmated males, but only in *B. marinus* was this reflected in a slight sexual dimorphism in limb length. No such relationship was found in two other toads, *B. quercicus* and *B. valliceps*, species in which direct competition among males for possession of females was thought to be rare.

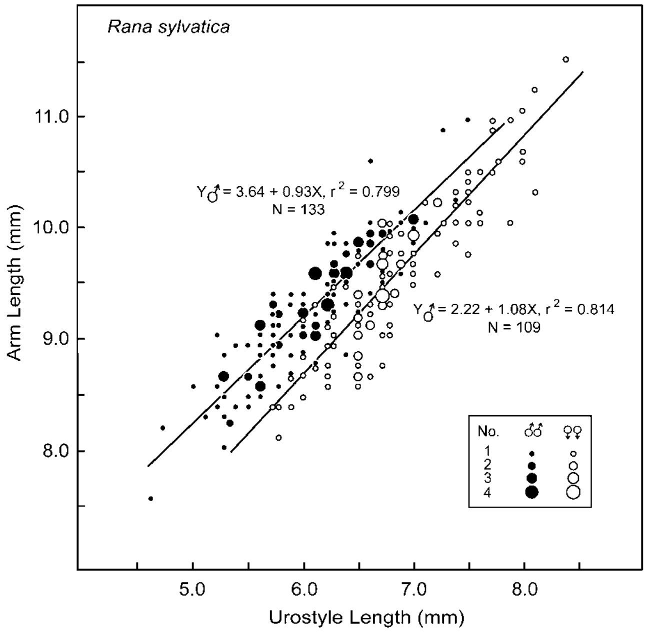

Fig. 8.27. Sexual dimorphism in arm length in *Rana sylvatica*. Males have longer arms relative to body length than do females. Here, the length of the urostyle is used as an index of body size. After R. D. Howard and Kluge (1985).

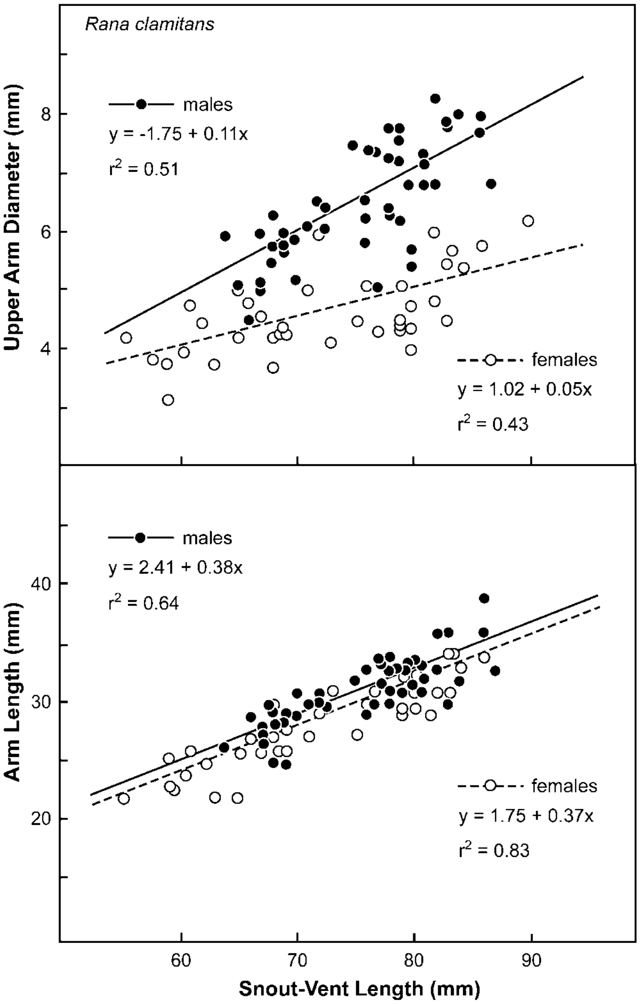

Fig. 8.28. Sexual dimorphism in upper arm diameter (top) and arm length (bottom) in *Rana clamitans.* Males have more robust but not longer arms than do females. Data are based on measurements of preserved specimens in the Cornell University collection (K. D. Wells, unpublished data).

There also was no evidence that arm length influenced mating success in an explosive-breeding hylid, *Triprion petasatus,* nor was there any evidence of sexual dimorphism in limb length. The same was true for another hylid, *Hyla marmorata,* but the mating system of this species has not been studied in detail.

One difficulty with these tests is that classifying the species simply by their mating systems obscures major differences in clasping behavior that in turn reflect major differences in the functional morphology of the forelimbs. Most authors simply categorize amplexus in anurans as being axillary (clasping the female under the forelimbs) or inguinal (clasping the female in front of the hind limbs; Duellman and Trueb 1986). Variation in clasping behavior actually is much more complex (Jameson 1955a). In most species of *Bufo,* for example, the male does not completely encircle his mate with the forelimbs, but instead presses his "fists" into the axillae of the female (R. Savage 1934; M. Smith 1969). Consequently, a male's ability to retain possession of a female probably is related more to forelimb strength than to its length, and this in turn is reflected in more massive development of certain muscles involved in holding the female (Emerson 1991). Indeed, subsequent work by Lee (2001) on *Bufo marinus* showed that forelimbs of males are much more robust than are those of females, and males with large forelimbs were more likely to be found in amplexus. Males of this species also have more robust hind limb muscles than do females, but it is not clear whether this difference is a result of sexual selection for more powerful leg muscles or a side effect of hormonally controlled hypertrophy of muscles in general (Lee and Corrales 2002).

In many anurans, the arm of the male has a greater diameter relative to its length than that of the female, and the front feet often are bent inwards (C. Liu 1936). This reflects greater development of the *flexor carpi radialis* muscle in males, as well as several other muscles involved in flexing the hand and forearm (Muller, Galavazi, and Szirmai 1969; Melichna et al. 1972; Thibert and Nicolet 1972; Kirby 1983; Rubenstein, Erulkar, and Schneider 1983; Oka et al. 1984; Yekta and Blackburn 1992; Peters and Aulner 2000; Lee 2001). Not only are these muscles larger in males than in females, but they also have more slow-tonic fibers and a greater capacity for prolonged tonic contraction, which enables the male to hold onto the females for hours or even days (Wacholder and von Ledebur 1930; Rubenstein, Erulkar, and Schneider 1983; Peters and Aulner 2000). The role of various forelimb muscles in clasping has scarcely been investigated, and indeed, comparative studies combining observations of clasping behavior with detailed functional analyses of limb morphology offer a wide open field for future investigators (Emerson 1991).

Even more dramatic examples of sexual dimorphism in limb morphology can be found in some tropical anurans, but often we have only sketchy information on their behavior. In most large species of *Leptodactylus,* including *L. pentadactylus, L. insularum, L. ocellatus,* and *L. chaquensis,* males are as large as or larger than females (Gallardo 1964; Heyer 1979b; Cei 1980) and have greatly enlarged arms compared to those of the female (fig. 8.29). The huge size of the arms in males mainly results from hypertrophy of the forearm flexor muscles. For example, in *L. ocellatus,* the *flexor carpi radialis* muscle can be nearly 20 times more massive in males than in females of the same body size, but there is little or no dimorphism in forearm extensor muscles (Scow 1965). These muscles are anchored on wide flanges that develop on the humerus of the male that are absent in females (Lynch 1971; Duellman and Trueb 1986). Similar enlargement of forelimb muscles and humeral flanges are

Fig. 8.29. Sexual dimorphism in the size of the arm in *Leptodactylus insularum* from Panama. (A) Male. (B) Female. Males develop hypertrophied arms in the breeding season and probably wrestle with one another. Photos by Kentwood D. Wells.

found in hylid frogs of the genus *Plectrohyla* as well (Duellman 1970; Duellman and Campbell 1992). Hypertrophied forelimbs are characteristic of males in several other groups of stream-breeding hylids, including *Hyla armata* and the *Hyla pulchella* group (Duellman 1970). These hylids are not closely related to one another, so the enlarged forelimbs of males are thought to have evolved independently several times (Duellman, de la Riva, and Wild 1997). Unfortunately, the behavior of these species is poorly known, so the function of the enlarged forelimbs is unknown, but it seems likely that males fight among themselves in at least some of these species.

In many frogs with hypertrophied forelimbs in males, there also are various kinds of sharp spines on the front feet, usually in the "thumb" region. For example, many species of *Leptodactylus* have sharp spines on the front feet, forelegs, or chest. Early workers (e.g., Noble 1931; C. Liu 1936) interpreted such structures as adaptations for enhancing a male's ability to hold onto a female during amplexus. In many species, however, enlargement of the forearms probably is associated with male combat, and males of several species are known to use spines to jab opponents in fights (Rivero and Esteves 1969; Wells 1977b; Shine 1979). The naturalist W. H. Hudson (1903) described the enormous arms and sharp spines of a male *Leptodactylus* and referred to the species as "the wrestler," but he believed these structures served mainly to protect the frog from its enemies. Large male size, enlarged arms, and spines also are characteristic of the Australian myobatrachid *Limnodynastes peronii*. J. Moore (1961) believed the male used the spines to clasp the female, but this species is known to be territorial and to engage in wrestling bouts during the breeding season (Clyne 1967, 1969).

Enlarged forelimbs, often armed with spines, are found in male frogs in other families around the world. For example, enormous forelimbs and a variety of spines are found in males of several Asian ranids, including *Paa boulengeri*, *P. phrynoides* (fig. 8.30), *P. spinosa*, *Rana holsti*, and *R. subaspersa* (Pope 1931; C. Liu 1935a, 1936, 1950; Inger

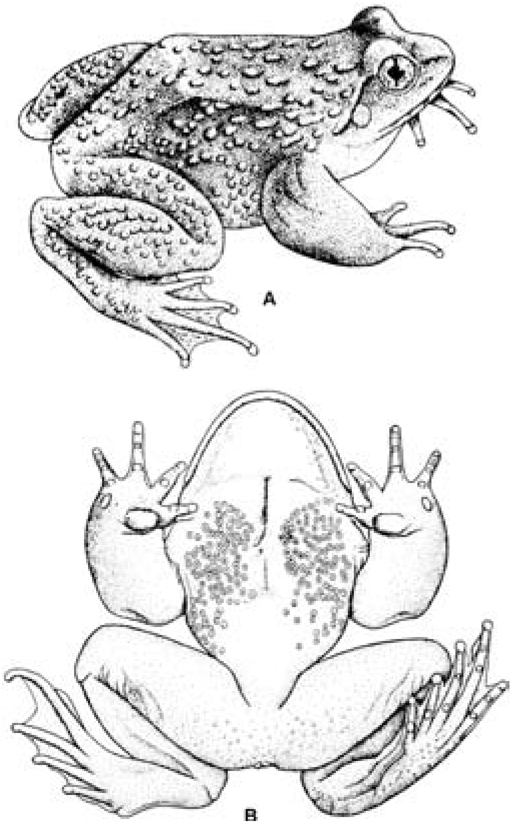

Fig. 8.30. Male of a large stream-breeding ranid frog, *Paa phrynoides,* from western China, showing (A) enlarged arms and (B) ventral spines. After C. Liu (1950).

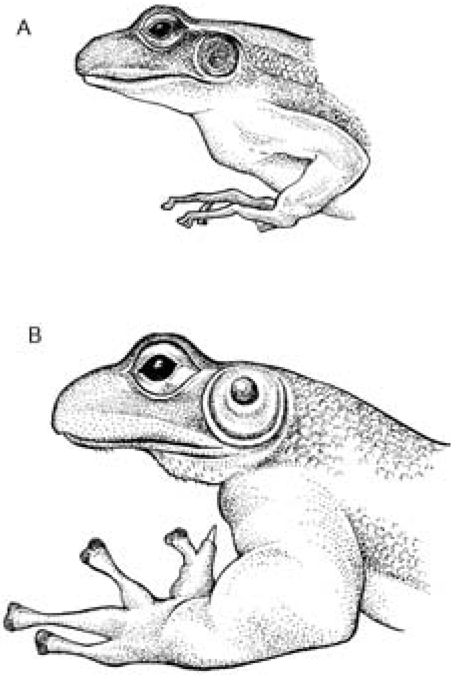

Fig. 8.31. Sexual dimorphism in the African frog *Petropedetes johnstoni.* (A) Female, showing slender arms. (B) Breeding male, showing robust arms and well-developed metacarpal spine. Many males also have scars that probably are derived from wounds received from the spines of other males during fights. Drawing by Mary Jane Spring after H. Parker (1936).

1947; Okada 1966). Unfortunately, their social behavior has not been studied. However, C. Liu (1950) reported that *P. boulengeri* males tend to remain in one place, with only one individual inhabiting a given pool; this suggests that males are territorial. *Rana subaspersa* lays eggs in mud nests similar to those constructed by *Hyla rosenbergi* (Utsunomiya and Utsunomiya 1983) and might be expected to have a similar mating system. Mature males of the African frog *Petropedetes johnstoni* also have enlarged forelimbs and sharp metacarpal spines (fig. 8.31). These characters apparently develop seasonally and are absent in mature, nonbreeding males (H. Parker 1936). Again, the social behavior of this species is unknown, but Sanderson (1936) reported that many nonbreeding males showed "laceration on the gular region, presumably relics of the preceding breeding period."

Sharp spines also are found in a number of groups of treefrogs. These include the nest-building gladiator frogs (*Hyla boans, H. faber, H. pardalis, H. rosenbergi,* and related species). The use of spines in combat by males in *Hyla rosenbergi* and related species was discussed earlier (see fig. 8.12). The forelimbs of the male are not greatly enlarged in these species (Kluge 1981). Prepollical spines are found in several other groups of Neotropical hylids that do not have enlarged forelimbs, including the *Hyla albomarginata* group, the *H. albopunctata* group, the *H. geographica* group, and the *H. granosa* group, but the function of the spines has not been determined in these frogs.

The *Hyla pulchella* group of Andean treefrogs and the *Hyla circumdata* group of southeastern Brazil both have sharp, prepollical spines as well as enlarged forelimbs in males, and on the basis of these characters, were combined into a single clade by Duellman, de la Riva, and Wild (1997). Again, the behavior of males and the use of the spines are unknown in these groups. The only other hylids that combine prepollical spines with enlarged forelimbs are frogs of the genus *Plectrohyla.* The prepollical processes in these frogs vary from blunt to very sharp in different species, suggesting they serve different functions. In two species with sharp spines, males in museum collections have scars on the head and forelimbs that suggest the use of the spines in combat (Duellman and Campbell 1992). Males of one South American hylid, *Hyla armata,* are unique in having clusters of spines on both the inner surface of the hand and on the humerus, as well as greatly hypertrophied forelimbs (fig. 8.32 D). It is not known whether these are used in male combat, to hold the female in amplexus, or both (Duellman, de la Riva, and Wild 1997). Sharp humeral spines also are found in centrolenid frogs of the genus *Centrolene,* and as discussed earlier, these apparently are used in fighting between males (Bolívar-G., Grant, and Osorio 1999).

Many male anurans that lack obvious weapons such as

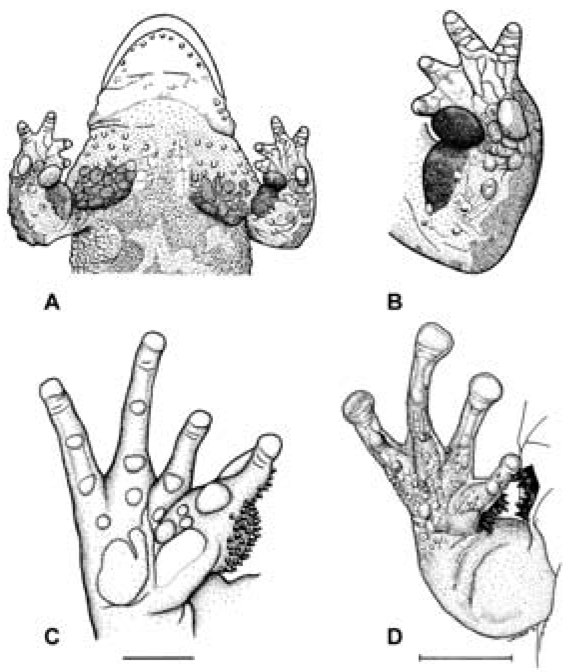

Fig. 8.32. Nuptial pads and spines on the feet of male anurans. (A, B) *Bombina maxima,* a bombinatorid frog that breeds in streams and pools in western China. (C) *Telmatobius truebae,* a stream-breeding leptodactylid frog from Peru. (D) *Hyla armata,* a stream-breeding hylid frog from the Andes of South America. (A, B) After Liu (1950); (C) After J. J. Wiens (1993); (D) After a drawing by Amy Lathrop from Duellman, de la Riva, and Wild (1997).

thumb spines do have nuptial pads or keratinized excrescences on the forelimbs or chest, which usually have modified mucus glands associated with them (fig. 8.32 A; C. Liu 1936; Duellman and Trueb 1986; Epstein and Blackburn 1997). Most authors have assumed that these structures help the male hold onto the female and prevent the female from escaping (e.g., Noble 1931; Duellman and Trueb 1986). Some have argued that well-developed nuptial pads are associated with breeding in water, with less-developed structures being found in terrestrial breeders (Duellman and Trueb 1986). Presumably this is because females would be more difficult to hold in water, particularly running water. Indeed, Paul Kammerer's famous experiments on the development of nuptial pads in the midwife toad (*Alytes obstetricans*) were based on the premise that breeding in water should induce pad development. By forcing the normally terrestrial toads to mate in water, he expected to produce heritable increases in the size of nuptial pads after several generations. Kammerer's career was destroyed when G. K. Noble showed that the nuptial pads on a key specimen had been faked (Koestler 1971; Aronson, 1975). Ironically, the original premise of the experiment was flawed, because the association between nuptial pads and aquatic reproduction seems to be partly spurious. A more likely reason for the lack of nuptial pads in midwife toads is the absence of intense male-male competition for females in these frogs.

R. M. Savage (1961) probably was the first to suggest that nuptial pads are not primarily adaptations for preventing the female from escaping, but rather enable the male to hold the female while fending off rival males. Consequently, the evolution of nuptial pads and other devices for grasping the female should be viewed in the context of mate guarding behavior, rather than mating behavior per se. Viewed in this context, one would predict that nuptial pads will be well developed in explosive breeders with extensive male-male competition for females, but not necessarily in prolonged-breeding, territorial species. This seems to be true for North American ranids. Explosive breeders such as *Rana sylvatica* typically have very large nuptial pads, but in territorial species such as *R. clamitans* and *R. catesbeiana,* the thumb of the male is somewhat enlarged, but there is no keratinized nuptial pad (Wright and Wright 1949; Wells, unpublished observations). Nevertheless, the elaborate nuptial excrescences of some species probably are adaptations for holding onto females in running water. For example, in some Chinese ranids that breed in mountain streams, males have extensive excrescences on the forelimbs, and much of the ventral surface of the body is covered with short spines (fig. 8.30 B), providing a rough texture for holding the female (C. Liu 1936, 1950). Very large, spiny nuptial pads also are characteristic of many other stream-breeding frogs (fig. 8.32).

Sexually Dimorphic Integumentary Structures

In addition to nuptial pads and the various kinds of spines that develop on the forelimbs and integument of some male frogs, there are a number of examples of sexual differences in integumentary structure. In many cases, the function of these structures is unknown. Males of the so-called hairy frog (*Trichobatrachus robustus*) from West Africa develop strange fringe-like projections from the skin during the breeding season (see fig. 1.12 D in chapter 1). These have been interpreted as supplementary respiratory structures (see chapter 4), but the biology of this frog has not been investigated in detail, and its behavior during the breeding season is unknown. In megophryid frogs of the genus *Vibrissaphora* from Southeast Asia and China, males have rough pustules on the skin that are lacking in females, and they develop bizarre keratinized spines on the upper jaw during the breeding season (fig. 8.33). Males apparently defend oviposition sites under rocks in streams and guard their eggs after they are laid. Ho et al. (1999) suggested that the keratinized spines are used to fend off predators that threaten the eggs, but the actual use of these structures has not been observed in the field. It seems equally likely that they are involved in some aspect of courtship or aggressive interactions among males.

Many other anurans exhibit sexual differences in skin texture, with either the male or female having rough or spiny skin that is not found in the other sex. These differences might function as tactile cues for sex recognition (Duellman and Trueb 1986), but in no case has the function of these differences been studied in detail. The same is true for sexual differences in coloration, which is especially common in toads that are diurnally active (Kagarise Sherman 1980). In some species, such as *Bufo canorus,* females are more brightly colored than are males, whereas in others,

Fig. 8.33. Male of the megophryid frog *Vibrissaphora ailaonica* from Vietnam, showing keratinized spines on upper lip. These develop during the breeding season, but their function is unknown. Drawing by Amy Lathrop from Ho et al. (1999).

such as *Bufo periglenes,* the male is more brightly colored. Marked sexual differences in coloration also are found in some hyperoliid frogs (Schiøtz 1967, 1999; T. Hayes and Menendez 1999). Again, these differences could be used for sex recognition, although this has not been demonstrated experimentally. The use of visual cues in mate choice has been demonstrated in a species of dendrobatid frog, *Dendrobates pumilio,* but in this case, females discriminated between different color morphs in a polymorphic species, rather than recognizing a characteristic male color (Summers, Symula, Clough, and Cronin 1999).

Some frogs have glands of unknown function on various parts of the skin, and in many cases, these are sexually dimorphic or found only in one sex (Duellman and Trueb 1986; Thomas, Tsang, and Licht 1993; Brizzi, Delfino, and Jantra 2003). For example, glands are found on the ventral surface of the body or legs in males of some microhylid, hylid, and mantelline frogs (Duellman and Trueb 1986). Ventral glands are known to produce mucus secretions that glue the male to the female during amplexus in some rotund microhylids (see chapter 10), but the function of the glands is not known in other frogs. They could assist the male in adhering to the female, or they could produce pheromones that are transferred to the female during courtship or amplexus. Sexually dimorphic glands are found in the dorsal skin of males of several European ranids (*Rana dalmatina, R. iberica,* and *R. italica*) that do not have vocal sacs. Brizzi, Delfino, and Pellegrini (2002) suggested that these glands produce pheromones that compensate for reduced acoustic signalling in these frogs, but experimental evidence is lacking.

Treefrogs of the genus *Plectrohyla* have unusual skin glands that might be used in sexual behavior. During the breeding season, the upper lip of the male becomes swollen, and in some species, unusually long maxillary and premaxillary teeth actually protrude through the lips. These could be used to scrape the skin of the female, to inoculate her with pheromones, as in some plethodontid salamanders (see chapter 9). Indeed, females of at least one species have been found with scratches on the head and back that could have been caused by the teeth of males (Duellman, de la Riva, and Wild 1997). Clearly, the whole question of possible chemical communication and its role in courtship in anurans needs further investigation.

Pheromonal communication has not been well documented in anurans, but in one species of *Litoria* from Australia, secretions produced by skin glands of the male and released into the water appear to enhance the receptivity of the female (Wabnitz et al. 1999, 2000). Males of the strictly aquatic African pipid frog *Hymenochirus* also produce chemical signals that attract females (Pearl et al. 2000). Pheromonal communication also has been reported in *Leiopelma hamiltoni,* although this is not necessarily connected with reproduction (J. S. F. Lee and Waldman 2002; Waldman and Bishop 2004).

Sexually Dimorphic Fangs and Tusks

In some anuran species, males lack spines on the forelimbs, but have bony, tusklike projections on the lower jaw. In *Ceratobatrachus, Hemiphractus,* and *Pyxicephalus,* tusks are present in both sexes and might be used for predation (all of these are frog-eaters; Duellman and Trueb 1986). *Pyxicephalus adspersus* males also are known to use their tusks in combat (B. Balinsky and Balinsky 1954). In a small hylid frog, *Phyllodytes luteolus,* males have larger tusks than females, and use them when fighting over bromeliads that serve as oviposition sites (Weygoldt 1981a). Very conspicuous tusks also are found in males of the African petropedetid frog *Dimorphognathus africanus* (Noble 1931; Duellman and Trueb 1986) and in several species that have already been discussed, including the Australian myobatrachid *Atelotus brevis* (J. Moore 1961; Katsikaros and Shine 1997) and fanged frogs of the genus *Limnonectes* (fig. 8.26), which are known to use fangs in combat.

Sexual Differences Related to Calling

A largely neglected aspect of sexual dimorphism is the relationship of sexual differences in morphology to differences in physiology, especially as related to calling behavior. Calling is energetically expensive and requires suitable metabolic machinery to supply the muscles used in call production with large amounts of energy and oxygen (see chapter 5). Most of the work involved in producing the call is done by the abdominal muscles, primarily the internal and external oblique muscles (chapters 5, 7). Noble (1931) stated that the abdominal muscles of male frogs are more powerful than those of females, but did not cite specific examples. Recent work has shown that trunk muscles of males are much larger than those of females, and have higher activities of enzymes involved in aerobic metabolism. They also differ from muscles of females in fiber type, mitochondrial density, capillary density, lipid concentration, and contractile properties (Taigen, Wells, and Marsh 1985; R. Marsh and Taigen 1987; Given and McKay 1990; Bevier 1995b; Ressel 1996; Girgenrath and Marsh 2003; see chapter 5 for a more detailed discussion).

In addition to morphological and physiological differences in abdominal muscles, there are other physiological differences between the sexes that probably are related to call production. The laryngeal apparatus generally is much larger in males than in females. The laryngeal muscles exhibit morphological and physiological adaptations for high aerobic capacity similar to those of the trunk muscles (Manz

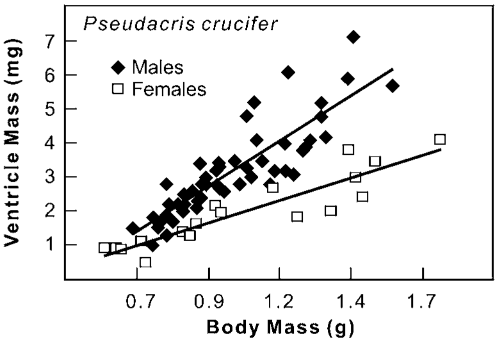

Fig. 8.34. Comparison of heart ventricle size in relation to body size in male and female spring peepers (*Pseudacris crucifer*). Males have much more robust ventricles for any given body size than do females, probably because of the greater demands for oxygen during call production. After Zimmitti (1999).

1975; Eichelberg and Schneider 1973, 1974; Eichelberg and Obert 1976; Schneider 1977; R. Marsh and Taigen 1987; Kelley and Tobias 1989; McClelland and Wilczynski 1989; McLister, Stevens, and Bogart 1995; Kelley 1996; McClelland, Wilczynski, and Rand 1997; Boyd et al. 1999). Noble (1931), citing several old references, reported that male frogs also have larger lung capacities and higher concentrations of red blood cells than do females. Zimmitti (1999) found that male spring peepers (*Pseudacris crucifer*) have relatively larger heart ventricles and higher hemoglobin concentrations than do females (fig. 8.34), features that appear to be related to the greater oxygen demands of calling males. There could be other physiological traits in frogs that differ between males and females that have yet to be investigated. For example, nesting male largemouth bass (*Micropterus salmoides*) exhibited a substantial increase in cardiac output and heart rate during the breeding season, and both variables were higher than in females, despite a lack of difference in relative ventricle mass (S. Cooke 2004).

Hormones and Sexual Dimorphism

Sexually dimorphic traits in anurans are under hormonal control, but the way in which hormones mediate the expression of sexually dimorphic traits varies (Emerson 2000). Some traits are affected by hormones early in development, including alterations in body size and body proportion and development of the vocal tract. Sexual differences generally first appear at or soon after sexual maturity, and are irreversible later in life (T. Hayes and Licht 1992; Kelley 1996). The development of sexually dimorphic traits, especially those related to calling, has been studied in great detail in *Xenopus laevis* by Kelley (1996) and her colleagues. Castration of males early in development results in an underdeveloped larynx, with muscles composed mostly of slow fibers characteristic of females. Subsequent exposure of the muscles to androgens results in proliferation of fast-twitch fibers characteristic of male laryngeal muscles. Castration of sexually mature males does not result in regression of the larynx, however, and castrated males are fully capable of calling, but do not do so unless the appropriate brain center is stimulated. If females are treated with androgens early in development, they will develop malelike laryngeal muscles, but hormone treatments after sexual maturity have no effect. The laryngeal muscles of male bullfrogs (*Rana catesbeiana*), which are larger than those of females and have more aerobic fiber types, also have androgen receptors, and probabably are androgen-sensitive (Boyd et al. 1999). Other permanent sexually dimorphic traits that have been shown to be under androgen control early in development include differences in body size (T. Hayes and Licht 1992), sexual differences in coloration (T. Hayes and Menendez 1999), and development of the vocal sac (T. Hayes and Menendez 1999).

Most other sexually dimorphic traits of male anurans are expressed during the breeding season in response to increases in circulating levels of androgens, but later regress during the nonbreeding period. These include hypertrophy of forelimb muscles (Muller, Galavazi, and Szirmai 1969; Melichna et al. 1972; Oka et al. 1984; Dorlochter, Astrow, and Herrera 1994; Blackburn et al. 1995), development of nuptial pads (Rastogi and Chieffi 1971; Kanamadi and Saidapur 1982; Kao et al. 1994; L. Lynch and Blackburn 1995; Epstein and Blackburn 1997; L. Harvey and Propper 1997), and expression of throat coloration (Greenberg 1942; Kao et al. 1994). In many cases, however, seasonal hypertrophy of muscles or other male sexual traits is superimposed on preexisting differences in underlying structure in males and females that originate early in development (Emerson 2000). For example, while forearm musculature and nuptial pads of males typically regress outside of the breeding season, they generally do not return to a female-like morphology.

Another trait that is likely to be affected by male hormones both early in development and on a seasonal basis is the size of the trunk muscles involved in call production. Male frogs typically have much larger trunk muscles than do females (see chapters 5 and 7), and trunk muscles in some species appear to be partly wasted away by the end of the breeding season (personal observations). In part, this is due to the depletion of energy stores (lipids and glycogen) that contribute substantially to the mass of the muscles, and it seems likely that seasonal accumulation of energy stores in muscles is under hormonal control. It also is likely that the muscle tissue itself undergoes seasonal cycles of hypertrophy and regression. Indeed, males of *Hyla chrysoscelis* exhibit a 50% reduction in trunk muscle mass during the postbreeding period, and contractile properties of muscles are altered as well. Treatment of postbreeding males with testosterone restored both muscle mass and contractile properties to breeding season levels (Girgenrath and Marsh 2003). As in most frogs, females of this species have much smaller trunk muscles with very different contractile properties than those of males. Again, treatment with testosterone produced marked changes in female muscles, with muscle mass and contractile properties similar to those of breeding males.

Species of frogs with high calling rates typically have greater relative trunk muscle mass than do those with low calling rates (Pough et al. 1992; Bevier 1995a, 1997b). Most frogs that have been examined exhibit substantial elevations in circulating androgen levels during the breeding season (Mendonça et al. 1985; Houck and Woodley 1996; L. Harvey et al. 1997), and one might expect higher androgen levels to be found in species with large trunk muscles and high calling rates. A preliminary study of a phylogenetically diverse group of frogs from Southeast Asia provided some support for this hypothesis. Species with high calling rates or loud calls had higher androgen levels than did those with low calling rates or soft calls, but differences in relative trunk muscle size were not examined (Emerson and Hess 1996).

Some frogs have unusually low androgen levels during the breeding season, and in some cases, this is correlated with a reduction in the occurrence of sexually dimorphic traits found in other frogs. For example, *Limnonectes leporinus,* a fanged frog from Southeast Asia, has unusually low androgen levels compared to other ranid frogs, and this species lacks many of the sexual dimorphic traits that commonly appear during the breeding season in other ranids, such as hypertrophied forelimbs and nuptial pads. This condition has been related to the evolution of extensive parental care in this group of frogs (Emerson, Rosewemitt, and Hess 1993; Emerson 1996). Nevertheless, these frogs retain the physiological responses to hormones that were present in their ancestors. When supplemental doses of androgens were administered to males of *L. leporinus,* they showed some development of thumb pads that normally are absent (Emerson, Carroll, and Hess 1997). Low hormone levels are not always associated with parental care or the absence of secondary sexual characters in males, however, because two other Southeast Asian species, *Occidozyga laevis* and *Bufo asper,* also have low hormone levels, but have nuptial pads and other sexually dimorphic traits and lack parental care. Clearly, more comparative data on the hormonal control of sexually dimorphic traits are needed before we will fully understand the processes involved.

Summary and Conclusions

When I first reviewed anuran mating systems nearly 30 years ago (Wells 1977b), information on male mating tactics, competition for females, and territoriality was almost entirely descriptive. There were no published studies exploring the factors that affect male mating success. Nevertheless, it was possible to make some generalizations from the descriptive natural history literature available at the time. In particular, I suggested a dichotomy between explosive breeders, characterized by synchronous arrival of females, and prolonged breeders, characterized by asynchronous availability of mates. The timing of reproductive activity appears to be influenced mainly by abiotic factors such as variation in temperature and rainfall, but it has a major effect on the tactics used by males to acquire mates and the degree of variation in male mating success in a breeding population. Because a high degree of synchrony tends to result in dense aggregations at breeding sites, I predicted that male-male competition would prove to be more important than female choice in explosive breeders, whereas female choice would play a major role in determining the mating success of males in prolonged breeders. I also predicted that the variance in male mating success should be greater in prolonged breeders because of greater opportunities for males to compete for many different females.

These predictions have been largely supported by subsequent studies. Direct competition for females is common in explosive breeders, and large males tend to be more successful than are small males. In prolonged breeders with lek-like mating systems, females often appear to select mates on the basis of male traits that are not strongly correlated with body size. In species that defend territories centered on oviposition sites, female choice seems to be based more on territory quality than on male phenotype, although these often are correlated, because large males are more likely to acquire good-quality territories than are small males. The prediction that male mating success should be more variable in species with prolonged breeding periods than in explosive breeders also has been largely supported by more recent work. Multiple mating by males is uncommon in explosive breeders, except in unusual cases where females outnumber males (e.g., Denton and Beebee 1993a), but often occurs in prolonged breeders.

In my original review, I pointed out that the dichotomy between explosive and prolonged breeders is somewhat artificial, since these categories actually represent two ends of a continuum of temporal breeding patterns. Indeed, more recent work has revealed a considerable degree of plasticity in the timing and length of the breeding period in many anurans. In general, species living in relatively variable environments, such as deserts or regions with pronounced temperature variation, tend to exhibit more plasticity in the timing of breeding than do species living in more stable environments. In the tropics, anurans in wet regions often breed more or less continuously during the rainy season, although there are some species that time their breeding to coincide with especially heavy rainfall. In drier tropical habitats, such as savannas, breeding seasons are likely to be more abbreviated, or to be broken up into a series of short episodes of breeding. In the temperate zone, summer-breeding anurans that utilize relatively permanent ponds almost always have prolonged breeding periods, whereas spring breeders tend to be more variable and are more likely to have breeding interrupted by cold spells.

This variability in the timing and duration of reproductive activity in response to changes in temperature and rainfall can lead to variation in population densities at breeding sites and in the relative numbers of males and females. Many anurans exhibit density-dependent shifts in mate-locating tactics. For example, males of explosive breeding species often shift from calling to active searching as densities increase, and some males adopt satellite tactics at intermediate densities. These changes in mating tactics are not unique to anurans, but are similar to density-dependent changes in mating tactics observed in insects (Thornhill and Alcock 1983; Finke, Waage, and Koenig 1997; Zuk and Simmons 1997) and other animals. Prolonged-breeding anurans exhibit density-dependent shifts in mating tactics as well, from resource-defense to lekking behavior, or from lekking to active searching. Again, these changes in behavior parallel similar density-dependent shifts in mating tactics seen in lek-breeding insects (Shelly and Whittier 1997) and vertebrates (Gosling 1986; Langbein and Thirgood 1989; Gosling and Petrie 1990; Apollonio et al. 1992; Balmford et al. 1993; Wikelski, Carbone, and Trillmich 1996; Lanctot and Weatherhead 1997; Thirgood, Langbein, and Putnam 1999).

Most work on anuran mating systems has focused on the tactics used by males to acquire mates. Much less attention has been devoted to the mating tactics of females. In part this is because female anurans tend to be cryptic in their behavior and difficult to observe. In nocturnal species that breed in heavily vegetated ponds or swamps, females usually are not seen until already in amplexus with males, so it is difficult to observe their mate-locating behavior in detail. Only a few studies have specifically focused on the movements of females (e.g., Wells 1977c; R. D. Howard 1978a; M. Morris 1989; Grafe 1997a). Despite the difficulty of observing females, their behavior deserves more attention. Just as males adjust their mating tactics to changes in male density, females do so as well. For example, females might spend less time comparing potential mates or their territories if males are highly aggregated, especially if females are subjected to harassment by males or are exposed to predators attracted to the aggregation. In explosive breeders, females in amplexus sometimes leave areas of high male density, perhaps to escape from intense competition among males, which can be fatal to females.

Harassment by males also could explain differences in oviposition behavior by females, which has led investigators to classify some mating systems as resource defense and others as leks. For example, Emlen (1976) interpreted the mating system of a population of bullfrogs (*Rana catesbeiana*) in Michigan as a lek largely because he observed females leaving the territories of males to lay their eggs. R. D. Howard (1978a) studied the same population and concluded the frogs had a resource-defense mating system because most females laid eggs in the territories of their mates. Possibly the higher population density during the years when Emlen studied the population caused many females to leave the chorus because it became difficult for them to lay their eggs without being disturbed by neighboring territory holders. The fundamental strategy of males, the defense of exclusive territories, did not change, however. Several investigators who have studied frogs that breed in rice fields, where densities often are very high, have observed males defending clustered territories, but females leaving the main chorus and moving to the periphery of the breeding area to lay their eggs (e.g., Shimoyama 1982, 1989). The mating system of these frogs resembles a lek, but it would be interesting to determine whether females ever lay eggs in the territories of their mates when competition among males is less intense. In other animals, avoidance of male harassment can affect both the mating and egg-laying behavior of females (e.g., Clutton-Brock et al. 1992; Finke et al. 1997).

Because of the difficulty of observing the behavior of females while simultaneously monitoring the behavior of large numbers of males, it is not a trivial matter to identify all of the factors that contribute to variation in male mating success in a natural population. Even for well-studied species such as the red-winged blackbird, years of work on many different populations were required to determine the relative importance of male behavior, male morphology, or resource quality as determinants of female choice (Searcy and Yasukawa 1995; Beletsky and Orians 1997). Similar problems plague studies of mate choice in anurans. Usually only one population of a given species has been studied intensively, although studies of multiple populations are becoming more common. Even when species have been studied more than once, results and interpretations often are quite different (e.g., *Rana catesbeiana,* Emlen 1976; R. D. Howard 1978a; M. Ryan 1980b; *Bufo americanus,* Gatz 1981a; Kruse 1981a; R. D. Howard 1988b). Often, the determinants of male mating success vary from year to year even in the same population.

The mating success of a male frog probably is determined by many factors. These include the length of his stay in the breeding pond, his ability to obtain a suitable calling site, his ability to displace other males from amplexus or avoid being displaced, his level of activity at the breeding site, and the quality of his territory, as well as phenotypic traits such as the dominant frequency of his calls, calling persistence, call duration, or call intensity. The relative importance of each factor depends on the details of the mating system. Consequently, any search for a single factor to explain most of the variation in male mating success in a population is likely to be futile. Furthermore, individuals with similar mating success sometimes follow different behavioral tracks to achieve the same results. One male might arrive at the pond early, another might be particularly active in searching for females, and a third might be particularly successful in displacing other males from amplexus. Without detailed behavioral observations of each individual, such differences would be obscured, and the investigator would be left with weak but possibly significant relationships between mating success and various behavioral and morphological characteristics of males. Different correlates of mating success often are correlated with each other as well, so the use of multivariate statistics to partition variation in reproductive success is desirable (Arak 1983b). Unfortunately, data on variation in male behavior has not been sufficiently detailed to allow most investigators to use this approach.

These problems are compounded when one considers lifetime reproductive success of long-lived species. R. D. Howard's (1978a, 1981a, 1983, 1984) work with bullfrogs showed that males attempt to obtain mates by different means at different ages, and a young male that has relatively poor reproductive success in one season might obtain several mates the next year. Therefore, size-related mating patterns evident on a seasonal basis do not necessarily reflect the distribution of matings over the lifetimes of all individuals in the population. In addition, many chance events can affect a male's lifetime reproductive success. For example, a harsh winter can greatly reduce the number of males competing for females, so that young males are more successful than in years when population densities are high (R. D. Howard 1983). Changes in the configuration of the breeding site, in the distribution of vegetation, or in the abundance of egg predators also can change the availability of high-quality territories and alter the distribution of matings in the male population. Without long-term observations over several breeding seasons, such events would go undetected (see also Beletsky and Orians 1997).

The importance of female choice in anuran mating systems varies because selection favors different mate choice tactics in different species, depending on the potential costs and benefits of discriminating between potential mates (Janetos 1980; Halliday 1983b; G. Parker 1983; Wittenberger 1983; Jennions and Petrie 1997). If the variance in male quality is low, and the costs of comparing males are high (e.g., Grafe 1997a), then selection should favor females mating with the first male encountered. This hypothesis has yet to be falsified for most anuran species. Alternatively, females might mate with any male that meets some minimum criterion of acceptability, but not make fine-scale discriminations among males. In many populations, very low-quality males are eliminated by male-male competition, so all individuals participating in a chorus are acceptable. Finally, if there is sufficient variation in the quality of potential mates, due either to variation in territory quality or male phenotype, then selection should favor active mate choice by females, providing the costs of such behavior are not too high. Even so, it seems likely that females of most species make comparisons among only a small subset of the males in the population (Janetos 1980; Wittenberger 1983), and one should not expect every female to choose the best possible mate. Furthermore, even if mate quality has a substantial effect on female fitness, the ability of females to distinguish minor differences in quality from male phenotype or behavior is limited.

Perhaps the most controversial problem yet to be resolved in studies of anuran mating systems is the extent to which females can use differences in call characteristics to assess differences in body size or even genetic quality of males. As discussed previously, there has been much speculation on this subject, but relatively little convincing experimental work. Several steps are required to demonstrate active female choice based on characteristics of male calls: (1) It must be shown that some males obtain more matings than expected by chance. This can be done only if complete data on male mating success throughout the breeding period are available. (2) Behavioral data showing that female frogs can actively assess male behavior and deliberately move toward particular males must be presented. Anecdotal reports of a small subset of females approaching calling males (e.g., L. Licht 1976) are not convincing evidence of female choice. (3) Characteristics of calls must be shown to vary in a predictable manner. For example, if dominant frequency is only weakly correlated with male body size, then females will not be able to derive reliable information about the size of males from their calls. (4) It must be demonstrated that females can discriminate between calls falling within the natural range of variation in the population. If females do not distinguish between the calls of most males in the population, then differences in calls probably will have little effect on male mating success.

Two-choice playback experiments must be interpreted cautiously. They demonstrate the ability of females to distinguish between calls in a simplified acoustic environment, but they cannot show conclusively that females do so in a chorus of several dozen or several hundred males. These experiments also cannot demonstrate that such discrimination is the principal determinant of male mating success. One difficulty in extrapolating from playback experiments to a natural situation is that females probably sample only a few males when choosing a mate. In many species, mate choice probably is a multistep process (Felton et al. 2006). Initially, a female probably is attracted to any continuous sound of the correct frequency, even choruses of other species (Gerhardt 1982). After arriving at the chorus, a female then moves to an area where one or more males of her own species are calling. Any comparisons among males probably involve only a few individuals in the local area, with others simply contributing to background noise (Wells and Schwartz 1984a). Consequently, evidence of active mate choice in the population as a whole can be difficult to detect.

Finally, even if active female choice has been documented, it will be impossible to determine whether mate choice is adaptive for females until additional genetic information is available. Some models of sexual selection indicate that females need not use adaptive criteria in choosing mates for active mate choice to be maintained in a population (Lande 1981; Andersson 1982; Arnold 1983b). G. Parker (1983) suggested that adaptive female choice based on criteria yielding only genetic benefits is not likely to be maintained because of the costs of exercising such choice, and Arnold (1983b) has cautioned against viewing female choice as a process of "shopping for good genes." Nevertheless, much of the speculation about why female anurans should prefer large males to small ones is based on adaptive arguments. Common assumptions are that (a) large males are older and therefore have demonstrated an ability to survive, or (b) large males have grown more rapidly and therefore probably are genetically superior in their ability to acquire and use energy (Arak 1983a; M. Ryan 1983b).

Unfortunately, evidence that traits affecting mate choice by females yield genetic benefits to their offspring is weak or nonexistent for most anurans. There is virtually no information on the genetic basis of fitness-related traits in adults (for example, differences in growth rates of juveniles and adults, physiological differences). Several investigators have used laboratory experiments to determine whether choice of large males by females yields genetic benefits to their offspring, such as enhanced growth rates or higher survivorship of tadpoles fathered by large males. Although these experiments produced some evidence for paternal effects on fitness-related traits of tadpoles, there was no consistent tendency for offspring of larger males to have faster growth rates, shorter larval periods, larger size at metamorphosis, or higher survivorship. Therefore, these experiments do not provide strong evidence that indirect selection favors choice of large males by females (Woodward, Travis, and Mitchell 1988; S. Mitchell 1990; Howard, Whiteman, and Schueller 1994; Semlitsch 1994). One study did suggest a link between female choice of males with high calling performance and larval fitness, although the genetic mechanism linking adult and larval performance is not known (Welch, Semlitsch, and Gerhardt 1998; Doty and Welch 2001). Two studies that investigated the relationship between parasite infection, male calling performance, and male mating success found little effect on male fitness (Hausfater, Gerhardt, and Klump 1990; Tinsley 1990).

The relationship of sexual dimorphism to mating systems and sexual selection has scarcely been explored. Many types of sexual dimorphism, such as large body size, enlarged forelimbs, and development of spines and other weapons in males often seem to be related to male combat. Nevertheless, information on aggressive behavior and the contribution of specific phenotypic traits to fighting ability is available for only a few species. Furthermore, the tradeoffs between sexual selection and natural selection acting on characters such as male body size (e.g., Wikelski and Trillmich 1997) are unknown for most species, so it is difficult to predict patterns of sexual dimorphism from comparative studies alone. The functions of many sexually dimorphic traits, such as differences in skin texture or coloration and the presence of cutaneous glands in some male frogs, remain unknown. Finally, physiological correlates of sex differences in morphology can be as important in determining reproductive success as the morphological traits themselves, but they have not been explored in detail. Studies of sexual selection in anurans thus provide an opportunity for interdisciplinary research combining approaches from diverse fields such as behavioral ecology, functional morphology, and physiological ecology.

Chapter 9 Communication and Social Behavior of Urodeles and Caecilians

A salamander . . . will remain absolutely motionless for an hour on or under some dead leaf, in the trickling waters that wend their way riverward from a mossy spring. To sit or stand for an hour, and watch this immovable creature, is both painful and monotonous, and when, at last, you disturb it, perhaps accidentally, away it goes to some similar spot near by, and resumes its motionless attitude. . . . Studies of salamander life soon become a bore.
—Charles C. Abbott, *A Naturalist's Rambles About Home* (1884)

Among the Newt tribe [sexual] characters take the form of frills and crests and vivid colours. They are intended to stimulate through the sense of sight, and arouse emotion, as a city is beflagged to welcome those it may delight to honour.
—W. P. Pycraft, *The Courtship of Animals* (1913)

Until relatively recently, most biologists, even those working on amphibians, probably gave little thought to the behavior of salamanders, perhaps sharing Charles C. Abbott's opinion that these small, secretive animals have little to offer the inquiring naturalist. Most early published reports of salamander communication and social behavior consisted of descriptive studies of courtship behavior (e.g., Noble and Brady 1933; Bishop 1941b; Stebbins 1954b; Organ 1958, 1960a; Joly 1966; Salthe 1967; Brandon 1970b; Garton 1972; Salthe and Mecham 1974) and brief reports of aggressive interactions (Kerbert 1904; Bishop 1941b; R. Gordon 1952; W. Grant 1955; Hutchison 1959; Brandon and Huheey 1971; Licht 1973; Thurow 1976). Although Darwin (1871) had noted the striking sexual dimorphism of European newts (fig. 9.1), most of the early work on salamander behavior did not relate observations of courtship and aggression to theories of sexual selection or use them as a basis for understanding the evolution of mating systems.

This changed in the mid-1970s, with a renewed interest in evolutionary interpretations of animal communication and social behavior. Of particular importance was the publication of several key papers on the courtship of newts by Halliday (1974, 1975a, b, 1976, 1977a) and North American salamanders by Arnold (1976, 1977). These pioneering studies were the first to place the behavior of salamanders in a conceptual framework of sexual selection theory, and they set the stage for all subsequent work in the field. The literature in this field has expanded at an accelerating rate in the last three decades, and a number of reviews have been published (Arnold and Houck 1982; Halliday and Verrell 1984; Houck 1986; Jaeger 1986; Verrell 1989c; Halliday 1990; Houck and Verrell 1993; Jaeger and Forester 1993; Houck and Sever 1994; Halliday and Tejedo 1995; Mathis et al. 1995; Sullivan, Ryan, and Verrell 1995; Griffiths 1996; Dawley 1998; Denoël 1999; Houck and Arnold 2003).

Caecilians have received much less attention. Although certain aspects of their reproductive biology have been studied in the laboratory (see chapter 10), we know next to nothing about their communication and social behavior in the field. In this chapter, I briefly discuss what little we know about caecilian communication and then review different modes of communication in salamanders and newts and the

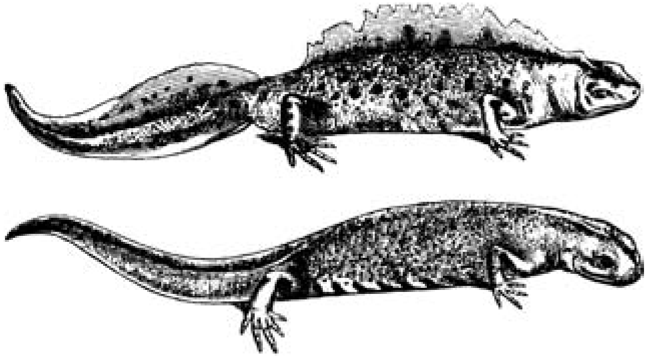

Fig. 9.1. Sexual dimorphism in the European crested newt (*Triturus cristatus*), from Charles Darwin (1871), *The Descent of Man, and Selection in Relation to Sex.* Male is on top, female on bottom.

use of communication signals for species, sex, and individual recognition. I then discuss aggression, spacing, and territoriality, the evolution of mating systems, and the action of sexual selection on traits of males and females.

Communication by Caecilians

Caecilians are mostly burrowing animals that spend their lives underground, although some have secondarily evolved aquatic habits. They are nearly or completely blind, so use of visual signals can be ruled out. There is no evidence that caecilians use sound for communication, so communication in this group almost certainly depends on chemical or tactile cues. The only species of caecilian for which we have any experimental evidence about modes of communication is the aquatic species *Typhlonectes natans.* Animals kept in captivity tend to be gregarious, sheltering under rocks in the water. They appear to mark shelter sites with chemical signals and are attracted to chemicals emanating from aggregations of conspecifics (Warbeck, Breiter, and Parzefall 1996). In this respect, they are remarkably similar to females of the European olm (*Proteus anguinus*), a blind aquatic cave salamander (Guillaume 2000a, 2002) and the gregarious terrestrial salamander *Salamandra luschani* (Gautier et al. 2006). Breeding male *Typhlonectes* in captivity are aggressive toward one another, but not necessarily territorial. Laboratory tests showed that nonreproductive females preferred chemical cues from other females to those from males, whereas reproductive females preferred cues from males. Reproductive males preferred cues from receptive females to those from nonreceptive females, but did not discriminate between related and unrelated females (Warbeck and Parzefall 2001). Because natural population densities and tendencies to aggregate in the field have not been studied, the nature of this animal's mating system remains unknown.

Modes of Communication in Urodeles

Acoustic Communication

In contrast to the dominant role of acoustic communication in the lives of anurans, communication by sound is of little importance to salamanders. A number of species of salamandrids, ambystomatids, and plethodontids are known to produce a variety of low intensity hisses, barks, clicks, squeaks, and whistles. In most cases, the function of these sounds is not known, although they seem to be associated with antipredator behavior (Maslin 1950; Bogert 1960), courtship (Wyman and Thrall 1972), or aggressive behavior (Licht 1973; J. Davis and Brattstrom 1975; Ovaska 1987; K. Nishikawa personal communication). The only attempt to play recorded vocalizations to salamanders failed to elicit a response (Wyman and Thrall 1972). Some of the sounds produced by salamanders contain energy at frequencies well above 2 kHz (Bogert 1960; Wyman and Thrall 1972; J. Davis and Brattstrom 1975). These animals lack external tympanic membranes and most have degenerate columellas (Wever 1985; Jaslow, Hetherington, and Lombard 1988). They can detect airborne or waterborne sounds and ground vibrations, but peak sensitivities generally are below 500 Hz, and hearing sensitivity falls off rapidly at frequencies above 1 kHz (Ferhat-Akat 1939; Ross and Smith 1978; Wever 1985). The relative insensitivity of salamander ears to anything but low-frequency sounds and vibrations makes it unlikely that the sounds produced by these animals function in intraspecific communication. Nevertheless, sound production is a regular feature of aggressive interactions in some species, such as *Plethdon vehiculum,* which makes clicks by snapping the jaws together (Ovaska 1987). Further investigation of the hearing capabilities of sound-producing species is needed.

Visual Communication

Many salamanders are nocturnal and often carry out their activities under cover objects or in other dark environments. They have eyes that are well adapted to functioning in dim light conditions and can capture prey even on relatively dark nights (Roth 1987). Nevertheless, dim light conditions probably select against the use of color in visual displays and select for displays consisting of relatively simple movements or postural changes that can be detected even when an animal is in silhouette. For example, red-backed salamanders (*Plethodon cinereus*) signal aggression by looking toward an opponent and raising the trunk off the ground, sometimes with the back arched (fig. 9.2). Changes in posture appear to form a graded signaling system that indicates gradual changes in aggressiveness (Jaeger 1981b, 1984; Jaeger and Schwarz 1991). Submission is signaled by looking away from opponents and by holding the body flat against the substrate (fig. 9.2). The condition

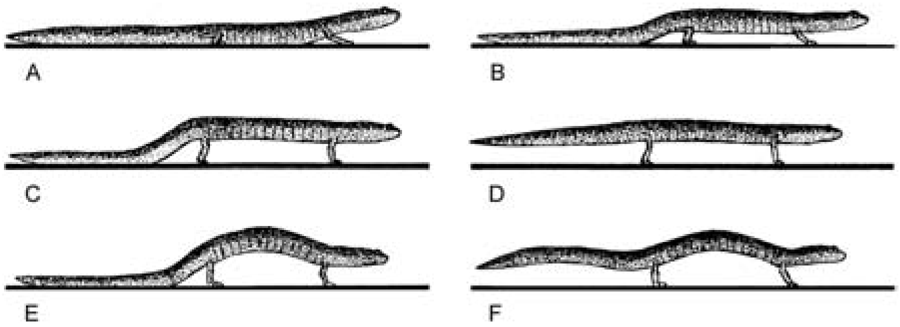

Fig. 9.2. Aggressive and submissive postures of the red-backed salamander (*Plethodon cinereus*). (A) Resting posture. (B) All trunk raised, low stance (ATR 1). (C) All trunk raised, high stance (ATR 2). (D) All trunk raised with tail raised (ATR 3). (E) All trunk raised with back arched (ATR 4). (F) All trunk raised with tail raised and back arched (ATR 5). After Jaeger and Schwarz (1991).

of a resident's tail also affects the responses of an intruder to a resident. Red-backed salamanders sometimes lose all or part of their tails in fights or to predators. Residents that have lost their tails are less successful in repelling intruders, even though they are no less aggressive than are individuals with complete tails (Wise and Jaeger 1998). Presumably this difference in behavioral response to the resident is mediated by visual inspection and assessment of the resident's tail condition by the intruder.

Some of the displays described in *P. cinereus* also have been observed in other plethodontids, including *Plethodon vehiculum* (Ovaska 1987), *P. serratus, P. websteri* (Camp 1999), *Aneides flavipunctatus* (Staub 1993), and *Ensatina eschscholtzii* (Wiltenmuth 1996). *Plethdon vehiculum* and *P. websteri* also exhibit tail-waving behavior, in which an animal moves its tail in a high arc over the body, usually immediately before attacking an opponent (Ovaska 1987; Camp 1999). Similar behavior has been observed during aggressive interactions in *Desmognathus fuscus* and *D. monticola* (Keen and Sharp 1984). Both larval and adult ambystomatids are reported to change body postures during aggressive encounters (Ducey and Ritsema 1988; Ducey 1989; Walls 1990, 1991), but it has yet to be clearly established that these constitute aggressive and submissive signals like those described for plethodontids (Mathis et al. 1995).

Visual signals also are used in courtship by some salamanders. In *Rhyacotriton olympicus,* the male wags the tip of his tail during courtship, presumably providing some sort of visual stimulus to the female (Arnold 1977). During the breeding season, males of *Hynobius nebulosus* develop a white throat patch that is pulsated in the presence of females (Thorn 1967). In most species of *Desmognathus,* males swing their forelimbs forward in a butterfly stroke pattern while approaching females. This behavior occurs in both the initial orientation and subsequent persuasion phases of courtship and sometimes is accompanied by undulation of the tail, another visual signal. Butterfly movements sometimes grade into stroking, a tactile signal in which the male strokes the female's head and neck with one forelimb, but not all species of *Desmognathus* engage in stroking behavior (Organ 1961a; Arnold 1977; Maksymovitch and Verrell 1992; Houck and Verrell 1993; Uzendoski and Verrell 1993; Brock and Verrell 1994; Verrell 1994a, b, 1995, 1997; Herring and Verrell 1996; Verrell 1999; Mead and Verrell 2002; Mabry and Verrell 2003).

The precise function of these visual and tactile displays is not known. In *D. ocoee,* there was not a significant correlation between male mating success in laboratory trials and the frequency of individual courtship acts, such as butterfly. Successful males did exhibit a higher composite score of persuasive ability that combined several courtship behaviors, including butterfly (Vinnedge and Verrell 1998), but it is not clear that frequency of this display actually affects mating success (Gershman and Verrell 2002). The butterfly display appears to have been secondarily lost in *D. ochrophaeus,* but is retained in its sister species, *D. orestes.* Mead and Verrell (2002) suggested that the loss of this display and another courtship behavior might account in part for the sexual incompatibility between *D. ochrophaeus* and *D. orestes.*

Visual signals are more prevalent in salamandrids, especially newts in the genera *Triturus, Paramesotriton, Pachytriton, Cynops, Euproctus, Calotriton, Neurergus,* and *Notophthalmus,* which can be active either at night or during daylight hours. The use of complex visual displays appears to be a derived behavior within the family Salamandridae. In most genera, males approach females and seize them in some form of amplexus, either from above or below (fig. 9.3). In species that have amplexus, visual signals seem to be less important than are chemical and tactile signals (Halliday 1990; Houck and Arnold 2003). In some species, such as the North American red-spotted newt (*Notophthalmus viridescens*), males sometimes perform a relatively simple lateral display (the hula) before seizing the female. This can be sufficient to elicit a response from the female, but most courtship bouts proceed to an extended period of chemical stimulation (Verrell 1982, 1983, 1990a).

In newts of the genera *Cynops, Paramesotriton, Pachytriton,* and *Neurergus,* amplexus is absent, but the visual displays of the males are relatively simple (Sparreboom 1983, 1984b, 1993, 1994; Sparreboom and Faria 1997; Thiesmeier and Hornberg 1997; Sparreboom and Thiesmeier 1999; Sparreboom, Sreinfartz, and Schultschik 2000). Males of these genera lack the conspicuous crests and tail fins found in some *Triturus,* but males of some species do develop breeding coloration. In *Paramesotriton,* males change from a dull brown color like that of the female to a much lighter yellow. Many male newts, including *Paramesotriton,* court females most actively after dusk, so the light yellow coloration probably serves to make the male more conspicuous in dim light. In *Neurergus strauchii,* males develop silvery-blue coloration on the sides of the tail in the breeding season, a pattern that also is highly reflective and probably makes the tail conspicuous in dim light (Sparreboom, Sreinfartz, and Schultschik 2000). Similar light blue coloration is seen in breeding males of some populations of alpine newts (*Triturus alpestris;* Bovero, Giacoma, and Andreone 1997).

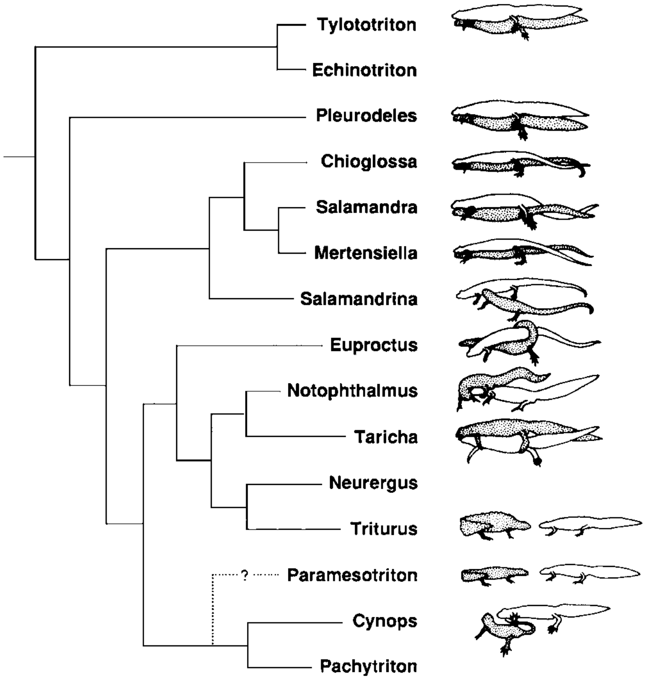

Fig. 9.3. Phylogeny of the genera of salamandrids, based on morphological characters, showing different types of amplexus during courtship. In each case, the male is the shaded individual. This figure illustrates the taxonomic distribution of different modes of amplexus among genera of salamandrids, but some more recent phylogenies differ from this one in the details of relationships among the groups. From Halliday (1990).

In *Paramesotriton,* males also have a bright spot or stripe on the tip of the tail, set off with dark lines on either side, a pattern likely to enhance contrast in dim light. Males move the tip of the tail during courtship, a behavior that has been interpreted as mimicking the movements of prey as a way of attracting the attention of females (Sparreboom 1993). Similar caudal luring has been reported in the courtship of several of the smaller species of *Triturus* (*T. alpestris, T. boscai, T. helveticus, T. italicus, T. vulgaris kosswigi*), but it is absent in large species (Rafiński and Czaja 1984; Wambreuse and Bels 1984; Pecio and Rafiński 1985; Giacoma and Sparreboom 1987; Arntzen and Sparreboom 1989; Faria 1993). In *T. boscai, T. italicus,* and *T. pygmaeus,* there is an additional visual display, the flamenco, in which the male raises his tail and waves the tip (fig. 9.4). This attracts the female, which sometimes even snaps at the tail tip (Arntzen and Sparreboom 1989; Faria 1993; Hidalgo-Vila, Pérez-Santigosa, and Díaz-Paniagua 2002). These displays can be considered a form of sensory exploitation (Ryan 1990), in which males have evolved a display that exploits the tendency of females to orient toward small moving prey animals. Female newts often orient toward the male's tail during spermatophore deposition, apparently following the movements of the tail until

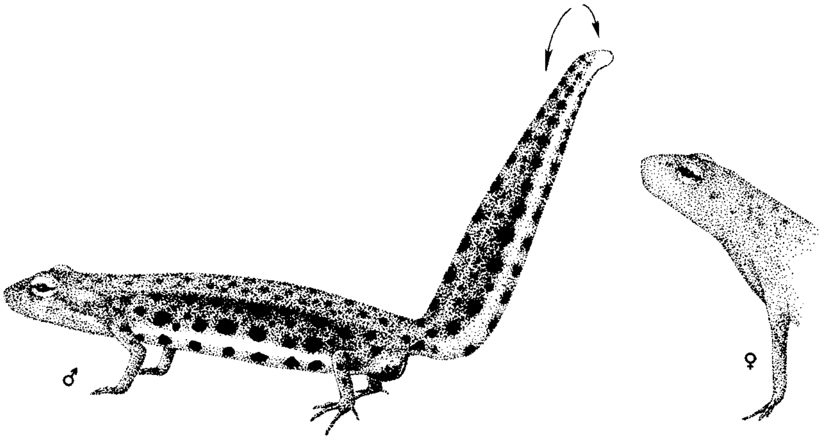

Fig. 9.4. Flamenco courtship display of *Triturus boscai.* The male wiggles the white tip of the tail from side to side, which attracts the attention of the female. The female orients toward the tail tip and sometimes snaps at it, suggesting that this courtship display exploits the tendency for females to orient toward moving prey. From Faria (1993).

they encounter the spermatophore (Arntzen and Sparreboom 1989). In the genera *Euproctus* and *Calotriton,* the male often holds his tail vertically, apparently as a display to attract the attention of the female, and then uses the tail to seize the female (Guillaume 1999). Males of this genus also restrain females by biting them (Houck and Arnold 2003), but use of chemical signals appears to be minimal (Guillaume 1999).

Most of the courtship displays of *Triturus* combine visual, tactile, and chemical signals in ways that make it difficult to unravel the functional components of the displays. A display that appears to be an ancestral trait for the whole genus *Triturus* is the fan. The male faces head-on toward the female, with the tail folded back along the side of the male. He rapidly beats or vibrates the tail, which directs a current toward the female's snout (fig. 9.5). This conveys pheromones toward the female, but the display probably provides tactile stimulation from the water movement and a visual signal as well (Halliday 1974, 1975b, 1990; Arntzen and Sparreboom 1989; Houck and Arnold 2003). It appears that there has been a gradual shift in the relative importance of chemical and visual display components in the evolution of newt courtship. The fan display is present in several genera that lack broad, visually conspicuous tail fins, including *Neurergus* (Fleck 1982; Sparreboom, Sreinfartz, and Schultschik 2000), *Paramesotriton* (Sparreboom 1983, 1984b), *Pachytriton* (Sparreboom and Thiesmeier 1999), and *Cynops* (Tsutsui 1931; Sparreboom and Faria 1997), and the smaller species of *Triturus* (Arntzen and Sparreboom 1989; fig. 9.6). Presumably the transfer of chemical signals to the female is the most important feature of the display in these species. In

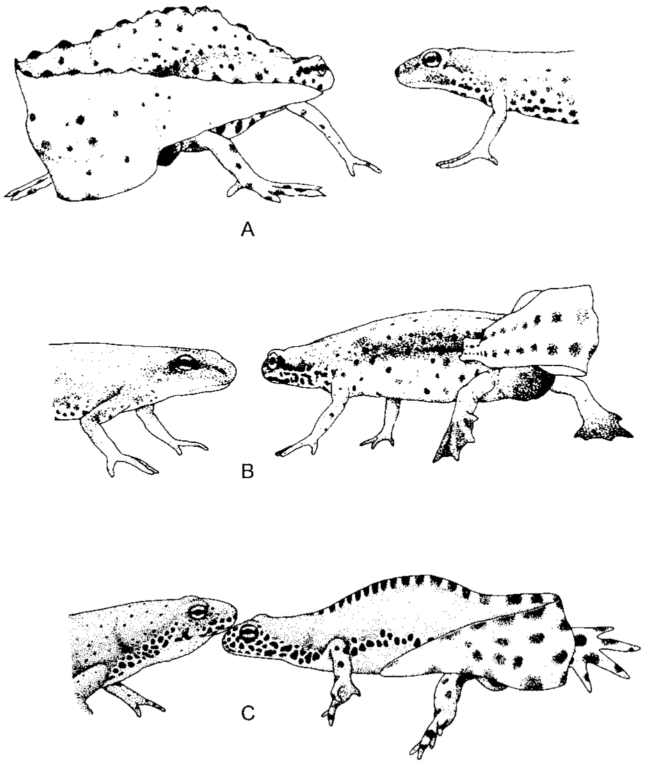

Fig. 9.5. Fan courtship displays of three species of European newts. In each case, the male directs a current of water toward the female with movements of his tail. This display appears to be ancestral for the entire genus, but has been secondarily lost in several large-bodied species. (A) *Triturus vulgaris.* (B) *Triturus helveticus.* (C) *Triturus alpestris.* After Halliday (1977a).

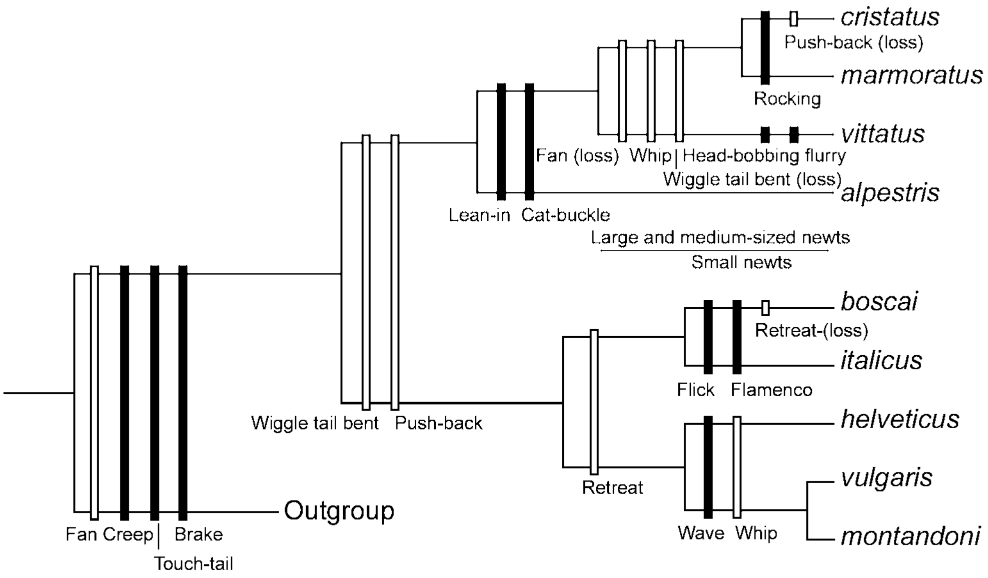

Fig. 9.6. Phylogeny of the genus *Triturus,* based on an analysis of biochemical and behavioral data, showing the evolution of various display traits. Solid bars are apomorphies. Open bars are homoplasous characters. This phylogeny and several other analyses of molecular characters support a division of large-bodied and small-bodied newts into distinct monophyletic clades, although some more recent phylogenies differ in details of relationships among species in the genus. After Arntzen and Sparreboom (1989).

species with broader tail fins, such as *Triturus vulgaris,* the visual component probably becomes more important. In *Triturus vulgaris, T. helveticus,* and *T. montandoni,* all of which have moderately broad tail fins and crests, there is another display, the wave, which appears to be primarily a visual signal. The male holds his tail up for a few seconds, presenting a full lateral view of the body and tail to the female (Halliday 1974; fig. 9.7). This display is absent in small species with inconspicuous tail fins, and therefore appears to be a derived signal in the more visually elaborate species.

Visual displays reach their greatest development in the very large species with extremely conspicuous tail fins and colorful crests, including *T. cristatus, T. marmoratus,* and *T. vittatus* (fig. 9.8A). Because these species are in a different clade than the small species of newts, the evolution of complex visual displays appears to have evolved at least twice independently (fig. 9.6). The visual displays of large newts are quite distinct from those of small newts. In the large newts, the male usually does not face the female head-on, and the ancestral fan display has been lost (fig. 9.7). Instead, the male presents himself laterally to the female, showing off his elaborate crest and fin, which would be visible in silhouette even in relatively dim light. Often the male will lean his body toward the female (the lean-in display). A somewhat similar but less intense version of this display is found in *T. vulgaris,* probably an independent derivation (Halliday 1974), but it is best developed in the largest, most brightly colored species. It often is accompanied by the cat-buckle display, in which the male arches his back and kinks the body around the female, showing off the crests and tail fins to maximum effect (fig. 9.8B). The shift toward these more elaborate visual displays is associated with a shift in mating systems, from mate-searching to lekking (Zuiderwijk and Sparreboom 1986; Arntzen and Sparreboom 1989; A. Green 1989; Hedlund and Robertson 1989; Raxworthy 1989; Halliday 1990; Hedlund 1990a, b; Sparreboom and Teunis 1990; see subsequent discussion of Mating Systems). Some of these same displays are used in aggressive interactions among males.

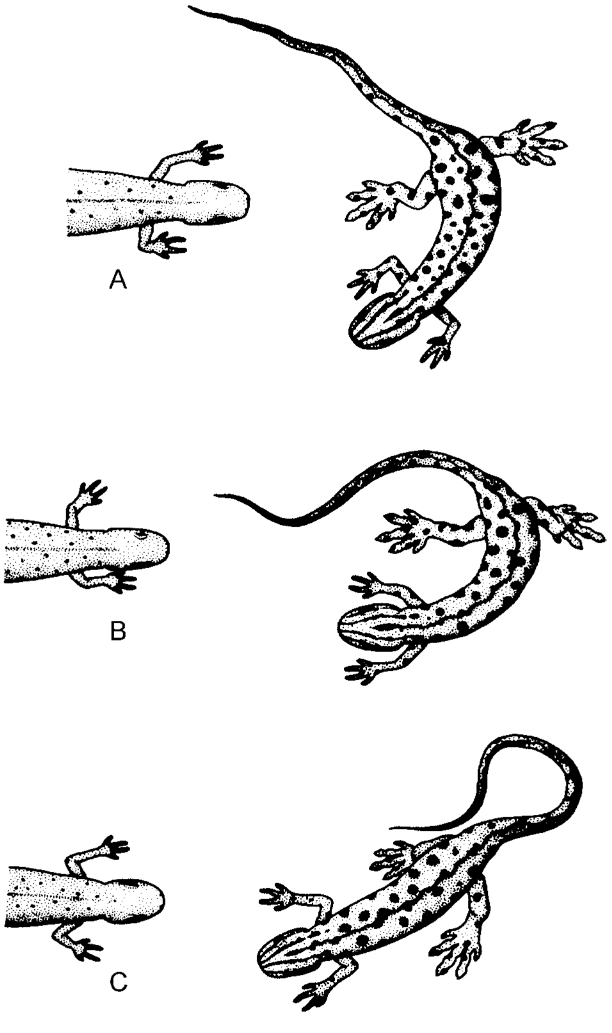

Fig. 9.7. Three courtship displays of the common newt (*Triturus vulgaris*). (A) The wave display, in which the male presents the female with a full lateral view of the tail. (B) The whip, a sudden lashing of the tail against the male's body, which directs a blast of water toward the female. (C) The fan, a delicate movement of the tail that directs a current of water toward the female (see also fig. 9.6). After Halliday (1977a).

Tactile Communication

Tactile communication probably is important in the courtship of many species of salamanders, but it is often hard to separate from visual and chemical communication. As already mentioned, tail fanning displays of European newts probably serve a dual function of directing pheromones toward the female and providing tactile stimulation that is detected by the lateral line system (Halliday 1974; 1975a; 1977a). Some species of newts have an even more intense tactile display, the whip, in which the male beats his tail toward the female with enough force to move the female backward (Arntzen and Sparreboom 1989). This display might provide cues that enable a female to assess the size and strength of the male, especially in dim light or darkness, when visual signals might be difficult to discern. In two small species, *T. boscai* and *T. italicus,* males perform a flick display, which is somewhat similar to the whip. In *T. boscai,* the tip of the male's tail sometimes brushes the female's cheek or snout, probably providing a tactile signal (Pecio and Rafiński 1985; Giacoma and Sparreboom 1987; Arntzen and Sparreboom 1989; Faria 1993, 1995).

Many forms of behavior observed in plethodontid courtship, such as slapping the female's snout with a gland on the male's chin or raking the female with premaxillary teeth, might provide some tactile stimulation, but their primary function is delivery of chemical signals (Arnold 1977; Arnold

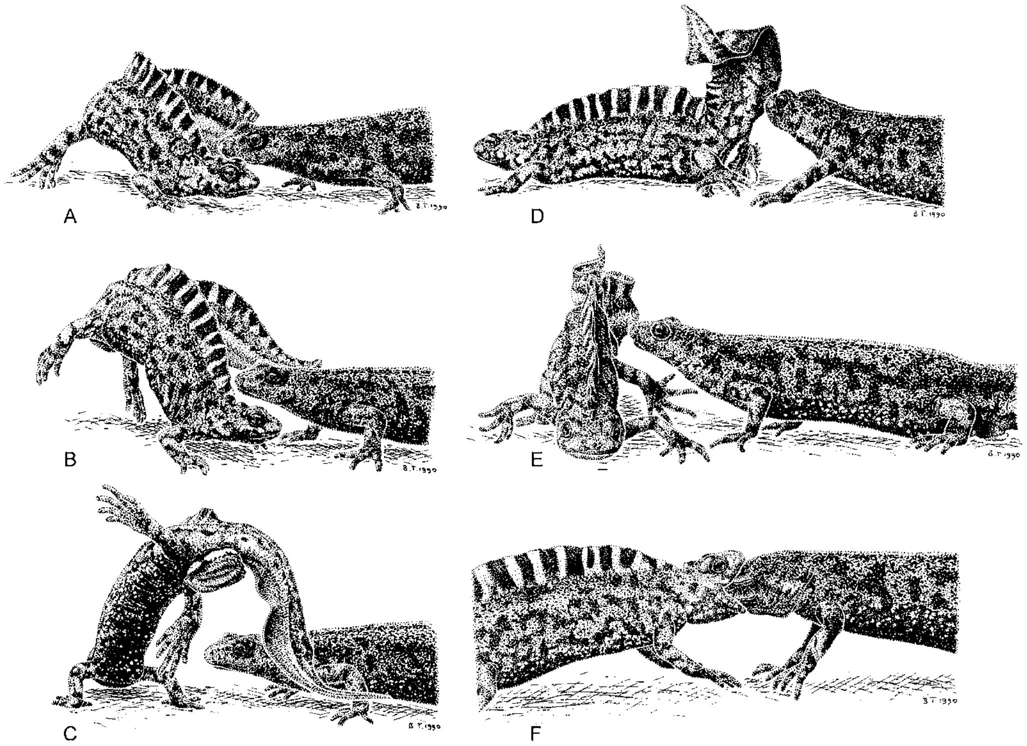

Fig. 9.8. Courtship behavior of the marbled newt (*Triturus marmoratus*). (A) The male takes up a position in front of the female, bends his tail in her direction, and arches his back (lean in). (B) The catbuckle display, with the male's back strongly arched and the hind legs off the bottom, sometimes accompanied by irregular waving movements of the tail. (C) Male standing on his front feet, delivering a powerful tail-lash toward the female, sometimes touching her head and body. (D) Male creeping ahead of the female. After the female touches the male's tail, he deposits a spermatophore, which can be seen emerging from the male's cloaca. (E) The male then turns 90° and blocks the female's path, sometime pushing her back with his body or tail (brake and push back). (F) After spermatophore deposition and pick-up, the male sometimes bites the head of the female. This form of post-mating mate-guarding behavior is not seen in most other species of newts. After original drawings by Bas Teunis in Sparreboom and Teunis (1990).

and Houck 1982; Houck and Sever 1994; see subsequent further discussion). Some plethodontids, such as *Gyrinophilus porphyriticus,* lack courtship glands on the chin, but during courtship, the male repeatedly rubs his snout on the snout, head, and body of the female (Beachy 1997a). Similar rubbing behavior occurs during courtship in ambystomatids and amphiumids, which lack courtship glands on the head. Beachy (1997a) suggested that such behavior evolved as a form of tactile stimulation and secondarily assumed the function of delivering chemical signals to the female. In contrast, Houck and Sever (1994) hypothesized that courtship glands and behavior to transfer chemicals to females evolved together, with the courtship glands being secondarily lost in some plethodontids, including *Gyrinophilus.*

In most urodeles, tactile signals transmitted from the female to the male are critical for the successful completion of courtship. In *Triturus,* a male will not deposit a spermatophore until the female touches his tail with her snout (fig. 9.9). Similarly, in many ambystomatids, the female signals her readiness to receive a spermatophore by nudging the base of the male's tail with her snout. In plethodontids, the female signals her receptivity by resting her chin on the dorsal surface of the male's tail and engaging in a tail-straddling walk (fig. 9.10). In all of these groups, males can be induced to deposit spermatophores if they are provided with artificial tactile stimulation (Halliday 1975a; Arnold 1976).

Chemical Communication

Chemical signals seem to provide the principal cues for individual, sex, and species recognition in most species of salamanders (Arnold 1977; Halliday 1977a, 1990; Madison 1977; Arnold and Houck 1982; Houck and Sever 1994; Dawley 1998; Houck and Arnold 2003; Sever 2003b; Gautier et al. 2006). These signals can be derived from pheromones produced by specialized glands, from odors emanating from unspecialized epidermal secretions, or from fecal material, which sometimes are supplemented with glandular secretions. In many species, chemical signals seem to be transmitted mainly through direct contact between individuals,

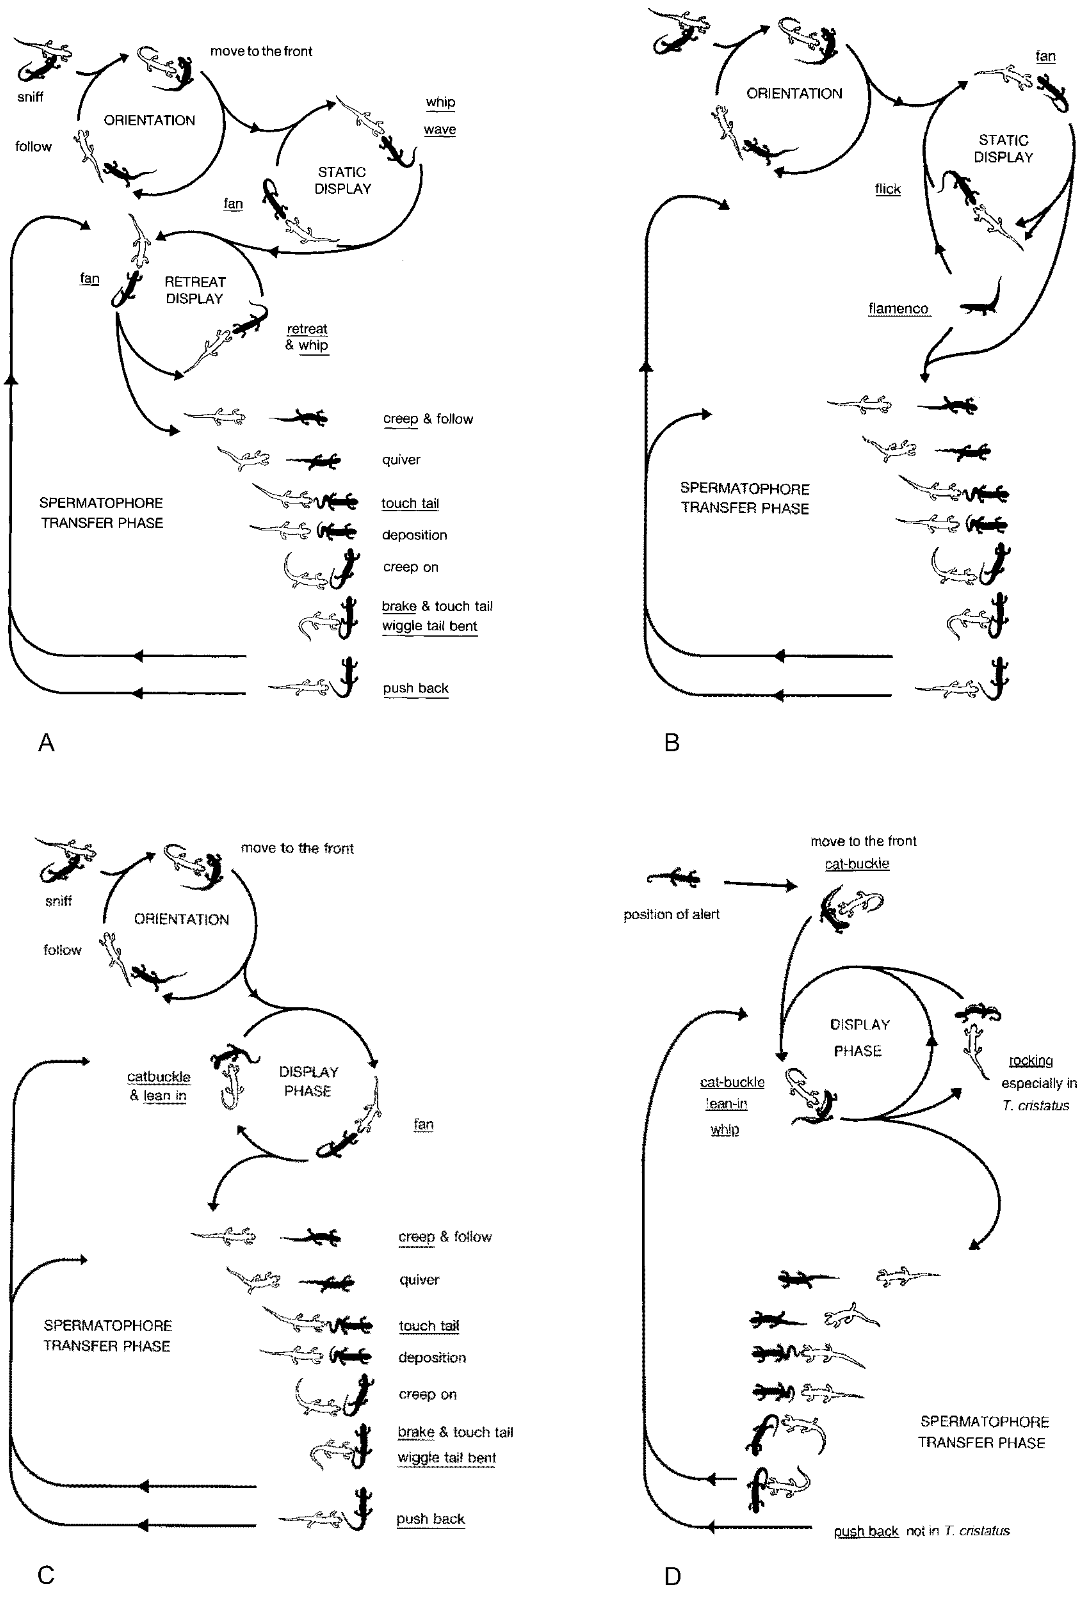

Fig. 9.9. Diagrams of courtship behavior of four species of European newts. (A) Courtship of *Triturus vulgaris,* a relatively small species. Courtship in this species and several others includes distinct orientation, static display, and retreat display phases. In the retreat display, the male backs away from the female while fanning or whipping his tail toward her. (B) Courtship of *T. boscai,* another small-bodied newt. This species lacks the retreat display, but has a distinct flamenco display (see fig. 9.5) that is not seen in *T. vulgaris.* (C) Courtship of *T. alpestris,* a medium-sized newt. This species also lacks the distinct retreat display, but has the derived lean in and catbuckle displays that also are seen in larger species. (D) Courtship of the largest species of newts, including *T. cristatus, T. carnifex,* and *T. marmoratus.* These species have lek mating systems and courtship displays that include frequent lateral displays of sexually dimorphic markings and coloration. After Arntzen and Sparreboom (1989).

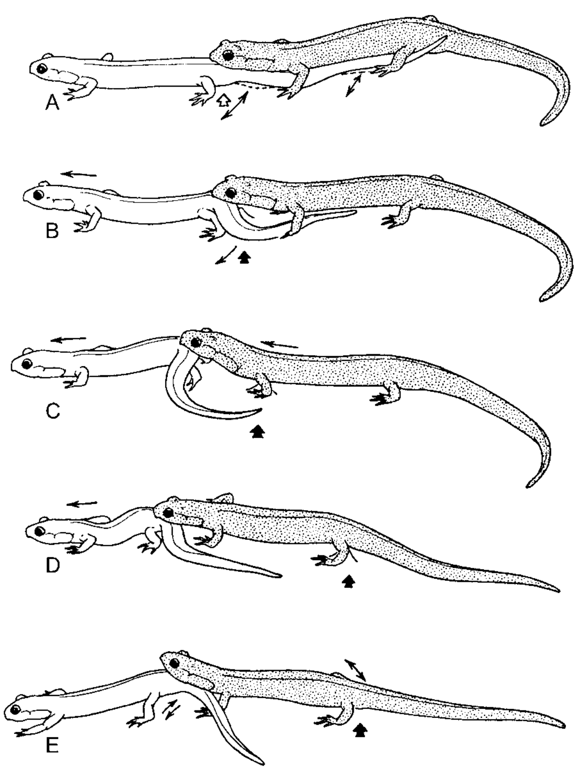

Fig. 9.10. Tail-straddling walk during the courtship of *Plethodon shermani.* The shaded individual is the female. (A) The female places her chin on the base of the male's tail and follows him as he moves. (B) The male deposits a spermatophore (black arrow) and moves his tail to the side. (C, D) The male leads the female forward until her cloaca is positioned over the spermatophore. (E) The male lifts the base of his tail as the female is positioned over the spermatophore, and she picks up the spermatophore with the lips of the cloaca. After Arnold (1976).

but some salamanders can obtain information from chemicals deposited on a substrate or from air- and water-borne chemicals. This section focuses on the production, delivery, and detection of chemical signals. The functions of these signals are described in more detail in later sections.

Production and Delivery of Chemical Signals

Male urodeles generally do not produce signals that attract females, although some species may exhibit a general attraction to conspecific chemical cues (Secondi, Haerty, and Lodé 2005). Typically males search for females in appropriate habitats (see Mating Systems). In some aquatic species, females facilitate mate location by males by producing chemical sex attractants. Behavioral experiments have shown that males of some species move toward chemical cues emanating from females, even without making direct contact (Zippelius 1948; Twitty 1955, 1966; W. C. Davis and Twitty 1964; Dawley 1984a; Malacarne and Giacoma 1986; Verrell 1986b; Andreoletti et al. 1988; Belvedere et al. 1988; Rowland, Robb, and Cortwright 1990; Cogălniceanu 1992, 1994; Park and Propper 2001; Park et al. 2004; Rohr et al. 2005; see further discussion under "Sex Recognition"). The origin of these sex attractants is not known. One likely source is material exuded from unspecialized glands in the skin, but in salamandrids, it also is possible that the ventral cloacal glands of females produce attractant pheromones (Houck and Sever 1994).

Once a male salamander has located and identified a female, he often courts the female using pheromones produced by specialized glands in the cloacal region, at the base of the tail, and on the head. The anatomy and histology of cloacal glands have been studied in all families of salamanders (Sever 1978, 1980, 1981, 1983, 1991a, 1992a, 1994; 2003b; Sever et al. 1990; Brizzi, Calloni, and Delfino 1990, 1992; Brizzi et al. 1995, 1996; Brizzi and Calloni 1992), but their role in chemical communication has been investigated only in salamandrids. The ancestral condition for salamanders with external fertilization is to have a relatively simple gland in the cloacal region of both males and females that produces chemical sex attractants (Sever 1991a). With the evolution of internal fertilization, cloacal glands of males evolved the secondary function of producing the spermatophore (see chapter 10).

In most urodele families, there are three sets of glands involved in spermatophore production: the pelvic glands, ventral glands, and Kingsbury's glands. One pelvic gland, which sometimes has more than one part, appears to be involved in production of courtship pheromones. In salamandrids, this has been called the dorsal or abdominal gland, although the latter term is now considered an inappropriate description of the gland's location (Sever et al. 1990). In all other salamander families, the putative pheromone-producing gland is called the vent gland, which appears to be homologous to the dorsal gland of male salamandrids. The term *dorsal gland* is somewhat confusing, because there are glands of the same name in female salamanders that are not homologous to the dorsal glands of males (Sever 1991a). Guillaume (2000b, c) described an entirely new type of clocal gland in *Proteus anguinus* that secretes onto the ventral skin around the cloaca and may be involved in producing chemical signals used to mark substrates (Guillaume 1999, 2000a). These glands are found in both males and females, but are larger and more active in males, which are territorial when breeding.

In all salamanders that have been studied, the cloacal glands of males involved in both spermatophore and pheromone production become enlarged in response to increases in male hormone levels during the breeding season; these are particularly conspicuous in salamandrids and ambystomatids. In salamandrids, secretory activity of these glands increases as well (Sever et al. 1990). Cedrini and Fasolo (1971) reported that dorsal gland extracts elicited strong responses in the olfactory bulb of female *Triturus,* and these glands appear to be the source of pheromones that help to bring females into a state of sexual receptivity (Malacarne et al. 1984; Malacarne and Giacoma 1986). Behavioral experiments with *Triturus carnifex* demonstrated that females are attracted to water containing courting male-female pairs in preference to water containing sexually inactive pairs or water alone (Malacarne and Vellano 1987). Females were not attracted to water containing males alone, however, suggesting that males do not produce a sex attractant. Instead, they probably release pheromones only when actively courting females. Kikuyama et al. (1995) reported that females of an Asian newt, *Cynops pyrrhogaster,* will orient toward water flowing from a chamber containing actively courting pairs, or to sponges treated with extracts from the cloacal glands. The pheromone that elicits responses from females is a peptide called sodefrin. A closely related species, *C. ensicauda,* produces a pheromone called silefrin, which has a similar structure. It is attractive to conspecific females, but not to females of *C. pyrrhogaster* (Kikuyama et al. 2002).

Pheromones probably are delivered to females during the tail fanning display of male newts (Halliday 1977a). In a study of the red-spotted newt (*Notophthalmus viridescens*), Verrell (1982) placed dye in the water near the male's cloaca; the dye moved toward the female's snout during courtship. In most salamandrids, secretory products of the dorsal gland empty into the cloaca, but in *Salamandra,* which has terrestrial courtship, glandular products discharge into skin furrows outside the cloaca (Brizzi et al. 1996). This suggests that males deposit glandular secretions on the ground during courtship. In another salamandrid with terrestrial courtship, *Echinotriton chinhaeiensis,* the male deposits a trail of mucus from his cloaca, but it is not yet clear whether the male deposits a pheromone that stimulates the female (Sparreboom, Xie, and Liang 2001). In *Euproctus* and *Calotriton,* the male clasps the female and deposits the spermatophore directly into her cloaca (see chapter 10). The delivery of chemical signals to the female seen in the courtship of other salamandrids seems to have been lost, and the dorsal gland is absent as well (Brizzi et al. 1995; Guillaume 1999). A similar and apparently independent loss of the dorsal gland has occurred in *Chioglossa lusitanica,* which also exhibits increased use of tactile signals and clasping during courtship (Brizzi et al. 1999).

The vent glands of other salamanders probably produce courtship pheromones as well, but behavioral experiments have not been performed with other families. The size and presumably the activity of vent glands vary among different groups of salamanders, and this probably reflects variation in the importance of vent gland secretions in courtship. Vent glands are relatively well developed in most salamanders that breed in water, such as proteids and ambystomatids. The female signals her receptivity by nudging the cloacal region of the male, but whether the female is orienting to pheromones produced by the male is not known (S. Arnold 1976, 1977). Vent glands tend to be smaller in most plethodontids, perhaps reflecting the increased importance of courtship glands in other regions, and they have been completely lost in some neotenic hemidactyliines (Sever 1991a, 1994, 2003b). On the other hand, vent glands are large in some plethodontids, including *Aneides lugubris, Pseudotriton montanus,* and a number of bolitoglossine salamanders (Sever 1994). Some of these species, such as *Pseudotriton,* lack pheromone-producing glands on the chin (Houck and Sever 1994), but others with enlarged vent glands do not. Until more behavioral work is done on these salamanders, the functional correlates of relative vent gland size will remain unclear.

Among urodeles as a whole, the occurrence of specialized glands on the head or chin that are used in courtship is a derived condition confined to some salamandrids and to plethodontids (Houck and Sever 1994; Sever 2003b). Noble (1931) referred to a variety of anatomically unrelated glands as hedonic glands, but Arnold (1977) proposed that these be termed courtship glands, and that individual glands be named by their anatomical position rather than their putative functions. In salamandrids, use of courtship glands differs among genera (Halliday 1990). In *Notophthalmus,* the male seizes the female around her neck with his hind legs and rubs her snout with genial glands on his cheeks (fig. 9.11 B). In *Taricha,* the male clasps the female with both pairs of legs and rubs her snout with a submandibular gland (W. C. Davis and Twitty 1964; Propper 1991). This seems to be an obligatory stage that can last for several hours before the male leads the female and deposits spermatophores (Arnold 1977). In the initial stages of courtship in the terrestrial genus *Salamandra,* the male approaches the female from above and rubs his throat on her snout, possibly to deliver pheromones from a submandibular gland (Joly 1966;

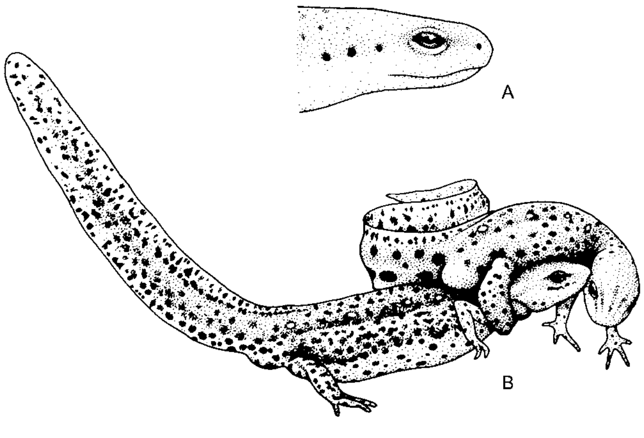

Fig. 9.11. Courtship of the North American red-spotted newt (*Notophthalmus viridescens*). (A) Secretory pits of courtship gland on side of the male's head. (B) Amplexus, with the male rubbing the courtship gland against the snout of the female while grasping her with the hind legs. After Halliday (1990).

Häfeli 1971). The male then moves under the female and clasps her in ventral amplexus. In *Triturus,* males lack courtship glands on the head, and, as discussed earlier, males do not clasp females during courtship (Halliday 1977a).

The structure and function of courtship glands have been studied in some detail in *Notophthalmus viridescens* (Pool and Dent 1977; Pool, Dent, and Kemphues 1977). Males and females have structurally similar glands on the sides of the head, but those of females do not normally produce secretory products. The courtship glands of males become functional during the breeding season, secreting a glycoproteinaceous product that accumulates in small epidermal pits on the side of the head (fig. 9.11 A). Secretory activity is induced by a combination of prolactin and testosterone. Administration of these hormones to females can induce glandular secretion as well, but normally females will not have circulating levels of testosterone high enough to produce secretions. The hormonal induction of courtship gland activity coincides with the development of secondary sexual characters such as broad tail fins and nuptial pads on the hind feet of males (Singhas and Dent 1975). Early experiments by Rogoff (1927) showed that a female would not follow a male or pick up spermatophores if the pores of the courtship glands were blocked, or if the female's nares were closed. If the female's snout was held against the male's glands, she would follow the male even if she had not gone through the preliminary stages of courtship. Subsequent work by Arnold (1972) and Verrell (1982) showed that use of the glands during courtship is facultative. When females are particularly receptive, the male skips this stage and proceeds directly to leading the female and depositing spermatophores.

In plethodontids, courtship glands are located on the chin and are termed mental glands (Sever 1976, 2003b). As in newts, seasonal enlargement of the glands occurs during the mating period and is correlated with high levels of circulating androgens (Woodley 1994). The structure of mental glands differs among different groups of plethodontids and roughly corresponds to the mode of pheromone delivery to females (fig. 9.12). The most widespread modes of pheromone delivery, which are considered ancestral for plethodontids, have been termed "pulling" and "snapping" (Arnold 1977; Arnold and Houck, 1982; Houck and Sever 1994). A male either rakes his premaxillary teeth across the female's dorsal skin, or he snaps his head down to puncture the skin (fig. 9.13 A, B). Both actions serve to vaccinate the female with mental gland secretions. Species with this mode of pheromone delivery typically have small mental glands and well-developed premaxillary teeth. In the two smallest species of desmognathines, *Desmognathus aeneus* and *D. wrighti,* males have an unusual mode of pheromone delivery derived from this ancestral mode. The male actually bites the female during courtship and holds on for several minutes while delivering mental gland secretions (fig. 9.13 C, D; Arnold and Houck 1982; Promislow 1987; Verrell 1999). In these species, secretions of the mental glands are released through pores at the base of the male's elongated teeth, in contrast to the usual condition of being released through pores in the skin (Sever 1976). *Desmognathus wrighti* and *D. aeneus* are not sister species, so their unusual mode of pheromone delivery appears to have evolved independently (fig. 9.14). Similar behavior also occurs in *D. imitator,* which is not closely related to either of these species (Verrell 1994b; Mead and Verrell 2002).

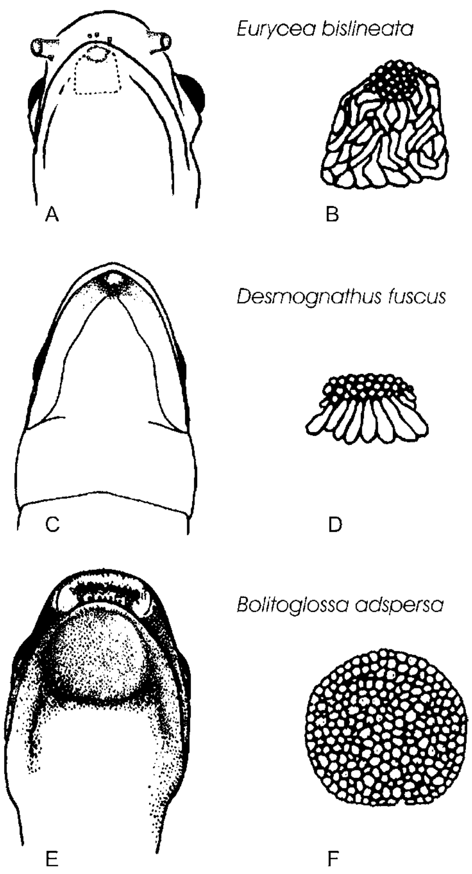

Fig. 9.12. Mental glands of plethodontid salamanders. (A) "Fan" type mental gland of *Eurycea bislineata.* The dashed line shows the part of the gland beneath the skin. The small circular area is the exposed secretory portion of the gland. The male also has enlarged cirri on the snout and elongated premaxillary teeth that protrude through the upper lip; these teeth are used to rake the skin of the female to deliver pheromones from the gland. (B) Fine structure of gland, showing horizontally oriented tubules that fan out from the terminal secretory pores. (C) Mental gland typical of the genus *Desmognathus,* a small protrusion at the tip of the chin. (D) Fine structure of the gland, showing vertical tubules and secretory pores, which are located only at the anterior portion of the protrusion. (E) Pad-shaped mental gland of *Bolitoglossa adspersa.* Four premaxillary teeth protrude through the upper lip of the male and are used with the gland to deliver pheromone to the female. Large species of *Plethodon* also have pad-shaped glands, but lack the protruding premaxillary teeth. (F) Cross-section of the gland, showing vertical tubules. The entire surface of the pad contains secretory pores. After Houck and Sever (1994).

In most small-bodied species of *Plethodon,* such as mem-

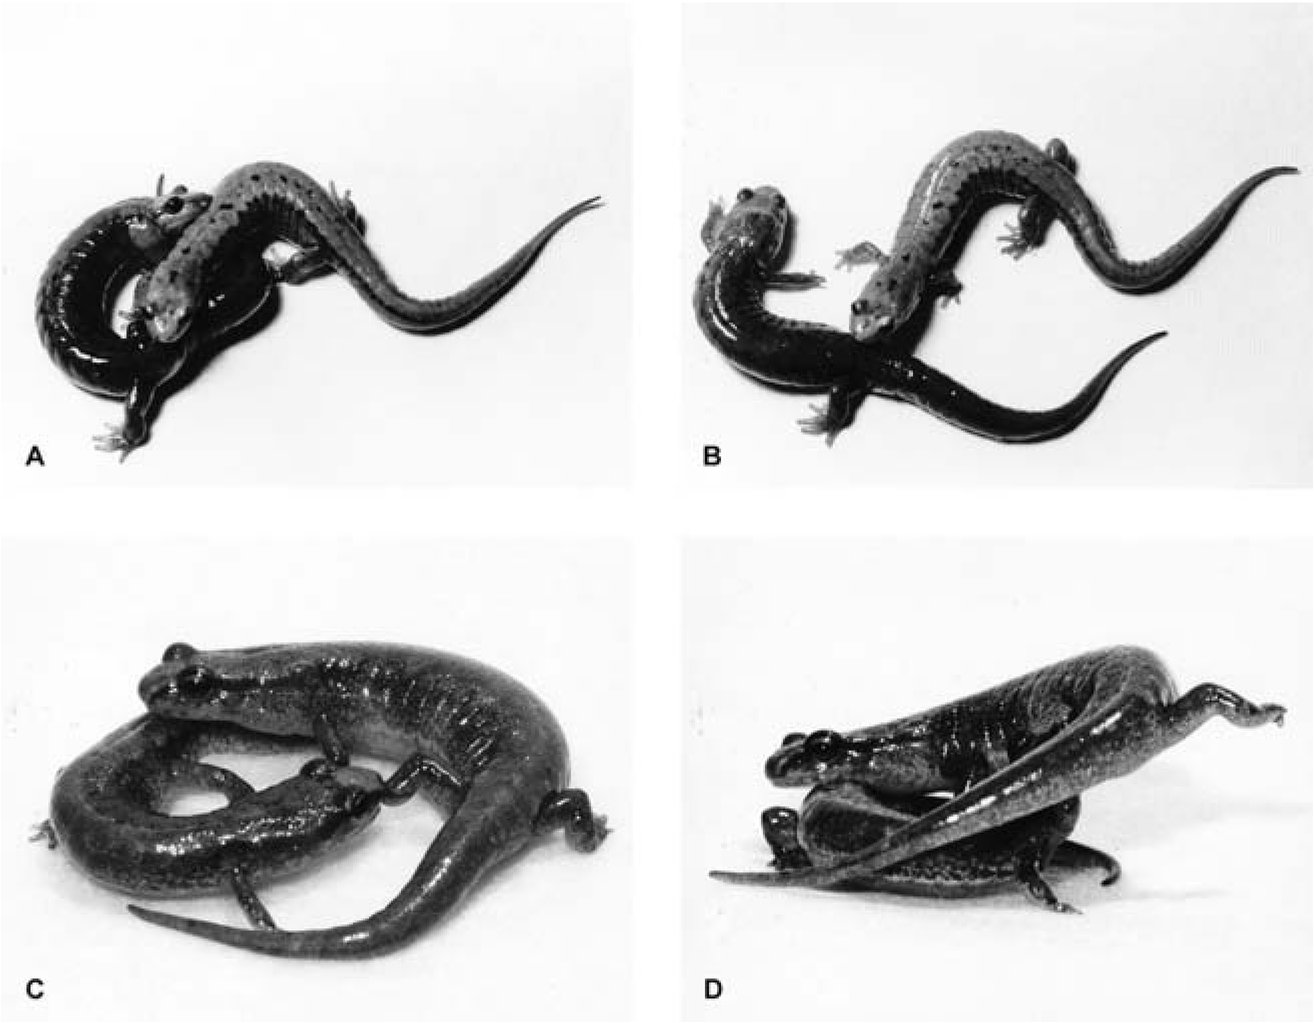

Fig. 9.13. Courtship behavior in the genus *Desmognathus.* (A) Male *D. orestes* (left) in position to initiate a snap, with premaxillary teeth in contact with the female (right). (B) Position of the male (left) after delivering a snap; the snapping action has thrown his body away from the female. (C) Male *D. wrighti* (left) biting the hind foot of the female (right), possibly delivering pheromones into her bloodstream. (D) Male *D. wrighti* biting the female's body, lifting her off of the ground. Photos by Stevan J. Arnold.

bers of the *P. cinereus* group, males transfer pheromones by vaccination before progressing to the tail-straddling walk. In large-bodied species of *Plethodon,* such as members of the *Plethodon jordani* and *P. glutinosus* complexes, males have very large padlike mental glands (fig. 9.12 E). They use a derived mode of pheromone delivery. During the tail-straddling walk, the male turns around and slaps his mental gland on the snout of the female (Arnold 1976; Marvin and Hutchison 1996; fig. 9.15). *Plethodon dorsalis* is a relatively small species from western North America that is phylogenetically intermediate between the small eastern *Plethodon* and the large-bodied species. In this species, the male applies pheromones by slapping or rubbing the mental gland on the female's snout, as in the large-bodied species, but does so before the tail-straddling walk, as in the *P. cinereus* group (Picard 2005).

A number of plethodontids in different clades lack both mental glands and pheromone delivery during courtship (fig. 9.14). Houck and Sever (1994) considered these to be instances of secondary loss of both glands and the behavior associated with pheromone delivery. In contrast, Beachy (1997a) suggested that the ancestral condition for all plethodontids was the absence of mental glands, and this condition has been retained in some groups, such as *Gyrinophilus, Pseudotriton, Ensatina,* and *Phaeognathus.* In this scenario, mental glands would have evolved independently several times within the family, perhaps accounting for the striking differences in mental gland structure in different lineages (fig. 9.12).

Arnold and Houck (1982) reported experiments designed to determine the function of mental gland secretions in *Desmognathus ocoee* (this population was formerly considered

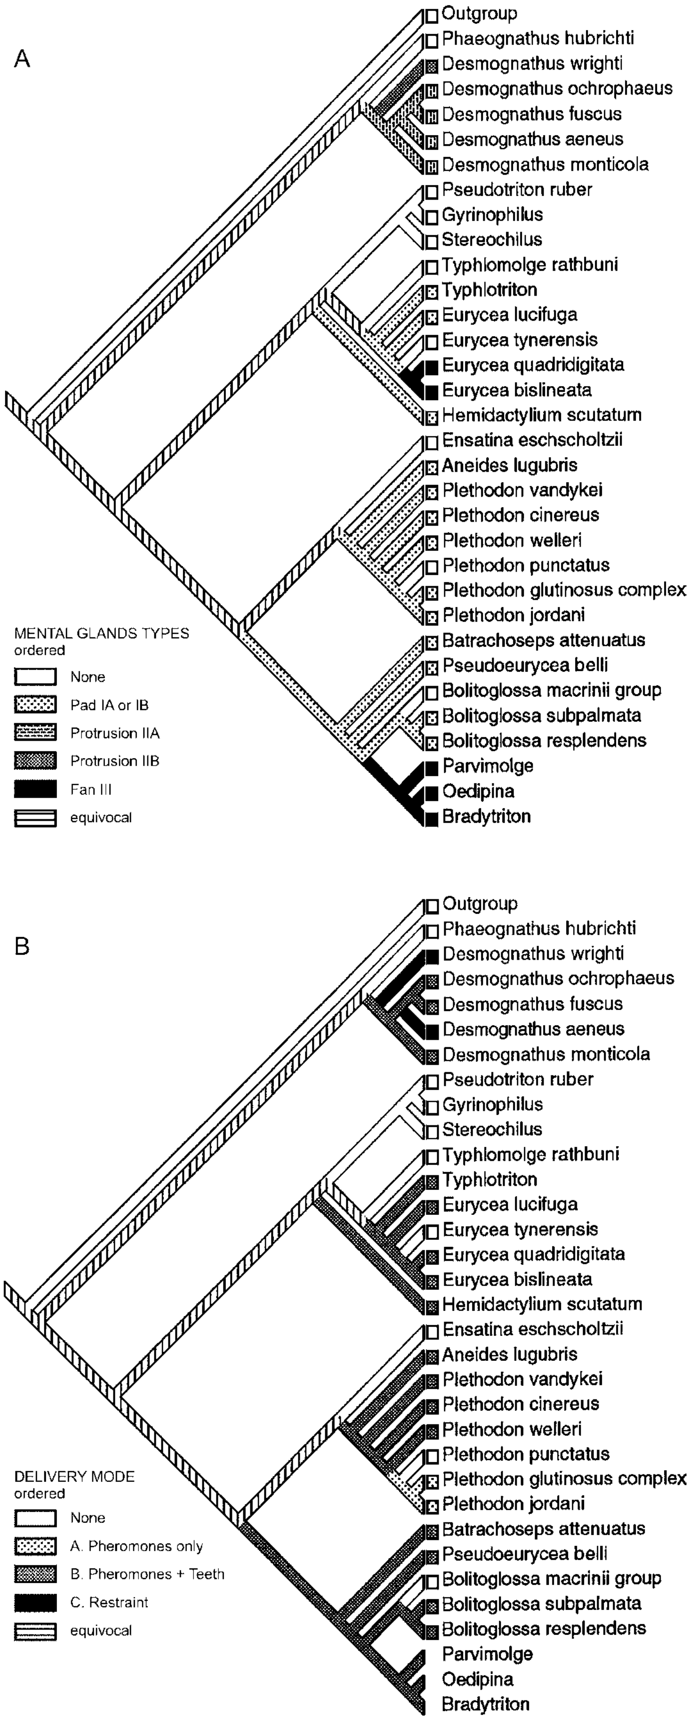

Fig. 9.14. Phylogeny of (A) mental gland types and (B) modes of pheromone delivery in plethodontid salamanders. The phylogeny is based on morphological and molecular characters and was derived independently of the mental gland and behavioral traits. The four major clades, from top to bottom, are the Desmognathinae, the Hemidactyliini, the Plethodontini, and the Bolitoglossini. More recent molecular phylogenies differ from this one in that desmognathines are thought to have evolved from within plethodontines, and the monophyly of the Hemidactyliini is doubtful. Consequently, the evolution of pheromone delivery modes may be more complex than depicted here. (A) Protrusion-type mental glands predominate in the Desmognathinae. All other groups have pad- or fan-type glands. Mental glands have been secondarily lost in several genera. (B) Most plethodontids use the premaxillary teeth to deliver pheromones from mental glands. Two species of *Desmognathus* have independently evolved a form of courtship in which the male bites the female and restrains her (see fig. 9.13). In large species of *Plethodon,* the male delivers pheromones by slapping the mental gland on the snout of the female, but does not use premaxillary teeth to rake the female's skin (see fig. 9.15). After Houck and Sever (1994).

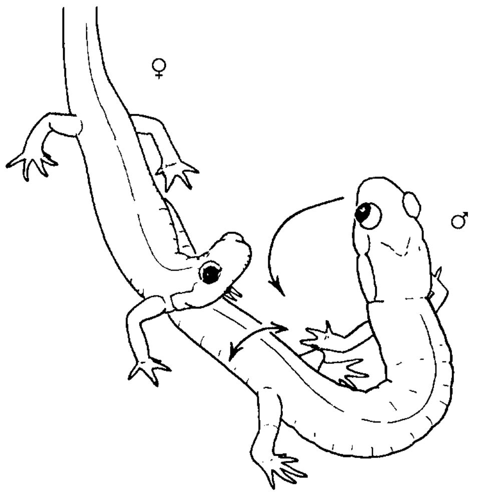

Fig. 9.15. Male *Plethodon shermani* slapping his mental gland on the snout of a female during the tail-straddling walk. After Arnold (1976).

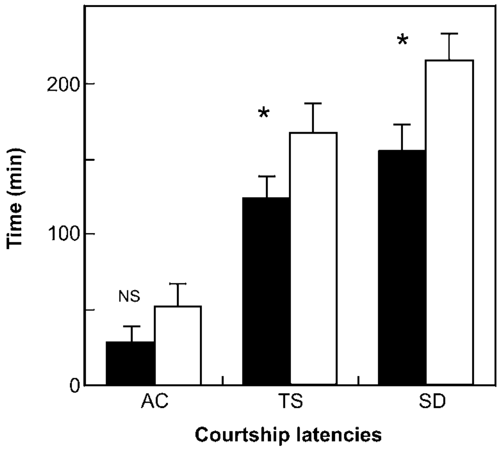

Fig. 9.16. Differences in timing of courtship events for 17 females of *Desmognathus ocoee* treated with pheromones (black bars) or saline (white bars). Data are mean latencies ± 1 SE. (AC) Latency to active courtship. (TS) Latency to tail-straddling walk. (SD) Latency to spermatophore deposition. Females treated with pheromones initiated the tail-straddling walk and deposited spermatophores significantly sooner than did those treated with saline. After Houck and Reagan (1990).

to be *D. ochrophaeus;* see Tilley and Mahoney 1996). They surgically removed mental glands, premaxillary teeth, or both from male salamanders and compared their success in inseminating females with that of control groups. Surprisingly, the absence of teeth and mental glands did not seem to reduce male mating success. Subsequent work by Houck and Regan (1990) on the same species did demonstrate that mental gland secretions can have an effect on courtship behavior. They removed mental glands from males and used extracts from the glands in courtship tests with females. Those females that received glandular extracts applied to the skin on filter paper progressed more rapidly to the tail-straddling walk stage of courtship than did control females, and the time to spermatophore deposition was shorter as well (fig. 9.16).

In a study of *Plethodon shermani,* a member of the *P. jordani* complex, Houck et al. (1998) applied mental gland extracts to the external nares of females, which were then courted by males from which the glands had been removed. Treated females were more receptive than control females, as shown by the shorter time to initiation of courtship and to active courtship by males. The pheromone involved consists mainly of two proteins. One of these, called plethodontid receptivity factor, is sufficient to increase female receptivity (Rollmann, Houck, and Feldhoff 1999), which is mediated by specific neurons in the female vomeronasal system that respond to the pheromone (Wirsig-Wiechmann et al. 2002). Modes of pheromone delivery are evolutionarily conservative in plethodontids, with courtship behavior being nearly identical among closely related species. In contrast, there is considerable variation in the biochemical structure of courtship pheromones among populations of the same species and between closely related species (Rollmann, Houck, and Feldhoff 2000), indicating strong directional selection on pheromones (Watts et al. 2004). Nevertheless, divergence in pheromone structure is not complete, and females of some species are stimulated by the pheromones of closely related species. For example, the pheromones of *P. montanus* and *P. yonahlossee* were as effective as conspecific pheromones in increasing female receptivity in *P. shermani* (Rollmann, Houck, and Feldhoff 2003). These species exhibit relatively low levels of divergence in the gene that codes for the courtship pheromone (Palmer et al. 2005). Indeed, species recognition is not perfect, and there is considerable genetic evidence of both past and present hybridization among closely related species (Highton and Henry 1970; Highton 1995; Highton and Peabody 2000; Weisrock, Kozak, and A. Larson 2005; see the following further discussion of "Species Recognition").

Plethodontids have glands located in other parts of the body that are used for chemical communication, but the functions of these glands are not as well understood as that of mental glands. Plethodontids engage in a tail-straddling walk during courtship, with the female placing her chin at the base of the male's tail (Arnold 1977; Marvin and Hutchison 1996; fig. 9.10). In several genera, including *Desmognathus, Eurycea, Plethodon,* and possibly *Hydromantes,* males have small glands on the dorsal surface of the tail base, where they probably deliver secretions to the nasolabial grooves of the female during the tail-straddling walk (Noble 1929c, 1931; Sever 1985, 1989; Brizzi, Calloni, and Delfino 1991; Houck and Sever 1994; Sever 2003b). These glands often are not visible on the surface of the skin, or form a slightly raised bump. They have been studied histologically in only a few species, and there have not been any experiments demonstrating the signal function of their secretions. Given the ubiquity of the tail-straddling walk in plethodontids, it is likely that such glands occur in many other species that have yet to be examined.

Some plethodontids also have glands used in chemical communication on the ventral side of the tail, just behind the cloaca (Noble 1929c). In *Plethodon cinereus,* the postcloacal gland appears to be used to mark fecal pellets with chemicals, which in turn are used to advertise ownership of a territory (Simons and Felgenhauer 1992; Jaeger and Gabor 1993; Simons, Felgenhauer, and Jaeger 1994). These glands are found in males and females, both of which are territorial (Horne and Jaeger 1988), and active glands have even been found in juvenile red-backed salamanders (Simons, Jaeger, and Felgenhauer 1995; see the subsequent further discussion of territoriality in this species). Postcloacal glands also have been described in both males and females of *Aneides lugubris* (Staub and Paladin 1997). Although present in both sexes, they are larger in males. Their precise function is not known, but it is possible that they are used to mark substrates for territorial advertisement. Members of this genus are known to be very aggressive toward conspecifics (Cupp 1980; Staub 1993). Substrate marking with fecal pellets, presumably carrying glandular secretions, also has been observed in the genus *Salamandra* (Gautier and Miaud 2003). Postcloacal glands appear to be modified granular glands that originally produced defensive chemicals (see chapter 14), and courtship glands on the dorsal surface of the tail are modified granular glands as well (Sever 1989; Brizzi, Calloni, and Delfino 1991; Staub and Paladin 1997). In contrast, mental courtship glands appear to have evolved from mucous glands (Houck and Sever 1994).

Detection of Chemical Signals

There are several ways in which chemical signals can be detected by salamanders: by unspecialized receptors in the skin, by specialized receptor organs in the nasal cavity, or possibly by brain receptors responding to pheromones that are presumed to be delivered directly into the bloodstream (as in the courtship of plethodontids that involves pulling, snapping, or biting with the teeth). Dawley (1998) provided a detailed review of the structure and function of nasal receptor organs in salamanders, as well as the physiology and neurobiology of chemoreception. Only a brief summary will be given here.

The chemosensory organs in the nasal cavities of salamanders are of two types—the main olfactory chamber and the vomeronasal organ. The chemosensory epithelium in the main olfactory chamber is used primarily to detect volatile airborne odors (in terrestrial salamanders) or waterborne chemicals (in aquatic species). In aquatic salamanders, the sensory epithelium is located in grooves in the nasal epithelium that run parallel to the direction of water flow through the nasal cavity, a structure that presumably facilitates detection of chemicals in the water (Dawley 1998). In contrast, the sensory epithelium is arranged in a flat sheet in terrestrial species, an arrangement that probably maximizes the surface area exposed to air flowing through the nasal cavity. In terrestrial salamanders that have aquatic larvae, the larvae have grooves lined with sensory epithelium, but the epithelium becomes more flattened at metamorphosis (Arzt et al. 1986; Dawley 1998). In some aquatic species, such as *Necturus,* the olfactory epithelium is much thicker than that of most other vertebrates (Farbman and Gesteland 1974; Graziadei and Monti Graziadei 1976). It is not clear whether this reflects a greater sensitivity to chemicals, or is simply a consequence of the large cell size characteristic of salamanders.

The vomeronasal organ is located in a special pocket, or diverticulum, off of the main olfactory chamber. In some terrestrial salamanders, such as *Ambystoma maculatum,* only a small portion of the wall of this chamber is lined with sensory epithelium, suggesting a relatively minor role for the vomeronasal organ. In contrast, a larger area of sensory cells is found in *Triturus* and especially in plethodontids, which have most of the diverticulum lined with sensory cells (Dawley 1998). In *Plethodon cinereus,* the vomeronasal chamber is distinctly separate from the main olfactory chamber (fig. 9.17; Dawley and Bass 1988). In addition, plethodontids have unique structures, the nasolabial grooves, which deliver chemicals directly to the vomeronasal organs, bypassing the main olfactory chamber (Dawley and Bass 1989). The nasolabial grooves are equipped with glands that secrete a lipid compound (C. Brown and Martof 1966; Sever 1975b, 1980). This fluid picks up chemicals when the sala-

Abbreviations: EN = external nares; LD = lateral diverticulum; MOC = main olfactory chamber; NLD = nasolacrimal duct; NLG = nasolabial groove; VNO = vomeronasal organ. After Dawley and Bass (1988).

mander touches its snout to the substrate (nose-tapping) or to another salamander, and the fluid and chemical molecules are then carried by capillary action to the vomeronasal organs (C. Brown and Martof 1966; Dawley and Bass 1989).

The relative sizes of the chemosensory organs of salamanders are correlated to some extent with habitat and behavior, but they reflect phylogenetic history as well. Some paedomorphic, fully aquatic salamanders, such as cryptobranchids and amphiumids, have greatly reduced vomeronasal organs (Jurgens 1971). In contrast, secondarily aquatic species with terrestrial ancestors have vomeronasal organs as large or larger than those of terrestrial relatives (Dawley 1992a), a pattern seen in aquatic caecilians as well (A. Schmidt and Wake 1990). In salamandrids and plethodontids, species that have an aquatic larval stage tend to have larger vomeronasal organs, with a more complex projection of nerves from the vomeronasal organ to the accessory olfactory bulb than do strictly terrestrial species with direct development or viviparity (Schmidt, Naujoks-Manteuffel, and Roth 1988; Dawley 1992a, 1998). For example, among plethodontids, semiaquatic species such as *Eurycea wilderae, E. guttolineata,* and *Desmognathus quadramaculatus* have larger vomeronasal organs in relation to body size than do either *Plethodon cinereus* or *Desmognathus wrighti,* both of which have direct development. On the other hand, bolitoglossine salamanders, all of which have direct development, not only tend to have relatively large vomeronasal organs relative to body size, but have large main and accessory olfactory bulbs in the brain as well (Dawley 1998). This suggests that there are phylogenetic patterns in vomeronasal organ evolution for which ecological or behavioral correlates have yet to be identified.

Plethodontid salamanders also exhibit sexual dimorphism in vomeronasal organs that is correlated with sexual differences in behavior. Both the vomeronasal and main olfactory organs are larger in males than in females (Dawley, 1992a, b), probably reflecting the tendency for males to search for and identify potential mates using chemical cues. In addition, *P. cinereus* exhibits seasonal changes in the size of the vomeronasal organ. The organ increases in size in both males and females during the summer, prior to the fall and spring mating season (Dawley and Crowder 1995), but at a time when both males and females tend to be highly territorial (Jaeger 1986). This is due to a seasonal proliferation of new sensory cells (Dawley et al. 2000). The ability to proliferate new cells is an unusual feature of vertebrate olfactory systems and probably reflects a need to regenerate sensory cells that have been damaged by chemicals (Dawley 1998). In the case of *P. cinereus,* and probably other plethodontids, this capacity to regenerate new cells has been adapted to seasonal changes in the need to detect chemical cues related to mate location, courtship, or territorial advertisement. Rather than being triggered by damage to sensory cells, the process leading to the production of new cells is initited by a regular seasonal cycle of events (Dawley et al. 2000).

Seasonal changes in the olfactory system and concomitant changes in sensitivity to chemical signals very likely are hormonally regulated. Thompson and Moore (2000) found that male newts (*Taricha granulosa*) treated with arginine vasotocin (AVT) spent more time with models of females impregnated with female sex pheromones than did untreated males. This is consistent with previous work showing that blocking AVT interferes with courtship behavior in this species (F. L. Moore and Miller 1983). Levels of AVT vary seasonal and increase during the courtship season (F. L. Moore and Zoeller 1979), so it seems reasonable to assume that the sensory system of the male becomes primed by AVT to respond to chemical signals produced by females.

Species, Sex, and Individual Recognition in Urodeles

The evidence that chemical signals are of primary importance in salamander communication comes mainly from observations of courtship and aggressive behavior. In contrast to the large literature on the ability of anurans to discriminate between different types of calls (chapter 7), there have been fewer experimental studies of chemical discrimination in salamanders. Such experiments are essential for determining the ability of either male or female salamanders to distinguish the odors of different species, sexes, or individuals. To ensure that visual and tactile cues have been eliminated, discrimination experiments must be designed so that the animals being tested do not actually contact the animals providing odor cues. Generally, odor discrimination has been tested by presenting test animals with a choice of previously marked substrates, or by presenting air- or water-borne odors from living salamanders in an olfactometer. Unfortunately, if the species being tested normally detects chemical signals of other individuals only through direct contact, then negative results in these experiments will not necessarily indicate an inability to discriminate odors. Nevertheless, these experiments can provide information on minimum discriminatory abilities.

Species Recognition

Many investigators have reported that male salamanders usually do not attempt to court females of the wrong species, especially if they have access to females of their own species (e.g., W. C. Davis and Twitty 1964; Arnold 1976, 1977). In *Taricha,* even blinded males easily distinguished between females of different species. In laboratory tests, however, males could be induced to attempt courtship with heterospecific females if water previously inhabited by conspecific females was added to test aquaria (W. C. Davis and Twitty 1964). This clearly indicates that chemical signals are important in species recognition.

Dawley (1984b, 1986b, b, 1987) investigated the ability of several large species of *Plethodon* to distinguish between conspecifics and heterospecifics on the basis of airborne odors alone. Test animals were placed in a glass Y-tube apparatus (fig. 9.18), which received odors from jars containing salamanders of different species. Dawley scored responses to odors by observing whether the test animal moved down the right or left arm of the apparatus. She tested the responses of males in several pairs of closely related species that do not hybridize at the collection sites: *Plethodon teyahalee* and *P. aureolus* from Monroe County, Tennessee; *P. teyahalee* and *P. jordani* from Madison County, North Carolina; and *P. glutinosus* and *P. kentucki* from Wise County, Virginia. These salamanders have undergone a series of confusing name changes as various cryptic species have been identified within what once were considered two widespread species, *P. glutinosus* (Highton 1989, 1995) and *P. jordani* (Highton and Peabody 2000). The Tennessee and North Carolina populations of the *P. glutinosus* complex were referred to as *P. glutinosus* in Dawley (1984b, 1986b), *P. teyahalee* in Dawley (1986a, 1987), and *P. oconaluftee* in Hairston (1993) and Petranka (1998). *Plethodon teyahalee* is name currently in use (Highton and Peabody 2000). *Plethodon aureolus* (Highton 1983) was called "Species A" in Dawley (1984b), while a population of *P. jordani* from Lemon Gap in Madison County, North Carolina, tested by Dawley (1986a), is now called *P. montanus* (Highton and Peabody 2000). Despite this taxonomic confusion, there is no doubt that the pairs tested in all of these experiments represent distinct species.

In all cases, males showed a clear preference for odors of their own species over those of heterospecifics. When males were given the opportunity to court a conspecific and a heterospecific female, they seldom showed any interest in heterospecific females (Dawley 1986b). The responses of females of these species to odors of conspecific and heterospecific males were less consistent. Most females tested during the breeding season showed a preference for odors of conspecific males over heterospecifics, but those tested outside of the breeding season either did not show a preference or actually avoided conspecific odors. The latter response could reflect avoidance of aggressively territorial males at times when females are not interested in finding mates. When salamanders were tested from populations known to hybridize in the field, the strength of behavioral preferences for conspecifics over heterospecifics was weaker in at least one of the species, suggesting that hybridization results from weak behavioral isolation (Dawley 1987). Recent work on the chemical structure of courtship pheromones in the *Plethodon jordani* complex has revealed considerable variation among geographically separated populations (Rollmann, Houck, and Feldhoff 2000; Watts et al. 2004). Nevertheless, the structure of the pheromones remains sufficiently similar that females of *P. shermani* were stimulated by courtship pheromones of closely related species (Rollmann, Houck, and Feldhoff 2003).

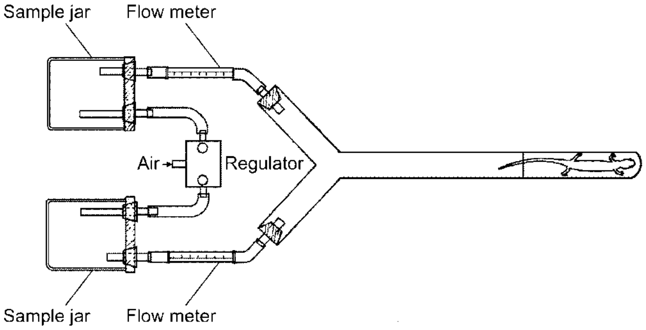

Fig. 9.18. Y-tube apparatus used to test for odor discrimination in experiments with members of the *Plethodon glutinosus* complex. The salamander was placed at the end of the tube, facing away from the arms of the apparatus to prevent it from running quickly down one arm of the Y-tube. After Dawley (1984a).

A considerable amount of work has been done on species recognition, sexual compatibility, and speciation in small streamside salamanders in the genus *Desmognathus* (Arnold, Reagan, and Verrell 1993; Verrell and Mabry 2000, 2003; Verrell 2003). This genus contains many very similar species, some of which have overlapping ranges. Genetic studies, based mostly on electrophoretic markers, have shown a wide range of variation in the degree of genetic differentiation among populations (Tilley et al. 1978; Tilley, Verrell, and Arnold 1990). Populations originally assigned to the widespread species *D. ochrophaeus* are especially confusing and have recently been partitioned into four cryptic species with ranges that show little or no overlap. Levels of genetic differentiation among these species (*D. ochrophaeus, D. ocoee, D. carolinensis,* and *D. orestes*) suggest that they have been evolving independently for considerable periods of time (Tilley and Mahoney 1996). Two other members of the *D. ochrophaeus* complex, *D. imitator* and *D. apalachicolae,* were previously separated as distinct species (Tilley 1981, 1985; Means and Karlin 1989). This pattern of differentiation into many very similar species is somewhat like the pattern seen in other complexes of cryptic salamander species (Highton 1989, 1995, 1997; Good and Wake 1992, 1993). The resulting changes in nomenclature mean that many behavioral studies refer to older names; careful attention to the geographic location of animals used in these studies is required to determine which species were being investigated (see Tilley and Mahoney 1996, for a guide to the literature on *Desmognathus*).

Behavioral experiments with many different populations in this complex have shown that sympatric populations of distinct species usually are strongly isolated from one another and do not mate with heterospecifics, even when not given a choice of mates. For example, in tests of sympatric populations of *D. ocoee* and *D. imitator* from the Great Smoky Mountains in Tennessee, Verrell (1989a) found that only 5% of heterospecific matings resulted in insemination of females. In most cases, males ignored heterospecific females and did not even initiate the preliminary stages of courtship. When males were tested in a Y-tube apparatus, both species showed a strong preference for conspecific female odors, indicating that chemical cues are used for species recognition. More detailed studies have been done on sympatric populations of *D. orestes* and *D. fuscus* from Mt. Rogers, Virginia. Houck, Arnold, and Hickman (1988) found nearly complete behavioral isolation between these populations in no-choice tests with heterospecifics. In a subsequent study, Uzendoski and Verrell (1993) found that only one of 60 courtship trials between heterospecifics resulted in deposition of a spermatophore by the male, and none resulted in insemination of the female. Again, males tended to ignore heterospecifics, and Y-maze tests showed a strong preference of males for conspecific female odors. Males of *D. orestes* that were reared in isolation in the laboratory showed the same lack of interest in females of *D. fuscus* as did field-collected males, indicating that prior experience is not necessary for species recognition (Verrell 1994c).

In addition to tests of sympatric populations that clearly belong to distinct species, there has been extensive investigation of behavioral isolation among allopatric populations of the *D. ochrophaeus* complex. Studies involving thousands of courtship trials have shown that behavioral isolation tends to be strongest in populations that are most widely separated geographically (Tilley et al. 1990; Verrell 2003). Although degree of genetic differentiation also was correlated with geographic distance between populations, genetic differentiation did not account for a significant amount of variation in degree of sexual isolation when geographic distance was held constant. It appears that gradual divergence of allopatric populations within the *D. ochrophaeus* complex has led to gradual evolution of reproductive isolation. Those populations now considered to be distinct species (*D. ocoee, D. orestes, D. carolinensis*) generally exhibit the strongest degree of behavioral isolation. Geographically close populations now considered to be the same species (Tilley and Mahoney 1996) generally exhibit low to moderate levels of isolation (Arnold, Verrell, and Tilley 1996; Herring and Verrell 1996), but may exhibit preferences for mates from their own population over those from other populations (Verrell 2003). Significant behavioral isolation also has been found among allopatric populations of *D. santeelah*, suggesting that these are in the process of splitting into distinct species as well (Maksymovitch and Verrell 1993).

In all of these salamander complexes, it appears that the complex topography of the southern Appalachians has resulted in populations becoming geographically isolated from one another for periods of time sufficient for gradual genetic divergence and divergence of mate recognition systems. Although the courtship behavior of most species of *Desmognathus* is very similar (Houck and Verrell 1993; Herring and Verrell 1996; Verrell and Mabry 2000, 2003), there are quantitative differences in the frequencies of different courtship behaviors. In addition, gradual divergence in chemical signals probably is responsible for much of the behavioral isolation among these populations (Verrell 2003). Not all plethodontids show this pattern, however. For example, there appears to be relatively little behavioral isolation among widely separated populations of *Eurycea wilderae* from different watersheds in North and South Carolina (Kozak 2003).

There has been some work on reproductive isolation in newts of the family Salamandridae. Although sympatric species normally breed only with members of their own species, hybridization between different species of newts is widespread but relatively infrequent in most regions (T. R. Halliday 1990; Arntzen et al. 1998; Michalak and Rafiński 1999; Babik, Szymura, and Rafiński 2003). Tests with allopatric populations of different species of Asian newts (*Cynops*) showed that interspecific courtship sometimes proceeded to spermatophore deposition, but usually the female failed to pick up the spermatophore (Kawamura and Sawada 1959; Sawada 1963). This was attributed to differences in the temporal patterning of courtship behavior. Michalak, Grzesik, and J. Rafiński (1997) tested for degrees of isolation between allopatric populations of two very closely related species, *Triturus vulgaris* and *T. montandoni.* Males in heterospecific tests were less likely to display to females than those in homospecific tests, and when display did occur, courtship was less likely to proceed to spermatophore deposition or transfer in hetersospecific pairings. Females were even less likely to mate with heterospecific males if they were given a choice between conspecific and heterospecific males (Michalak and Rafiński 1999). The overall courtship behavior of these two species is very similar, but color patterns of males are quite different and might be important for species recognition. It also is possible that chemical signals delivered during courtship displays differ, but this has not been investigated.

Much less work has been done on species recognition in other families of salamanders. In general, salamanders in other families tend to be well differentiated from sympatric species, but occasional hybridization has been reported. Present or past hybridization among different species of *Ambystoma* has resulted in the production of triploid hybrids, which usually live in association with one of the parental species. Reproduction by hybrid females depends on matings with males of a parental species. However, the male genome is not permanently incorporated into the offspring, so males that mate with hybrid females instead of conspecifics suffer lost reproductive success (Bogart 1989; Licht 1989; Lowcock 1989). In many populations, hybrid females outnumber diploid females of the parental species, so such matings are likely to be common (Bogart and Klemens 1997). However, males of one parental species, *Ambystoma jeffersonianum,* can distinguish the odors of conspecific females from those of triploid females associated with them and show a strong preference for conspecifics (Dawley and Dawley 1986). This would ensure greater fitness of males and help maintain males in the population, because hybrid offspring almost always are females.

Sex Recognition

It is possible that salamanders could distinguish between their own odors and those of other species, but not obtain any information about the sex of these individuals. Olfactory cues are widely assumed to be important in sex recognition in these animals, but it is surprising how few experiments to test chemical sex recognition have been performed. Twitty (1955, 1966) placed sponges impregnated with skin secretions from females of *Taricha rivularis* in streams and found that the sponges attracted males from long distances downstream. Control sponges without secretions did not attract males. Unfortunately, sponges bearing male secretions were not tested. Similar results were obtained in experiments with *T. granulosa* using pheromone-soaked realistic rubber models of female newts (Thompson et al. 1999). Verrell, Strand, and Hanson (2001) impregnated sponges with chemicals from females of *Ambystoma macrodactylum;* the sponges were then placed in traps in ponds. Males were attracted to sponges with female cues, but not to sponges alone, and males also entered traps containing live females. Females, on the other hand, were not attracted to males. Gauss (1961) reported that males of *Triturus* mark branches and other surfaces in ponds by pressing their cloacal glands to the substrate. Females passing through the area investigated these marks, and Gauss suggested that females are attracted to odors of males. This has not been confirmed by any other investigators, however.

In *Notophthalmus,* males can distinguish between odors of males and females and are strongly attracted to female odors. However, females did not show discrimination in laboratory experiments, nor did they tend to move toward male odors (Dawley 1984a). This is consistent with behavioral observations on newts that suggest males initiate courtship after chemically identifying females (Verrell 1982). When several male newts are attempting to court a single female, the combined pheromones of the males actually repel other males, even though males are attracted to chemical cues from noncourting males (Park and Propper 2001). It is not clear, however, whether males in the field use chemical cues from other males to avoid situations where competion for females would be intense. Rohr et al. (2005) suggested that males assess local operational sex ratios from chemical cues. They found that males were more attracted to cages housing females alone than to those with both males and females, especially early in the breeding season. Later in the season, males were equally attracted to caged females with and without courting males. They suggested that this indicated a tendency for late-season males to be more likely to accept competitive situations, but in fact the lack of difference in response was due mainly to a reduction in overall responsiveness and not to increased responsiveness to cages that included males.

In another aquatic species, the European cave salamander (*Proteus anguinus*), neither males nor females exhibited clear differences in responses to chemical cues emanating from males or females in the water, nor did they discriminate between substrates previously inhabited by males or females. Nevertheless, a male evidently can determine the sex of another individual within a few seconds of making contact with his snout. Males and sexually immature individuals evoked an aggressive response, but females did not (Parzefall 1976). Breeding males are territorial and use chemical signals to mark their courtship territories, but nonbreeding males and females often are gregarious and apparently use chemical cues to locate conspecifics under suitable shelters (Guillaume 2000a, 2002). In contrast, the stream-breeding salmander *Calotriton* (= *Euproctus*) *asper,* which sometimes lives in caves, shows little site attachment and does not mark substrates with chemical cues. They appear to tolerate other individuals under shelter sites, but are not positively attracted to them (Guillaume 2002) and apparently do not use chemical cues for sex recognition (Guillaume 1999).

Dawley (1984b) investigated chemical sex recognition in *Plethodon montanus* and several members of the *P. glutinosus* complex. She found that both nonbreeding and breeding males and females could distinguish sex by airborne odors in an olfactometer. When given a choice between male and female odors, or between female odors and a blank, males oriented toward female odors. Males showed no preference in tests of male odors versus blanks. Females consistently avoided odors of conspecific males. They even chose odors of heterospecifics over conspecific males, perhaps because of a strong tendency to avoid territorial males during the nonbreeding season. Neither males nor females differed in their reactions to substrate odors of nonbreeding males and females. These results contrast with those of Jaeger and

Gergits (1979), who found that adults of *Plethodon cinereus* could distinguish sex from substrate odors. Both males and females tended to avoid male-marked substrates, and subsequent work has shown that both males and females use chemicals to mark territories (see the following discussion). Avoidance of male-marked substrates also has been reported in *P. vehiculum,* a species that does not appear to be strongly territorial in the field (Ovaska 1988a). A. Evans, Forester, and Masters (1997) reported that females of *Desmognathus ochrophaeus* preferred substrates marked by males from a different population to those marked by males from the same population. Their experimental design did not, however, distinguish between attraction to foreign male odors and avoidance of familiar male odors.

Individual Recognition

Many salamanders probably can distinguish their own chemical signals from those of other individuals, and in some cases, they can distinguish between the signals of different individuals (Mathis et al. 1995). In the blind, aquatic European cave salamander, *Proteus anguinus,* nonbreeding adults could distinguish between cover objects that had never been occupied and those previously occupied by other salamanders, and they preferred the occupied sites even when odor cues were five days old (Parzefall 1976). When given a choice between cover objects marked with their own odors and those of other individuals, they often preferred those of other individuals. This species is gregarious outside of the breeding season and apparently uses substrate odors to locate communal hiding places (Briegleb 1962; Gillaume 2000a). Adults preferred water that had been inhabited by at least three other salmanders over fresh water, but they showed no difference in response to water inhabited by one or two salamanders compared to control water (Parzefall 1976).

Adult *Proteus* apparently can learn the odors of particular individuals if the odor is associated with negative reinforcement. Parzefall (1976) introduced males into the defended territories of other males and allowed the intruders to be attacked. These males were then placed in a new aquarium and given a choice of cover objects marked with their own odors or those of their attackers. Even on the day after being attacked, the salamanders showed a strong avoidance of the odors of the males that had attacked them. Males given a choice of odors from an unknown sexually immature individual and a previous attacker also avoided the attacker's odor. In contrast, test males that had not been previously attacked showed no difference in their reactions to odors of mature males and sexually immature individuals. Odor discrimination has been investigated in less detail in another proteiid, *Necturus maculosus.* Adults could distinguish between control water and water inhabited by other individuals and preferred the latter. They also preferred substrates marked with odors of their own species to unmarked substrates, but their ability to distinguish the odors of different individuals is unknown (Parzefall, Durand, and Richard 1980).

Some larval ambystomatids apparently use chemical cues to identify close relatives. Such kin recognition can mediate aggressive or cannibalistic interactions among larvae (Walls and Roudebusch 1991; Pfennig and Collins 1993; Pfennig, Sherman, and Collins 1994; Walls and Blaustein 1995; Hokit, Walls, and Blaustein 1996); this is discussed in more detail in chapter 12. There is no evidence that aquatic salamander larvae can identify particular individuals, as opposed to classes of individuals, from chemical cues. However, in laboratory tests with recently metamorphosed juvenile marbled salamanders (*Ambystoma opacum*), Walls (1991) found that when animals were siblings, they showed different behavioral responses to familiar and unfamiliar individuals. This was interpreted as evidence for possible neighbor recognition, but the spatial dispersion of juveniles of this species in nature is unknown. There is some evidence for discrimination among familiar and unfamiliar individuals in *Notophthalmus viridescens* as well (Wise et al. 1993), but how this relates to spatial interactions among individuals in the field is unclear.

Terrestrial salamandrids of the genus *Salamandra* often exhibit strong site attachment to particular shelter sites, moving relatively little and sometimes using the same sites for many years (see chapter 6). Laboratory experiments with two species, *S. lanzai* and *S. atra,* showed that these salamanders can use fecal pellets to identify shelter sites. They also seem to be able to identify the individual residents of particular sites and therefore use fecal pellets as territorial markers (Gautier and Miaud 2003). Territorial behavior and scent-marking in this species develop in older juveniles before they reach sexual maturity, which occurs at about eight years. Young juveniles show little reaction to odors of other salamanders, and other salamanders do not react to odors of young juveniles (Gautier, Léna, and Miaud 2004). In contrast to the territorial behavior of these species of *Salamandra,* the closely related species *S. luschani* is gregarious and uses chemical cues to locate suitable rock crevices, which are used as shelters. The more gregarious nature of this species apparently is related to the aridity of its habitat and a shortage of suitable retreat sites (Gautier et al. 2006).

The most detailed work on individual odor recognition has been done with plethodontids. Tristram (1977) reported that *Plethodon cinereus* given a choice of substrates marked with their own odors or those of unfamiliar conspecifics tapped their naso-labial grooves to the substrate more frequently in response to their own odor. Jaeger and Gergits (1979) subsequently showed that nonbreeding males spent more time on substrates marked with their own odors than on those marked with odors of conspecific males. Females exhibited a weaker tendency to avoid odors of conspecific males, but did not differ in their reactions to their own odors and those of unfamiliar females. Nevertheless, *P. cinereus* females are territorial in the field and mark substrates with fecal pellets and pheromones secreted by glands on the underside of the base of the tail, as do males (Horne and Jaeger 1988; Simons and Felgenhauer 1992; see further discussion that follows). Although salamanders in the field frequently investigate fecal pellets by contacting them with their snouts, they also are capable of detecting airborne components of these territorial markers (S. Martin, Jaeger, and Prosen 2005). Avoidance of substrates marked by conspecifics has been reported in *P. dunni* and *P. serratus* as well, two small species that both appear to be territorial (Ovaska and Davis 1992; Mathis, Deckard, and Duer 1998). Dawley (1984b) performed a similar experiment with *P. glutinosus* from three different localities in Virginia and Tennessee. Salamanders were tested during the nonbreeding season, and most males and females preferred substrates marked by other individuals of the same sex to substrates marked with their own odors. Attraction to substrates marked by conspecifics also has been reported in males of two species from the Ozarks, *P. caddoensis* and *P. ouachitae* (Anthony 1993), but the reason for this behavior is unclear. Individuals of *Batrachoseps attenuatus* also exhibit discrimination between substrates marked with their own odors and those of other individuals (Gillette 2002).

In addition to discriminating between their own odors and those of other individuals, some terrestrial plethodontids also can discriminate between odors of different individuals. McGavin (1978) tested odor preferences of nonbreeding *P. cinereus* that had been exposed to the odors of other individuals for two weeks. Both males and females performed significantly more nose-taps in response to the odors of familiar salamanders than to the odors of unfamiliar ones. Jaeger (1981b) exposed adults of the same species to the odors of other individuals for a week and then staged encounters between test animals and animals with both familiar and unfamiliar odors. The test animals were significantly less aggressive toward familiar conspecifics. This type of "dear-enemy" recognition has been reported in many territorial birds and probably provides a mechanism to reduce the cost of aggression toward individuals that do not represent an immediate threat to the owner's territory (E. O. Wilson 1975). Females also exhibit "dear-enemy" recognition in interaction with other females and are more aggressive toward unfamiliar individuals (Jaeger and Peterson 2002).
