Amphibian eggs that are laid in exposed, sunny locations typically are heavily pigmented with melanin, which provides a shield against UV radiation. Consequently, nearly all summer-breeding amphibians that lay eggs in shallow water have black embryos. In contrast, embryos laid in sheltered locations under rocks in streams, in hidden locations on land, or in heavy shade, often have little or no pigment (Licht and Grant 1997; Licht 2003b). Grant and Licht (1995, 1997) and Licht (2003b) reported that the jelly surrounding many aquatic amphibian egg masses also absorbs UV-B radiation and helps to protect embryos, but other studies have reported that egg jelly has no effect on the dosage of UV radiation received by embryos (Hansen, Fabacher, and Calfee 2002; Räsänen et al. 2003). Certainly the protective effect is likely to be much less than that of melanin. Amphibians also can protect their embryos from exposure to UV-B radiation by selecting oviposition sites in deep water, where UV-B radiation is attenuated (Adams, Schindler, and Bury 2001; Kiesecker, Blaustein, and Belden 2001; Licht 2003b), or by wrapping eggs in vegetation to block UV-B radiation (Marco et al. 2001).

Amphibian embryos also have biochemical defenses against UV-B radiation damage. The embryos contain a light-induced enzyme, photolyase, which repairs DNA damaged by UV radiation. Studies of a variety of amphibian species have shown that photolyase activity tends to be highest in species habitually exposed to high levels of sunlight, and consequently, high doses of UV-B radiation. Species that lay eggs in deep water or other sheltered locations tend to have lower photolyase activity, and hence lower capacities for DNA repair (Blaustein et al. 1994, 1996, 1998, 1999; Licht and Grant 1997; van de Mortel et al. 1998; Smith et al. 2002; Licht 2003b; Palen et al. 2005). Not only is there considerable variation among species in photolyase activity, but there also can be adaptive variation in UV-B sensitivity within species as a function of latitude, altitude, or natural exposure to UV-B radiation (Belden and Blaustein 2002a).

Amphibian embryos also may have the capacity to increase photolyase activity in response to UV-B exposure. Smith, Kapron, and Berrill (2000) reported that wood frog (*Rana sylvatica*) eggs exposed to full sunlight had higher photolyase activity than did those kept in the dark. Their experiment did not separate the effects of exposure to UV-B radiation from exposure to longer wavelengths of light, because the embryos were exposed to unfiltered sunlight. Exposure to longer wavelengths, including visible light, is necessary to induce photolyase activity and DNA repair (Palen et al. 2005). In natural environments, intensity of visible light and UV-B radiation are likely to be positively correlated, but it is not yet clear whether amphibian embryos have the capacity to increase DNA repair capabilities if ambient UV-B radiation levels continue to increase in response to ozone depletion, even as visible light levels remain the same. The effects of embryos being exposed to UV-B radiation may carry over to the larval stage. In *Ambystoma maculatum,* larvae that had been exposed to enhanced levels of UV-B radiation as embryos had higher survival when exposed to high UV-B levels than did larvae not previously exposed to high doses of radiation (Calfee, Bridges, and Little 2006).

A study by Blaustein et al. (1994) first raised alarm about the possible effects of increasing exposure to UV-B radiation on amphibian populations. In experiments conducted in Oregon, they found that embryos of *Bufo boreas* and *Rana cascadae* placed in shallow (5–10 cm) water in full sunlight or under filters that transmitted UV-B radiation suffered high mortality, whereas those placed under filters that blocked UV-B radiation had low mortality. Embryos of *Pseudacris regilla,* on the other hand, were not affected by the experimental treatment and had high survivorship with both high and low doses of UV-B radiation. The authors suggested that increasing levels of UV-B radiation could be contributing to the decline of some amphibian species. Subsequent studies reported that exposure to ambient levels of UV-B radiation increased the susceptibility of *Bufo boreas* embryos to a pathogenic water mold, *Saprolegnia* (Kiesecker and Blaustein 1995), but the effect was strongly mediated by water depth. Eggs placed 10 cm under water suffered high mortality, whereas those placed at 50 or 100 cm, where UV-B radiation would be almost completely attenuated, did not (fig. 16.22 A, B). In unmanipulated ponds, mortality of eggs from *Saprolegnia* was much higher in shallow water than in deeper water (fig. 16.22 C). The authors suggested that unusually dry conditions in the Pacific Northwest, and a lack of spring snowmelt, may have resulted in toads laying eggs in unusually shallow water, perhaps accounting for the very high mortality observed in natural populations in the area (Kiesecker, Blaustein, and Belden 2001).

The work of Blaustein and his colleagues on embryonic mortality has generated unusually heated debate among amphibian biologists, with numerous critical articles and reviews and exchanges of comments in the scientific literature (see K. Grant and Licht 1995; Licht 1996, 2003a, b; Licht and Grant 1997 *versus* Blaustein et al. 1996, 1998; Blaustein and Kats 2003). Subsequent studies, all involving experiments with filtered and unfiltered UV-B radiation, have produced mixed results. Some studies have shown higher mortality in embryos of some species exposed to ambient UV-B radiation than in those under filtered sunlight (Anzalone, Kats, and Gordon 1998; Lizana and Pedraza 1998; Broomhall, Osborne, and Cunningham 2000; Häkkinen, Pasanen, and Kukonen 2001; Tietge et al. 2001). Several of these studies tested more than one species under the same conditions and often found differences among species in susceptibility to UV-B radiation. A number of other studies have shown no effect of ambient UV-B radiation on embryonic mortality (K. Grant and Licht 1995; Blaustein et al. 1996, 1999; Corn 1998; Cummins, Gleenslade, and McLeod 1999; Langhelle, Lindell, and Nyström 1999; Merilä, Laurila, and Pahkala 2000; Smith et al. 2000; Starnes, Kennedy, and Petranka 2000; Pahkala, Laurila, and Merilä 2001; Pahkala et al. 2001; Bruner et al. 2002; Pahkala et al. 2003).

In some cases, studies of the same species in different localities have produced different results. Blaustein et al. (1994) reported a strong effect of UV-B radiation on embryonic mortality of *Bufo boreas* in Oregon, but Corn (1998) found no effect in Colorado. Similarly, Häkkinen, Pasanen, and Kukonen (2001) reported an effect of UV-B radiation on embryonic mortality in *Rana arvalis* in Finland, whereas Pahkala, Laurila, Björn, and Merilä (2001) failed to find any such effect in Swedish populations. Lizana and Pedraza (1998) reported a negative effect of UV-B radiation on embryonic survival in *Bufo bufo* at high altitude in Spain, but

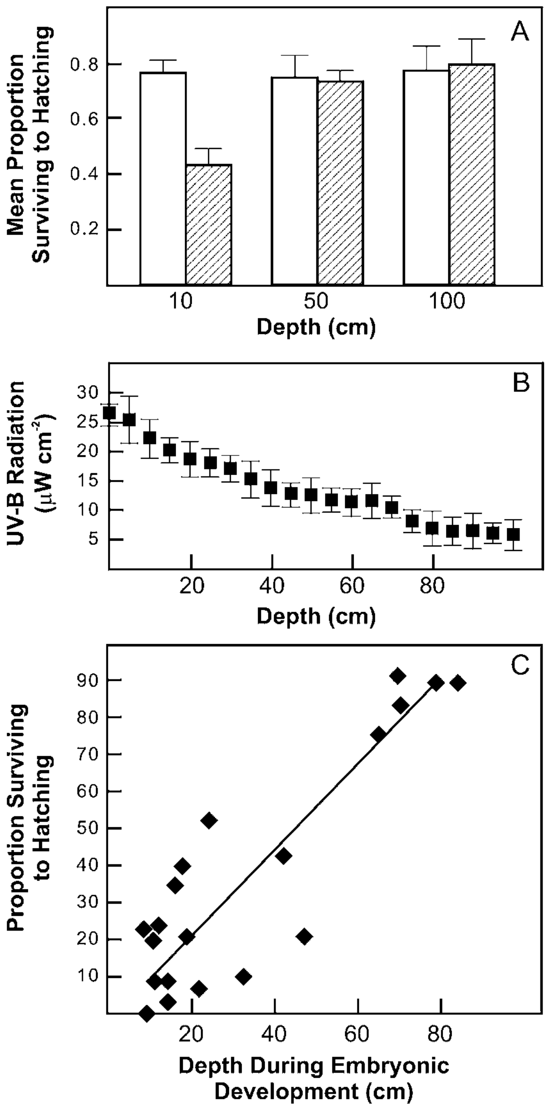

Fig. 16.22. Interaction between water depth, intensity of UV-B radiation, and survival of *Bufo boreas* embryos in a clear lake in Oregon. (A) Proportion of embryos surviving without UV-blocking filters (open bars) and with UV-blocking filters (hatched bars). The filters improved survivorship only in shallow water. (B) Attenuation of UV-B radiation with depth in the lake. Only shallow areas are exposed to high doses of radiation. (C) Relationship of water depth to proportion of embryos surviving in egg mass infected with *Saprolegnia ferax,* a water mold. Survivorship of embryos was poor in shallow water, possibly because exposure to increased UV-B radiation increases susceptibility to the water mold. After Kiesecker et al. (2001).

no effect on *B. calamita.* In contrast, Langhelle , Lindell, and Nyström (1999) found no effect of UV-B radiation on embryonic mortality in either *B. bufo* or *B. calamita* in Sweden, and Häkkinen, Pasanen, and Kukonen (2001) found no effect on *B. bufo* in Finland. A number of factors may account for these inconsistent results, including slight differences in experimental design, interspecific and intraspecific differences in photolyase activity and sensitivity to UV-B radiation, variation in water chemistry at the experimental sites, and differences in synergistic interactions with other factors such as pH or the presense of disease organisms.

In natural bodies of water, two physical factors that affect tranmission of UV-B radiation are water depth and the amount of dissolved organic material present in the water. Ultraviolet wavelengths attenuate rapidly with depth. In most bodies of water used for breeding by amphibians, eggs placed near the surface are likely to receive relatively high doses of UV-B radiation, whereas those placed more than 50 cm under the water surface are likely to experience low doses (Licht 2003b). This is especially true when the amount of dissolved organic material in the water is high, which often is the case in the late spring and summer, when levels of ambient UV-B radiation are highest (M. Adams, Schindler, and Bury 2001; Corn and Muths 2002; Diamond et al. 2002; Palen et al. 2002; G. Peterson et al. 2002; Little et al. 2003).

In swamps, marshes, and eutrophic ponds, where many summer-breeding amphibians lay their eggs, levels of dissolved organic material can be high enough to filter out most UV-B radiation within the top few centimeters of the water column (Berrill and Lean 1998; D. Crump, Lean, Berrill, Coulson, and Toy 1999). Amphibians most at risk from UV radiation are likely to be those that breed at high altitudes in very clear lakes, where UV-B penetration is highest. For example, Palen et al. (2002) surveyed 136 ponds and lakes at high altitudes in the Cascades and Olympic Mountains and found that 85% were well protected from UV-B radiation by dissolved organic material, despite being in a region expected to have relatively high UV-B exposure. Lost Lake, Oregon, where the original experiments with *Bufo boreas* were conducted (Blaustein et al. 1994), is one of the clearest lakes, with the highest transmission of UV-B radiation, in the Pacific Northwest (Palen et al. 2004). Although the interpretation of these results has been disputed (Blaustein et al. 2004), there seems to be little doubt that amphibian eggs laid at moderate depths generally are well protected from UV-B radiation. Indeed, there is some evidence to suggest that amphibians with poor inherent protection against UV-B radiation actively choose oviposition sites that minimize exposure to UV-B radiation (M. Adams, Schindler, and Bury 2001; Palen et al. 2005). Another survey of 172 ponds in Glacier National Park failed to support the hypothesis that the distribution of *Bufo boreas* is limited by ambient UV-B radiation (Hossack, Diamond, and Corn 2006).

Breeding phenology clearly has a major impact on the amount of UV-B exposure experienced by amphibian embryos. Temperate-zone amphibians tend to breed later in the year at high altitudes, or high latitudes because of low environmental temperatures (see chapter 3). For example, widely distributed species, such as *Rana temporaria* in Europe, breed in early spring in southern parts of their ranges at low altitudes, but in early summer at higher altitudes or latitudes. Consequently, late-breeding populations will receive higher doses of UV-B radiation and can be expected to have greater inherent protection against UV-B than do early-breeding populations (Merilä, Laurila, and Pahkala 2000). In addition, gradual warming of the climate has resulted in earlier breeding by *Rana temporaria* and some other amphibians in northern latitudes (see chapter 3), and this actually could reduce the amount of UV-B radiation to which embryos are exposed (Merilä, Laurila, and Johanson 2000; Cummins 2003). Breeding phenology also can be affected by other factors, such as rainfall and snowmelt in montane habitats. For example, Corn and Muths (2002) showed that in Colorado, chorus frogs (*Pseudacris maculata*) breeding in dry years with little snowmelt could be forced to breed in relatively shallow water, but they also tend to breed earlier in the year, when levels of UV-B radiation are lower than in late spring. Again, these conclusions have generated some controversy (Blaustein et al. 2004; Corn and Muths 2004), but it is clear that a number of factors interact in complex ways to determine actual exposure of amphibian embryos to UV-B radiation.

Although most research has focused on the effects of UV-B radiation on amphibian embryos, it also is possible for UV radiation to affect both aquatic larvae and terrestrial adults. Unlike embryos, larvae and adults are able to move throughout their habitats and therefore have the potential to select microhabitats that are shielded from UV radiation. Nevertheless, in some situations, such as open shallow pools, it may not be possible to escape such radiation. For amphibian larvae that develop in desert rain pools and other exposed ephemeral sites, exposure to intense sunlight is unavoidable, and indeed, necessary to speed development so that larvae can metamorphose before their ponds disappear (see chapter 13). One can expect larvae in such habitats to be well protected against the harmful effects of UV-B radiation.

The results of experiments with amphibian larvae and UV-B radiation have been somewhat mixed. In some species, exposure to ambient levels of UV-B radiation was lethal to larvae that were prevented from seeking shelter or moving to deeper water (K. Grant and Licht 1995; Häkkinen, Pasanen, and Kukonen 2001; Tietge et al. 2001). Belden et al. (2003) reported a small decrease in survival of *Rana cascadae* tadpoles exposed to full sunlight in shallow water (20–26 cm) for six weeks, even when aquatic vegetation was provided for cover. In other cases, there was no effect of ambient UV-B exposure on larval survivorship, even in clear, shallow water (Crump, Berrill, Coulson, Lean, McGillvray, and Smith 1999; Langhelle, Lindell, and Nyström 1999; G. Smith, Waters, and Rettig 2000; Little et al. 2003). Some of these different results probably reflect inherent differences among species in sensitivity to UV radiation. Belden, Wildy, and Blaustein (2000) reported that larvae of *Ambystoma macrodactylum* from high elevations, where UV-B exposure would be highest, were less sensitive to UV radiation than were larvae from low elevation.

In one experiment with *Rana temporaria* tadpoles, mortality was actually slightly higher in tadpoles shielded from UV-B radiation than in those exposed to normal sunlight, but mortality was even higher in tadpoles exposed to enhanced levels of UV-B (Pahkala, Merilä, Ots, and Laurila 2003). Other studies have demonstrated lethal or sublethal effects of enhanced levels of UV-B on amphibian larvae, indicating a potential for future effects on amphibian populations if levels of UV-B were to increase (K. Grant and Licht 1995; D. Crump et al. 1999; Ankley et al. 2000; Calfee, Bridges, and Little 2006). Nevertheless, larvae of some amphibians appear to be well protected, even against abnormally high levels of UV-B radiation (Little et al. 2003). In some species, larvae can enhance protection by avoiding sunny locations or increasing melanin production in the skin (Nagl and Hofer 1997; van de Mortel et al. 1998; Langhelle, Lindell, and Nyström 1999; Belden, Wildy, and Blaustein 2000; Hofer and Mokri 2000; Belden and Blaustein 2002b; Garcia, Stacy, and Sih 2004). Nevertheless, exposure to ambient UV-B radiation can have a variety of sublethal effects on larvae, with effects on metabolism, growth, development, and behavior that may have fitness consquences for metamorphosed individuals (Belden, Wildy, and Blaustein 2000; G. Smith, Waters, and Rettig 2000; Belden and Blaustein 2002b; Formicki, Zamachowski, and Stawarz 2003; Pahkala, Laurila, and Merilä 2001; Pakhala, Merilä, Ots, and Laurila 2003). These effects are likely to increase if ambient levels of UV-B radiation increase signficantly in the future (Calfee, Bridges, and Little 2006).

In summary, what can we say about the role of ultraviolet radiation in the decline of amphibian populations? (1) It is clear that small increases in UV-B radiation are occurring in various parts of the world, with the greatest impact likely to be at high latitudes in summer. (2) UV-B has a variety of harmful effects on embryos and larvae of amphibians, and some species are sensitive to UV-B in shallow water at current ambient intensities. (3) There is considerable intra- and interspecific variation in how well amphibian embryos and larvae are protected from UV-B, with populations occurring in high-dosage areas having the highest level of protection. (4) Exposure to UV-B in nature is strongly affected by habitat characteristics, with rapid attenuation of UV-B with increasing water depth and levels of dissolved organic material. Many amphibian breeding sites are likely to be well shielded from harmful radiation, although clear ponds and lakes at high altitude may be less well protected. (5) Ambient levels of UV-B, perhaps acting in concert with other factors such as disease, have been implicated in high levels of mortality observed in unmanipulated populations of some amphibian species. (6) There is no evidence that current levels of UV-B radiation have been responsible for widespread declines of amphibian populations in either tropical or temperate regions.

Global Warming

Despite the claims of some politicians that evidence of human-induced global warming is insufficient, there is little doubt among scientists that human activities are having a significant and accelerating impact on global climate. Indeed, global warming and its effects on the world's ecosystems may be the most important environmental challenge of the twenty-first century, and at the same time, it is one of the most difficult problems to solve, because solutions require widescale international cooperation on a host of issues. The chief cause of global warming is a buildup of greenhouse gases, including carbon dioxide and methane, in the atmosphere, which increases the amount of solar radiation retained at the earth's surface. Although burning of fossil fuels contributes heavily to this accumulation of greenhouse gases, methane emissions from livestock and some types of agriculture, such as rice cultivation (Yan et al. 2005), also make significant contributions, as does the increased use of nitrogen-based fertilizers. Although industrial emissions of greenhouse gases have occurred mostly in the last 150 years, human activities such as burning of forests and grasslands and raising livestock have contributed to greenhouse gas emissions for the last 2,000 years (Ferretti et al. 2005).

The effects of global warming are difficult to predict precisely because of the complexity of interacting factors that affect climate on regional and global scales, but the impact is expected to be widespread and ecologically significant. Average global temperatures are expected to increase by 1.5–5.8°C by the end of the century, but actual temperature changes in different parts of the world will vary (Poff, Brinson, and Day 2002). Some regions are expected to become much warmer, whereas others are expected to become colder. Accompanying these changes will be major alterations in patterns of wind circulation, rainfall, snowfall and snowmelt, and ocean circulation, all of which can affect marine, freshwater, and terrestrial ecosystems.

Global warming is expected to have a major impact on agriculture, forestry, and fisheries, all of which are critical for supporting human life. Some regions, particular northern parts of the temperate zone, actually may become more productive, whereas areas closer to the equator, especially arid regions, may become drier and less productive (MacIver and Wheaton 2005; Maracchi, Sirotenko, and Bindi 2005; Motha and Baier 2005; Salinger, Sivakumar, and Motha 2005; Sivakumar, Das, and Brunini 2005; Zhao et al. 2005). In addition, climate in many parts of the world is expected to become more variable, with increasing frequency of large-scale perturbations such as El Niño events in the Pacific, which impact weather over wide areas. This increased climate variability, coupled with increasing ocean surface temperatures, may lead to a variety of catastrophic events, such as increased drought and fire in some regions, and increased frequency and intensity of hurricanes and typhoons (Salinger 2005; Zhao et al. 2005). These climate changes are expected to alter carbon and nutrient cyles and water cycles, with significant impacts on both agriculture and unmanaged natural ecosystems (Izaurralde et al. 2005; Kim 2005; Thomson et al. 2005). To make matters worse, the negative effects of climate change are likely to be amplified by patterns of human land use, including changing agricultural practices, deforestation and other types of habitat degradation, and urbanization (Siegert et al. 2001; Travis 2003; Zhou et al. 2004; Foley et al. 2005; Tao et al. 2005).

The effects of global climate change on natural ecosystems are expected to be significant and widespread, albeit difficult to predict precisely. Indeed, many such changes already are detectable in response to changes in temperature that have occurred in the last 50–100 years. For example, there is mounting evidence of a poleward extension of the geographic ranges of many warm-adapted marine and terrestrial organisms in the northern hemisphere, with a corresponding reduction in the ranges of many cold-adapted species (Walther et al. 2002; Parmesan and Yohe 2003; Austin and Rehfisch 2005; Hickling et al. 2005; Perry et al. 2005; Hickling et al. 2006). In addition, there is evidence of shifts to earlier breeding in many kinds of organisms, including plants, invertebrates, amphibians, birds, and mammals (Walther et al. 2002; Root et al. 2003). Other potential effects of climate change include either increased or decreased susceptibility of organisms to disease (Harvell et al. 2002), alteration of community structure and food web dynamics (Quinlan, Douglas, and Smol 2005), changes in productivity of high-latitude lakes and ponds (Karlsson, Jonsson, and Jonsson 2005), both positive and negative changes in food supply and growth rates for many kinds of organisms (Yom-Tov and Yom-Tov 2005), and effects on individual reproductive success (Gaston, Gilchrist, and Hipfner 2005). Although some types of organisms will benefit from a warmer climate, the overall impact of global warming is expected to be a rapid increase in the rate of extinction across a wide range of organisms (C. Thomas et al. 2004). Habitat specialists, which often have limited dispersal abilities, are likely to be faced with shrinking habitats and are likely to be the first to disappear.

What is the likely impact of global climate change on amphibians? As with other types of organisms, the effects are hard to predict because different parts of the world are likely to be affected in different ways. Consequently, most of the literature to date is relatively speculative and presents possible scenarios rather than making precise predictions (Donnelly and Crump 1998; Carey et al. 2003). Considerable attention has been given to reports of earlier breeding in various spring-breeding amphibians in the northern hemisphere, because these data provide clear evidence of a biological effect of increasing temperature on amphibian biology. Nevertheless, while some species show a clear trend toward earlier breeding in recent decades, others do not (Terhivuo 1988; Beebee 1995a, b, 2002; Forchhammer, Post, and N. C. Stenseth 1998; Blaustein et al. 2001; Gibbs and Breisch 2001; Blaustein et al. 2002; Tryjanowski, Rybacki, and Sparks 2003). The magnitude of change in breeding date is relatively small, often within the year-to-year range of variation for a given region. Amphibians are notoriously plastic in their breeding phenology, often shifting the date of first activity by several weeks in response to yearly changes in temperature or the timing of snowmelt (see chapter 3). It also is not clear whether earlier breeding is likely to have a negative or a positive effect on these northern amphibians (Merilä, Pahkala, and Johanson 2000; Cummins 2003).

There is relatively little evidence that climate change is currently a major cause of amphibian declines or extinctions in most parts of the world. For example, Alexander and Eischeid (2001) analyzed data on variation in temperature and other weather variables in relation to amphibian declines reported from Colorado, Puerto Rico, Central America, and Queensland, Australia. In some cases, such as Puerto Rico, Central America, and Queensland, amphibian declines corresponded to periods of slightly higher than normal temperatures, but these temperatures were within the normal range of variation for these regions and therefore probably were not responsible for the population declines. In Colorado, temperatures were near normal when amphibian population declines were reported. Similarly, an analysis of climatic data for Puerto Rico alone did not reveal any obvious link to amphibian declines (Stallard 2001). Climate models using these data also suggested that unusual climatic events were not responsible for amphibian declines (Carey et al. 2001). Nevertheless, there is a potential for climate change to impact amphibian populations, especially in conjunction with other factors (Pounds 2001). For example, Kiesecker, Blaustein, and Belden (2001) reported that several years of warm, dry weather in the Pacific Northwest of the United States resulted in western toads (*Bufo boreas*) laying eggs in unusually shallow water. This resulted in increased exposure to UV-B radiation, which in turn increased the susceptibility of the eggs to attack by a water mold (*Saprolegnia ferax*).

Perhaps the habitats in which amphibians are most vulnerable to future climate changes are cool montane forests, both in temperate and tropical regions. Amphibians adapted to cool climates, such as plethodontid salamanders, exhibit marked depression of metabolic rates at temperatures above about 15° C, so populations at lower elevations in mountains may be living near their physiological limits. Any increase in average environmental temperatures may cause a vertical contraction of ranges by driving populations up the mountainsides (Bernardo and Spotila 2006). These effects may be even more pronounced in the tropics, where gradients between high- and low-elevation habitats are steeper than in the temperate zone, and where amphibians generally lack the capacity for long-term temperature acclimation (Navas 2002). As discussed earlier in this chapter, tropical montane forests often are hotspots of amphibian diversity, with large numbers of endemic species, most of which are forest-interior specialists. Tropical montane rainforests also are among the most endangered of all terrestrial amphibian habitats because of accelerating rates of deforestation. Even when high-elevation forests remain intact, amphibians adapted to cool conditions are vulnerable to climate changes that result in shrinking habitat on mountaintops. As warming temperatures push the amphibians higher up into the mountains, they eventually will run out of habitat, and they lack the ability to disperse between mountains. The result could be wholesale extinction of many tropical montane amphibians (S. Williams, Bolitho, and Fox 2003; Parra-Olea, Martínez-Meyer, and Pérez-Ponce de Leon 2005). In addition, as already discussed, there may be synergistic interactions between climate change and the effects of diseases such as chytridiomycosis, which is prevalent in tropical mountains (Pounds et al. 2006).

The threat to montane amphibians comes not only from changes in temperature, but also from changes in the altitude at which clouds form, because mist from clouds often provides the most important source of moisture for these species (P. Foster 2001). The negative effects of rising temperatures may be increased by habitat destruction at lower elevations. For example, there is good evidence that conversion of lowland forest on the Pacific slopes of Costa Rica has resulted in cloud layers moving higher up the mountains, and this may have been responsible, at least in part, for the disappearance of the golden toad (*Bufo periglenes*) and several other high-altitude amphibians in the Monteverde Cloud Forest Preserve in the late 1980s (Pounds and Crump 1994; Pounds, Fogden, and Campbell 1999; Pounds and Puschendorf 2004). Similar effects may be occurring in deforested parts of the Caribbean slope of Costa Rica as well (Lawton et al. 2001) and very likely are occurring in cloud forests and montane rainforests in other parts of the world.

The effect of climate change on amphibians in other habitats is hard to predict. Some climate models suggest that with rising temperatures, rainfall will increase in some wet tropical regions, including Southeast Asia, possibly favoring the expansion of lowland tropical rainforest (Zhao et al. 2005). Nevertheless, the rate at which lowland rainforest is being destroyed by human activity is likely to exceed the rate of forest expansion. This rapid deforestation not only removes critical habitat for many amphibians, but also is likely to increase the incidence of climate-related events, such as catastrophic fires, which until recently were virtually unknown in wet tropical forests (Siegert et al. 2001). In addition, forest fragmentation is likely to result in warmer, drier conditions in the remaining forest fragments, conditions that are likely to be made worse by global warming (Donnelly and Crump 1998). Other wet tropical regions are predicted to experience reduced rainfall (Zhao et al. 2005), a trend that is likely to accelerate with increasing deforestation.

If a warming climate is likely to have the greatest impact on cool-adapted amphibians in the tropics, the reverse is likely to be true in the temperate zone. In these regions, increasing temperature may cause cool-adapted species to expand their ranges toward the poles. In the northern hemisphere in particular, there is a large area for potential expansion of amphibians now found at lower latitudes, particularly those well adapted to forest habitats. In contrast, grassland, semiarid, and desert regions of the northern hemisphere may experience drier conditions than occur today (Kim 2005; Maracchi, Sirotenko, and Bindi 2005; Motha and Baier 2005; A. Thomson et al. 2005). Although many amphibians in such habitats are well adapted to dry climate regimes, most species depend on temporary ponds for reproduction and therefore are highly sensitive to climate changes that result in shorter hydroperiods in breeding ponds and to general water stress caused by reduced soil moisture. In temperate montane regions, such as western North America, increasing temperatures may reduce precipitation or shift precipitation from mostly snow to mostly rain (Kim 2005). The result is likely to be faster runoff of precipitation and alteration of water cycles that could impact amphibians that depend on melting snow to form breeding ponds (Corn and Muths 2002).

What Difference Does It Make if Amphibians Decline or Disappear?

Since the widespread decline of amphibian populations was first noticed in the 1980s, most research efforts have focused on documenting the extent of these declines and searching for their causes. Very little attention has been given to the impact of amphibian population declines on ecosystems and on other organisms that live with amphibians. For most amphibian biologists and environmentalists, it seems self-evident that the decline of amphibian population is a bad thing. Each amphibian species is a unique product of evolution, and for aesthetic reasons alone, we want to preserve as many of them as possible. Even for the general public, there is a general sense that biodiversity is inherently valuable, if not essential, for human life, and that preservation of biodiversity is a good idea.

Nevertheless, all conservation efforts come with economic, political, and social costs. In wealthy countries, we often are faced with decisions about whether to preserve a swamp or a set of vernal pools or to build yet another supermarket or shopping mall. For most environmentalists, decisions about such tradeoffs are easy: protect the environment and give up the shopping mall. Often public opinion can be rallied to support this point of view. In other parts of the world, decisions usually are more difficult. How do we compare the value of a patch of montane rainforest and all of its inhabitats, including amphibians, with the value of land to grow crops for an impoverished human population? If the Kihansi toad (*Nectophrynoides asperginus*) in Tanzania is endangered by a giant hydroelectric dam (Krajik 2006), how do we compare the value of the toad and other organisms that live in Kihansi Gorge with the value of the dam, which provides one third of Tanzania's electricity to the citizens of one of the world's poorest countries? If the toad is to be saved, how much money should be spent on captive breeding programs or environmental restoration efforts?

These questions do not have easy or obvious answers, and policymakers and the public at large often demand more specific answers to questions about the value of amphibians or any other kind of organism threatened with extinction. Often people want to know not only what amphibians do for the ecosystems in which they live, but also what they do for us. If the Boreal toad (*Bufo boreas*) disappears from Rocky Mountain National Park, will the functioning of the surrounding ecosystem be affected? Will the average visitor to the park even notice the absence of this toad? If most of the frogs along mountain streams in the rainforests of Costa Rica and Panama are wiped out by disease, what impact will this have on the stream ecosystems and the surrounding forest? If frogs disappear from rice paddies in Southeast Asia, will the number of mosquitos that carry human diseases increase?

Unfortunately, despite the vast amount of research that has been done on the ecology of amphibians, biologists often are embarrassingly short of answers to such questions. Efforts to protect amphibians or conserve key ecosystems tend to be justified with fairly generic arguments about the value of particular organisms or the ecosystem services they provide: lost opportunities to cure diseases with chemicals extracted from the skin of frogs, lost services of amphibians as biological control agents for noxious insects, or the importance of amphibians as indicators of overall ecosystem health (the familiar "canary in the coal mine" argument). My feeling is that the canary in the coal mine analogy is overused. After all, humans have demonstrated a remarkable ability to adapt to even the most degraded habitats, from the garbage dumps of India and Colombia to the barren wastelands of the southern Sudan and the eroded hillsides of Haiti. We don't really need a survey of amphibians to tell us these environments are in bad shape; by the time they are uninhabitable by humans, the amphibians probably are long gone.

All too often, evidence for the value of amphibians is anecdotal rather than quantitative. For example, amphibians are commonly cited as important agents in the control of insect pests, and increases in populations of mosquitos and crop-eating insects in various parts of the world have been attributed to declines in frog populations (Abdulali 1985; Barfield 1986; Oza 1990; Bazilescu 1996; Jacques 1999). Yet an official web site of the State of Michigan dealing with emerging infectious diseases and mosquito control flatly states that "There are no amphibians or reptiles that are effective at mosquito control" (http://www.michigan.gov/emergingdiseases). In neither case is there much quantitative information to support these arguments.

Because amphibians tend to be inconspicuous parts of most ecosystems, even when they are very abundant, their role in ecosystem functioning has not been intensively studied. Amphibians generally do not perform ecosystem services that are likely to be clearly important to humans: they do not pollinate crop plants, dispose of decaying carcasses of animals, aerate the soil, or provide oxygen to the atmosphere. If all of the amphibians were to disappear from the Greater Yellowstone Ecosystem, it is unlikely that the effects would be as noticeable as the effects of the disappearance and reintroduction of wolves to the area. Nevertheless, what little research has been done on the role of amphibians in ecosystems suggests that removal of amphibians could have a significant impact on ecosystem structure and function.

Amphibians as Food

Perhaps the most frequently cited role of amphibians in ecosystems is their role as food for other kinds of animals. The idea that amphibians can be a significant source of energy for animals at higher trophic levels originated with the classic study of Burton and Likens (1975a, b) showing that the biomass of salamanders in the Hubbard Brook Experimental Forest in New Hampshire exceeded that of small birds and mammals. Subsequent work has shown that the biomass of amphibians in other forest ecosystems can be even higher than that reported by Burton and Likens (reviewed in Davic and Welsh 2004). Pough (1980, 1983) pointed out that because of their low metabolic rates, amphibians are far more efficient than are endotherms at converting food into biomass, so they consume a relatively small proportion of the primary productivity of an ecosystem, while providing a large source of energy to higher tropic levels. Studies of the diets of both invertebrate and vertebrate predators have shown that many kinds of animals eat a lot of amphibians (see chapter 14). The key question, however, is what would these animals eat if amphibians were not available? To what extent are animals at higher trophic levels dependent on amphibians for survival, such that the disappearance of amphibian populations would significantly impact populations of these predators?

As discussed in chapter 14, many kinds of invertebrates eat amphibians at all life-history stages, but relatively few are specialist predators of amphibians. Various species of flies with larvae that prey on frog eggs may be an exception, although the extent to which any of these species is dependent upon amphibian eggs for survival is unknown. All sorts of aquatic insects prey on amphibian eggs and larvae, and some species may derive much of their energy from amphibians. For example, caddisfly larvae (Trichoptera) are major predators of ambystomatid salamander eggs, and some species of caddisflies require a diet of protein to complete development (see chapter 14). *Ambystoma* eggs laid in the spring represent a major energy input into vernal pools and other temporary ponds (Regester, Lips, and Whiles 2006), and it is conceivable that populations of caddisflies and other predators would diminish if the number of salamander eggs were reduced. In addition, different species of *Ambystoma* larvae readily prey on each other (see chapter 14), so a decline in one species is likely to impact other species. Nevertheless, we cannot say with certainty that the complete disappearance of a species of *Ambystoma* would have a dramatic effect on any of these predators, because we lack information on the ability of these predators to switch to alternative prey. Most adult aquatic insects are generalist predators that probably can switch from one prey species to another as the relative abundance of different species changes. On the other hand, at least one giant waterbug in Japan is considered sufficiently dependent on tadpoles as prey to be endangered by declining numbers of frogs in rice fields (Hirai and Hidaka 2002).

Most ectothermic vertebrate predators of amphibians also are generalist predators that adjust their prey selection in response to changes in relative abundance of different prey items. For example, there is no evidence that any species of fish or amphibian is solely dependent upon amphibians as a food source (see chapter 14). Even frogs that prey on other frogs generally have relatively broad diets that include a wide range of invertebrate prey (N. Scott and Aquino 2005), although it is conceivable that such predators could suffer declines if smaller species of frogs decline or disappear.

Probably the ectothermic vertebrates most likely to be affected by amphibian declines are snakes, many of which have diets composed largely or exclusively of amphibians (see chapter 14). Indeed, there is good evidence for major declines in several populations of snakes in response to declines in amphibian abundance. For example, garter snakes (*Thamnophis elegans*) virtually disappeared from High Sierra lakes in California where the introduction of nonnative trout had eliminated most frog populations (Matthews, Knapp, and Pope 2002). Neotropical rainforests are particularly rich in snakes that are specialist predators on frogs, tadpoles, or frog eggs. At montane sites in Costa Rica and Panama where dramatic declines of anuran populations have occurred, the abundance of frog-eating snakes has similarly declined (Lips et al. 2006; Whiles et al. 2006). The impact of amphibian population declines is likely to be greater in areas such as these, where whole assemblages of amphibians are declining, than in areas where only the rarest species are threatened.

The impact of amphibian population declines on other vertebrate predators is hard to predict, but most birds and mammals that eat amphibians do not specialize on them. Even though amphibians can comprise a substantial proportion of the diet of some waterbirds, especially food delivered to nestlings (see chapter 14), these predators readily switch to alternative prey if amphibians are scarce. Even those predators that have been characterized as specialist amphibian predators in some parts of their ranges, such as European polecats and badgers, often do not specialize on amphibians in other regions and exhibit considerable plasticity in diet choice both within and between seasons. It seems unlikely that even the complete extinction of amphibians in a particular region would result in the elimination of predatory birds and mammals, although in some cases, they could suffer from reduced food availability and experience decreases in population density.

Amphibians as Grazers and Predators

Most research on the effects of amphibians on their surrounding ecosystems has focused on their roles as consumers. Most anuran tadpoles are grazers on algae, phytoplankton, and periphyton growing on plants, rocks, or other substrates. Salamander larvae and adult amphibians are significant predators on invertebrates. In some ponds, numbers of larval amphibians can run into the hundreds of thousands or even millions, with a total biomass exceeding that of other animals, even when fish are present (Gehlbach and Kennedy 1978; Deutschmann and Peterka 1988). Even in streams, which generally are less productive than ponds, densities can be high enough to make these animals the dominant consumers in the ecosystem (Huang and Sih 1991; Lips 1999; Davic and Welsch 2004; Whiles et al. 2006). Although these larvae are present in aquatic ecosystems only temporarily, we can expect them to have a major impact on energy flow and nutrient dynamics in bodies of water ranging from high alpine lakes to mountain streams, eutrophic ponds, and vernal pools.

As discussed in chapter 13, dense populations of tadpoles can substantially reduce the standing crop of algae in ponds and streams and alter the composition of the algal community (Dickman 1968; Seale, Rodgers, and Boraas 1975; Seale 1980; Lamberti et al. 1992; Kupferberg 1997a; Graham and Vinebrooke 1998; Holomuzki 1998; Flecker, Feifarek, and Taylor 1999; Ranvestal et al. 2004). Grazing by tadpoles can actually facilitate growth of some algae, thereby increasing primary productivity (Osborne and McLachlan 1985; Kupferberg 1997b; Whiles et al. 2006), so the impact of these animals on ecosystem dynamics can be complex. Comparisons of stream ecosystems in western Panama in areas where anurans already have declined and areas ahead of the spreading front of disease-related declines provide one of the few opportunities to directly assess ecosystem-level impacts of amphibian declines. Although declines of amphibian populations in these areas are relatively recent, there already have been measureable changes in productivity, nitrogen cycling, sediment dynamics, and several other aspects of ecosystem function in streams where tadpoles have disappeared (Ranvestal et al. 2004; Lips et al. 2006; Whiles et al. 2006). These changes, in turn, are likely to impact other grazers in the system, including snails, aquatic insects, and herbivorous fishes, and not just animals that depend on tadpoles as food. In short, the disappearance of a major cohort of consumers from tropical streams has the potential to permanently alter the functioning of these ecosystems.

The role of salamander larvae and adult amphibians such as newts as keystone predators in aquatic ecosystems was discussed in chapter 15 and need not be reviewed in detail here. Not only do these animals affect overall survival of other amphibians and various invertebrates, but they also alter competitive dynamics among species of tadpoles, which in turn can affect the relative abundance of adults of different species. In many of these pond systems, the whole ecosystem may be threatened by habitat destruction or degradation, changes in hydroperiod, or other factors that affect all members of the community together. Nevertheless, one can predict that some future threat to one of these keystone predators alone, such as a newly emergent disease, could have major effects on the whole assemblage of amphibian species, as well as other components of the ecosystem. Similarly, salamander larvae are the dominant vertebrate predators in many forest stream ecosystems in North America. Changes in the terrestrial habitat surrrounding these streams, such as logging activities, may differentially impact certain salamander species in ways that eventually alter the aquatic ecosystem as well (Corn, Bury, and Hyde 2003; Davic and Welsch 2004).

Terrestrial frogs and salamanders also can reach extraordinarily high population densities (Davic and Welsch 2004; Woolbright et al. 2006) and can be expected to have a major impact on populations of invertebrate prey animals. Only a handful of studies have documented these effects. Wyman (1998) used small enclosures (3 m^2) placed on the forest floor in upstate New York to investigate the effect of red-backed salamanders (*Plethodon cinereus*) on invertebrate densities and leaf litter decomposition rates. The enclosures were stocked with either two or six salamanders, or had no salamanders present. Fewer invertebrates, especially small ones, were collected in enclosures with salamanders than in those without salamanders, although the differences were small. There also was a small decrease in rate of litter decomposition when salamanders were present, presumably because they consumed insects that serve as leaf fragmenters. Although this experiment was conducted at a very small spatial scale, it suggests the potential for a decline in salamander populations to affect both invertebrate populations and the carbon cycle of the leaf-litter community.

A more elaborate set of experiments examined the effects of the Puerto Rican frog *Eleutherodactylus coqui* on leaf-litter invertebrates and forest nutrient dynamics at different spatial scales (Beard, Voget, and Kulmatiski 2002; Beard et al. 2003). Both small enclosures (1 m^3) and large (20 × 20 m) removal plots were used to compare the presence and absence of frogs. Densities of aerial insects were lower at both spatial scales when frogs were present, but leaf-litter insects were not affected. The presence of frogs also decreased rates of herbivory on live plants, suggesting that they were consuming significant numbers of leaf-eating insects. The exclusion of frogs also reduced the amounts of several kinds of nutrients in the leaf litter, including dissolved carbon and nitrogen, but the effect was not from changes in invertebrate densities, but apparently was an effect of frog waste products and decomposition. In the smaller enclosures, the presence of frogs increased plant growth rates and decomposition rates, but this effect was not detectable at the more realistic larger spatial scale. Hence, while these experiments demonstrate an effect of frog population on some invertebrates and some nutrient dynamics, one must be cautious in extrapolating from small mesocosm experiments to larger ecosystem-level spatial scales.

In both the experiments with red-backed salamanders and those with coquis, the forest floor community is dominated by a single species of amphibian, neither of which is currently threatened. While the results suggest that the removal of amphibians can have a detectable impact on ecosystem-level processes, they do not address the question of what might happen if most of a large and diverse amphibian community were to disappear, as has been occurring in the montane forests of Costa Rica and western Panama. Even in those areas, some species of frogs have persisted even as most of the stream breeders have succumbed to chytridiomycosis. Clearly the disappearance of the tadpoles of these species has the potential to affect the stream ecosystems in the area, but we do not yet know how the disappearance of the terrestrial juveniles and adults will impact the leaf-litter community, or the extent to which the remaining frogs will take the place of the missing species in terms of ecosystem function. Preliminary analysis of stable isotopes of carbon and nitrogen indicate that the adults of different anuran species in these forests have surprisingly diverse diets, with some feeding in terrestrial upland habitats and others in riparian habitats, so the decline of different species may have different impacts on the surrounding ecosystem (Whiles et al. 2006). Clearly more studies of this type are needed, and in a variety of habitats, from Asian rice fields to tropical forests and North American vernal pools, before we will fully appreciate the role of amphibians in ecosystems.

The Future of Amphibians

Predicting the future of almost any long-term process, from human population growth and economic trends to the survival of amphibians, is notoriously difficult, because we are limited to observing conditions as they are today. Most such predictions are made with qualifying phrases such as "If current trends continue," but in many cases, we do not know whether current trends will continue as they are, or will improve, or will get worse. This certainly is true for amphibian populations. We have had clear evidence for widespread population declines only in the last two decades, and we are just beginning to understand the principal causes of these declines. In reading through the litany of threats to amphibians described in this chapter, it would be easy to become pessimistic, to assume that amphibians throughout the world face a bleak future. Indeed, one author described his book on amphibians of arid lands as "a requiem for the amphibian class, which is on the verge of extinction" (Warburg 1997). Titles such as *Tracking the Vanishing Frogs* (K. Phillips 1994), *Nature's Fading Chorus* (G. Miller 2000), and *Disappearing Jewels* (Young et al. 2004) have reinforced the view that amphibians throughout the world are under seige. Clearly one function of such titles is to sound a warning, to describe what could happen if current trends continue, not necessarily to precisely predict future events.

I will use three examples to illustrate the difficulty of projecting current trends into the future. In 1813, John James Audubon observed immense flocks of passenger pigeons flying over the woods of Kentucky in numbers so great that "the light of noonday was obscured as by an eclipse." Although the local farmers blasted away at the pigeons with every sort of weapon, Audubon felt confident that no amount of hunting could ever diminish these multitudes of birds. "I have satisfied myself," he wrote, "by long observation that nothing but the gradual diminution of our forests can accomplish their decrease" (quoted in A. B. Adams [1966, 152]). Yet 100 years later, the last passenger pigeon died alone in the Cincinnati Zoo, the rest having succumed to unrelenting commercial slaughter that filled Victorian dinner tables with pigeon pie, but wiped out the species in the process.

About 80 years after Audubon made his prediction about the pigeons, a report from the Canadian Ministry of Agriculture stated that "As to those fishes which, like cod, makerel, herring, etc. are the most important of our sea fishes . . . I say it is impossible, not merely to exhaust them, but even to noticeably lessen their number by the means now used for their capture" (quoted in Kurlansky [1998, 123]). Yet the fish did decline, and Newfoundland's fishermen are now unemployed; both the fish and the fishermen were victims of ever more effective technology that eventually depleted the seemingly limitless stocks. This is an old story of human interactions with animals whose very abundance makes them vulnerable to exploitation—sperm whales, fur seals, elephant seals, sea otters, the North American bison, and even the North American beaver have suffered similar fates, although some of these species have since recovered. Both Audubon and Canadian fisheries officials made the wrong prediction about future trends because they could not conceive of such enormous abundance ever being diminished, nor could they envision future improvements in hunting technology that would make the slaughter of the animals more efficient. Amphibians have largely escaped this sort of indiscriminant slaughter, although some large ranid frogs are threatened by overexploitation, particularly in Asia (Stuart et al. 2004).

In 1962, Rachel Carson made a very different sort of prediction about the future. In her classic book *Silent Spring,* she painted a bleak picture of the possible consequences of environmental degradation, especially from unrestrained use of toxic pesticides:

> "There was once a town in the heart of America where all life seemed to live in harmony with its surroundings. . . . The countryside was in fact famous for the abundance and variety of its bird life, and when the flood of migrants was pouring through in spring and fall people traveled from great distances to observe them. . . . Then a strange blight crept over the area and everything began to change. . . . There was a strange stillness. The birds, for example—where had they gone? Many people spoke of them, puzzled and disturbed. The feeding stations in the backyards were deserted. The few birds seen anywhere were moribund; they trembled violently and could not fly. It was a spring without voices. On the mornings that once throbbed with the dawn chorus of robins, catbirds, doves, jays, wrens, and scores of other bird voices there was now no sound; only silence lay over the fields and woods and marsh" (Carson 1962, p. 2).

In fact, there was no silent spring—the birds did not disappear, but not because Rachel Carson was wrong in her prediction, but because her book changed peoples' behavior. Her description, which she called "A Fable for Tomorrow," was not meant to be an accurate prediction of the future, but rather a warning cry, a call to arms to protect the environment before it was too late. Largely because of her book, DDT and other persistent pesticides were banned, and birds such as the Peregrine Falcon, which had been in decline, rebounded. Yet even today, some people insist on drawing the wrong conclusions about her book. One only need type "Rachel Carson Silent Spring" into Google to immediately find blogs for publications like *Capitalism Magazine* arguing that her conclusions, and indeed the entire environmental movement, were based on myths, going on to blame Rachel Carson for the deaths of millions from mosquito-borne diseases such as malaria (the evolution of DDT resistance in mosquitos apparently not entering into the picture; Brockerman 2002).

We are in the warning cry stage in the decline of amphibian populations. Alarm bells have been sounded, both in the technical literature and in the popular press. What we need now is a realistic assessement of what the future holds for amphibians, what conservation measures can be taken, and which species can be saved. Are all amphibians on the brink of extinction, as some writers have suggested? Certainly not. Many amphibians have adapted well to human-altered habitats, and often are more abundant in such habitats than in pristine forests. Others, such as the cane toad (*Bufo marinus*) in Australia have actually spread, with human assistance, to the point of being a threat to other wildlife. Even in areas devasted by chytridiomycosis, some amphibians have survived, apparently enjoying innate immunity to the fungal infection. In Europe, North America, and elsewhere, protection of amphibian habitats, changes in forestry and agricultural practices, restoration of wetlands, creation of new breeding habitats, building of road tunnels for migrating amphibians, and removal of introduced and invasive predators (Vredenburg 2004; Ahola et al. 2006) show great promise in reversing the declines of some species.

Clearly much more needs to be done. We cannot save all species of amphibians, and we are going to lose some pretty spectacular products of evolution, particularly in the tropics. Many frogs with strange and unusual breeding habits, especially those adapted to the interiors of tropical forests, are likely to be lost, as are some species equipped with arsenals of chemical weapons in their skins, some of which might be used to fight human diseases in the future. In many cases, we may lose species of amphibians before we even know they exist. Yet there is some hope.

Despite the frightening nature of emerging diseases such as chytridiomycosis, the most immediate threat to amphibians throughout the world remains the wholesale degradation, fragmentation, and outright destruction of habitats, especially tropical forests (Stuart et al. 2004). Fortunately, the major hotspots of amphibian diversity, and especially areas with a large number of endemic species, represent a relatively small proportion of the earth's land, and these same regions often are rich in endemic species of other kinds of vertebrates (Lamoreux et al. 2006). Some thoughtful allocation of limited resources to protecting such areas has the potential to save many kinds of vertebrates, including amphibians. Saving these hotspots, many of which are in poor tropical countries with expanding human populations, is not just a matter of biology, but also of anthropology, sociology, economics, and politics. Conserving amphibians, or other components of biodiversity, not only means setting aside land, but seeking creative alternatives to forest destruction for people seeking to scrape out a living from the land. It means not only educating people about the value of biodiversity for its own sake, but also for theirs—for the preservation of sources of drinking water, conservation of valuable forest resources, protection against catastrophic floods and landslides in degraded environments, and a host of other reasons. It means encouraging the World Bank and other international agencies to focus on sustainable development, not just rapid development. It also means finding ways to reduce our own use of resources while alleviating the enormous disparity between rich and poor in human societies around the world. It is essential to develop an environmental consciousness and a cohort of local conservation biologists in countries where such concerns now seem mere luxuries for the rich.

Finally, efforts to conserve amphibians and biodiverity in general, from better education to land protection and restoration to the alleviation of poverty—all will be little more than stopgap measures if we fail to recognize the real elephant in the environmental living room, global climate change. The issue here is not relatively small and incremental changes in temperature and rainfall regimes, which already can be detected around the world. Amphibians exhibit a high degree of phenotypic plasticity that enables them to deal with substantial amounts of environmental variation, and there is evidence for a capacity for evolutionary adaptation to changing conditions on very short time scales and small spatial scales (e.g., Skelly 2004). The real danger is that climate change will accelerate, that the melting of glaciers and ice sheets will push climate systems toward a tipping point that will cause major and permanent alteration not only of local climate, but of ecosystems around the world. If individuals and governments continue to ignore problems of global warming, then all of us, amphibians and humans alike, will be in serious trouble.

As Rachel Carson wrote more than 40 years ago, "The road we have been traveling on is deceptively easy, a smooth superhighway on which we progress with great speed, but at its end lies disaster. The other fork of the road—the one 'less traveled by'—offers our last, our only chance to reach a destination that assures the preservation of our earth. The choice, after all, is ours to make" (Carson 1962, p. 277). To assume that individuals and governments will consistently make the wrong choices, as so frequently seems to be the case now, is to give into despair, to conclude that most current efforts to save amphibians and biodiversity in general are doomed to failure. I prefer to assume that humans, the most intelligent species on the planet, eventually will make the right choices, at least part of the time, and that amphibians will continue to be part of our natural world.

It is spring in New England now, as I write the last words of this book. The spring peepers have returned, as they always do, to swamps, marshes, and ponds, with their "world-filling, mind-altering choruses" that so simply and so definitely announce that life is resurgent again. Wood frogs and spotted salamanders have moved to vernal pools, depositing their eggs and starting their offspring on an uncertain journey, an annual race to the land before the ponds dry up. To our south, the rains will soon come again to the lowlands of Panama. A multitude of frogs, large and small, will move to swamps and ponds, feeding, calling, defending territories, laying eggs, avoiding snakes, and otherwise going about their lives, just as they did so many years ago as I rode the train from Balboa Station. If we make the right choices, if we take the correct fork in the road, they will continue to do so for generations of amphibians and humans to come.

Index

Full or abbreviated chapter titles serve as main subject headings in the index (**boldface**), with major topics indexed under those main headings. Topics in Chapter 1 are indexed under the three major groups of amphibians, Anura (frogs), Gymnophiona (caecilians), and Urodela (salamanders), along with other topics specific to those groups. Family synopses are indexed under family names. Amphibian species are indexed by Latin name only, because many species mentioned in this book do not have standardized English common names. All non-amphibian organisms are indexed by Latin name, followed by a descriptive common name in parentheses. Author names are not indexed, except for historically important figures (e.g., Charles Darwin).

"For many years now the herpetological community has awaited Kentwood D. Wells's work on the ecology and behavior of amphibians. It was well worth the wait, for the book is truly a masterpiece. Every topic that Wells addresses in *The Ecology and Behavior of Amphibians* is a stunning synthesis of the state of our knowledge. He has the gift of both being able to write clearly and synthesize vast quantities of information. I have no doubt this will be the book to which every amphibian biologist turns for factual information, reference, and ideas for future research."

Marty Crump

"Kentwood D. Wells is probably the only person in the world with such a breadth of knowledge and grasp of the literature in amphibian biology to even attempt such a monumental book. Indeed, I consider *The Ecology and Behavior of Amphibians* to be a masterpiece in the field. I have been awaiting this book for the last fifteen years and, after reading it, I am not only satisfied with it but am amazed by the clarity of writing and the wealth of information presented. This is a magnificent book."
